Mechanical Engineering

The Monthly Journal Published by

The American Society of Mechanical Engineers

Publication Office, 207 Church Street, Easton, Pa. Editorial and Advertising Department at the Headquarters of the Society, 29 West Thirty-ninth Street, New York

Volume 45 | January 1923 | Number 1

CONTENTS OF THIS ISSUE

DEPARTMENTAL

ADVERTISING

Price 50 Cents a Copy, $4.00 a year: to Members and Affiliates, 40 cents a Copy, $3.00 a Year. Postage to Canada, 75 Cents Additional; to Foreign Countries, $1.50 Additional. Changes of address should be sent to the Society Headquarters.

Entered as second-class matter at the Post Office at Easton, Pa., under the Act of March 3, 1879.
Acceptance for mailing at special rate of postage provided for in section 1103, Act of October 3, 1917, authorized on January 17, 1921.

Contributors and Contributions

National Leadership

That universal well-being, depending primarily upon the industrial background, may be attained under the leadership of the engineer, was the sentiment of the presidential address of Dexter S. Kimball at the Annual Meeting of the A.S.M.E.

Since his graduation from Leland Stanford, Jr. University in 1896, with the exception of a few years spent with various engineering firms, Dean Kimball has been a member of the Cornell faculty. Until 1915 he was professor of machine design and construction, and since that time he has occupied the chair of industrial engineering. He became dean of the College of Engineering in 1920.

He is co-author with John H. Barr of Elements of Machine Design, and author of Industrial Education, Principles of Industrial Organization, Elements of Cost Finding, and Plant Management, as well as of many contributions to the technical press.

Engineering and Economics

At a joint meeting of the American Economic Association and the A.S.M.E. during the Annual Meeting two papers on engineering and economics were presented. Wesley C. Mitchell who spoke on Making Goods and Making Money, is director of research at the National Bureau of Economic Research and professor of economics at Columbia University.

Dr. Mitchell was graduated from the University of Chicago in 1896 and studied at the Universities of Halle and Vienna in 1897 and 1898. He was instructor in economics at the University of Chicago for two years and in 1902 went to the University of California as professor of political economy. He joined the faculty of Columbia University in 1913.

E. M. Herr, who is president of the Westinghouse Electric & Mfg. Co., East Pittsburgh, Pa., clearly defined the manager's responsibilities in relation to the human problem in industry. Mr. Herr is a graduate of the Sheffield Scientific School, and has received degrees of D.Sc. from Franklin and Marshall College and A.M. from Yale University. He is a member of the corporation of the latter institution. Previous to his present position, which he assumed in 1911, Mr. Herr was connected in various capacities with several railway lines in the northwestern United States, with the Grant Locomotive Works in Chicago, and with the Westinghouse Air Brake Co.

Symposium on Stokers

Three papers presented at a joint meeting of the Stoker Manufacturers' Association and the A.S.M.E. during the Annual Meeting are abstracted in this issue. The authors of these articles are men of long experience in stoker work. Thomas A. Marsh, an Englishman by birth, is a graduate of the University of Illinois and since 1906 has been connected with the Green Engineering Co. at East Chicago, Ind.

George I. Bouton, for seven years chief engineer for the Murphy Iron Works, Detroit, Mich., is a graduate of Washington University. He spent seven years as engineer for Bryan & Humphrey in St. Louis, nine with the Heine Safety Boiler Co., and four in consulting mechanical engineering in New York.

Howard F. Lawrence has devoted the most of his time since his graduation from Stevens Institute to the development, operation, and general design of underfeed stokers, with particular reference to the Taylor stoker.

Tests of a Type "W" Stirling Boiler

Using information obtained from extensive tests conducted during 1921 on a large Type "W" Stirling boiler at the Connors Creek power house of The Detroit Edison Co., seventeen of these large boilers have been rebaffled with a resulting improvement in boiler-plant efficiency and an increase in the degree of superheat of the steam. These tests were described in a paper presented at the A.S.M.E. Annual Meeting and included in this issue. Its author, Paul W. Thompson, has been connected with the Detroit Edison Co. since October, 1913, as technical director of the operation of generating plants. Mr. Thompson is a graduate of Cornell where he taught heat-power engineering for two years.

Power Required for Cutting Metal

Fred A. Parsons, chief engineer of the Kempsmith Milling Machine Co., Milwaukee, Wis., through the Machine Shop Division of the A.S.M.E., contributed to the Annual Meeting a paper giving the results of an investigation to determine the fundamental laws governing milling, turning, planing, and drilling operations on the various metals and alloys used in machine construction. This paper contains formulas and tables by means of which the power required to machine metal in any given case may be calculated.

Mr. Parsons has been connected with the Kempsmith Milling Machine Co. since 1911, with the exception of a few months when he was machine designer for the Cincinnati Milling Machine Co. His early experience was obtained in various shops in Kalamazoo and in the metal plant of the Baker-Vawter Co. at Benton Harbor, Mich.

Testing Involute Spur Gears

The Machine Shop Division of the Society also contributed to the Annual Meeting a paper by Mansfield Estabrook reviewing some of the more commonly used methods of testing or inspecting spur gears. Mr. Estabrook was graduated from Harvard in 1899 with a B.A. degree and from the Massachusetts Institute of Technology in 1901 with the degree of S.B. in mechanical engineering. Since his graduation he has been with the Niles-Bement-Pond Co., except during the war, when he was a captain in the Ordnance Department, connected with the inspection of small arms.

Lumber-Cutting Waste and Production

This issue contains an article outlining the principles and application of a wage-incentive plan which has been successfully operated to reduce lumber-cutting waste and increase production. Its author, Carle M. Bigelow, chief engineer for Cooley & Marvin Co., Boston, Mass., since 1916, is a graduate of Rhode Island State College. From 1912 to 1916 he was in the employ of the Glenlyon Dye Works, Saylesville, R. I.

The Engineering Index

Attention is called to two important changes in regard to The Engineering Index: the location of the main portion at the end of the advertising section and the supplementary list of last-moment items on page 82. The reasons for these changes will be found on the editorial pages.

MECHANICAL ENGINEERING

Volume 45 January, 1923 No. 1

National Leadership[1]

By DEXTER S. KIMBALL, ITHACA, N. Y.

THE ultimate criterion by which any civilization will be judged will not be its armies or navies, its great edifices nor its wealth, but the degree of well-being—physical, mental and spiritual—that it bestows upon its people. This problem of universal well-being is most ancient and comes naturally from man's desire to enjoy the good things of life before he goes hence. The attainment of even an approximate realization of this desire was denied to all the old handicraft civilizations that preceded the present era. It does not appear to be possible to create by handicraft methods sufficient worldly comforts to support a great nation without having the larger part of the population work as menials with little or no mental development. The national ideals of all handicraft nations are, therefore, those of necessity and hold little hope of physical comfort this side of the grave.

The Problem of Universal Well-Being

But there has been born to us in these latter days a hope that this old desire may yet be realized, and this hope comes to us through the use of modern methods of production. Our civilization differs from those that have gone before, and from some that exist even today, only in one important particular. Our philosophy and our religions are built up for the most part of beliefs inherited from our forefathers, but our power to produce the necessities of life, to feed, clothe, and house the multitude, stands out as a thing apart and unlike anything that has as yet appeared on this earth so far as we have record. This power has come to us through the use of what we are pleased to call the "scientific method," by which we aim finally to replace the words "I think" with the words "I know" in all of our mundane activities. Our success in the use of this method in conquering unfriendly nature and turning her resources to our use has been most remarkable, and as it has become increasingly clear that physical, mental, and spiritual well-being depend primarily upon the industrial background, the insistence that the benefit of modern industrial methods be more widely distributed has increased in like proportion. If I read the ideals of American democracy aright, we are committed in this country to an endeavor to secure universal well-being.

Past-President Dexter S. Kimball

The benefits that have accrued to all classes of people in modern civilization are beyond question and are more apparent when comparison is made either with older forms of civilization, or even with existing handicraft nations. The general level of physical comfort and education as seen in modern nations is unquestionably higher than has ever before been attained. Nevertheless, no single class of people is satisfied with its position in the nation, and there is a deep feeling of unrest and discontent among those workers who actually produce the comforts of life. This is probably not new and undoubtedly has had its parallel in all older civilizations wherever large bodies of people dwelt closely together and where division of labor was at all a feature of industrial life. A multitude of reasons are advanced for this dissatisfaction and a multitude of remedies are offered for its mitigation, many of them having little or no bearing upon the real roots of the problem. It is obvious, however, from these suggested remedies that much if not most of these troubles have their roots in the industrial system under which we live—as might be expected, for industry is the very backbone of all existence. An examination of industrial laws preceding the present era and going back into remote antiquity indicates that modern industry has introduced few, if any, new problems. It has, however, accented and made more acute industrial problems that always arise where congregated industry and division of labor are factors in production.

Changes Wrought by Modern Methods Upon Industrial Life

Briefly, and without detail, the most important changes wrought by modern methods upon industrial life are as follows: The separation of agriculture and mechanic arts that began hundreds of years ago has been completed and widened. The agricultural worker now depends upon others for his tools of production. Within the mechanic-arts group the actual worker has been separated almost entirely from the ownership of the tools of industry. A complex system of transportation independent of either of these older fields of occupation has been developed. And, lastly, both in transportation and the mechanic arts, division of labor has been extended to a degree unheard of by our ancestors and made possible only by the use of modern tools of industry. The resulting complexity of human relations coupled with the vast increase in population has accented the time-old problem of "what is mine and what is thine?" to a point where many people despair of a solution and openly advocate a return to simpler methods and consequent simpler relations. The cry for justice, whatever that may be, is still abroad in the land, and we do not appear to have made much progress in attaining justice since the day when Plato described it as the essence of all good things.

Qualifications of the Engineer for Attacking the Problem of Effective Wealth Distribution

This charge that modern civilization is a failure or at least no improvement upon former civilizations, is, or should be, of peculiar

[1] Presidential Address at the Annual Meeting, New York, December 4 to 7, 1922, of The American Society of Mechanical Engineers.

interest to the engineer, using this term in its widest sense to include all industrial workers who use the scientific method. For modern civilization is largely what he has made it, and the civilization of the future will be largely what he wishes it to be. It is too much of course to claim that the engineer, unaided, can solve these difficult problems, but it is undoubtedly true that if he will direct his energies to the problem of the distribution of wealth as earnestly as he has devoted them to its production he can make a contribution to industrial economics that will be exceedingly helpful. The engineer, and he alone, has a direct and personal knowledge of the great industrial machine that he has created. Until recently he has entrusted the operation of this machine to others who often knew little about its refined mechanism. It is high time that he took charge and operated this complicated mechanism himself.

There would seem to be little doubt but that modern productive methods on the farm and in the factory will eventually produce sufficient wealth to make universal well-being possible if our methods of distributing this wealth can be made properly effective to this end. Economists tell us that, as yet, we have not reached this point of production. It would seem, however, that even now if our energies were all bent more upon the production of necessities and less upon luxuries and pleasure-giving products, a great rise in the general level of well-being would occur. A superficial examination of every-day surroundings will convince any one of the tremendous amount of productive effort wasted now upon the things that profit us but little physically, mentally, or spiritually. To say the least, the prospect of a higher level of well-being viewed from the standpoint of necessary production is very hopeful.

Furthermore, it should be noted that the efforts of the engineer are no longer confined to the design and actual production of commodities. The principles of mass production that have so greatly reduced the cost of commodities he has now quite fully developed. The wide application of the principles of mass production has been made possible by mass financing, the work of the financier. The engineer, in turn, is now developing the principles of mass management, and his contributions to the philosophy of management are already noteworthy. I believe most business men would be surprised to know to what a large extent the methods of the engineer have invaded their chosen field, and there can be little doubt but that the near future will see the engineering type of manager a predominant figure in all industrial administration.

This adventure into a broader field has brought the engineer for the first time face to face with the greater problem of human relations in industry and the distribution of wealth. In times past he has given little or no thought to these problems, but has assumed that they lay outside of his field. This assumption is no longer true, and whether he wishes to consider these problems or not, they confront him in this new field of industrial management. He cannot avoid the issue.

It will be freely conceded that the preparation of the engineer for these new duties is far from adequate, and two of his shortcomings stand out conspicuously. The first is his lack of knowledge of the economic principles of industry and commerce. It is true, of course, that the field of abstract economics is still far from being an exact science and many of its theories are controversial. But that is no excuse for a lack of knowledge, on the part of the industrial manager, of this important and growing subject which aims to replace ignorance and empiricism with accurately reasoned results. Furthermore, every engineer is by nature an economist. The location of an industrial plant, the design of a great power house, the location of a railway are all problems in economics, and the tangible things with which economics is concerned are familiar objects to every engineer. This need in the equipment of the engineer is now fully recognized, and in a fair way to be remedied. All first-class engineering colleges now prescribe more or less economic study, and students of engineering recognize this study as a necessary part of their mental equipment.

Another important weakness in the mental processes of the engineer is his lack of knowledge of human nature and, worse still, his lack of sympathy with human problems. He is by nature a constructive individualist and usually impatient to obtain results; and, as a consequence, impatient of any obstruction, human or physical, that stands in the way of these results. And he is by nature a cave dweller given to introspection, unskilled in expressing his views verbally, and lacking usually in the companiable qualities that take strong hold upon subordinates. Of course there are many exceptions to these general criticisms, but in the main I believe they are true. This weakness, no doubt, is responsible for the failure of engineers as a class to take an interest in all civic matters and the reason why they have been, until very lately, a negligible factor in national affairs; though some of the present-day national problems are of especial interest to all men of this calling. But it would seem that this difficulty is, also, in a fair way to be overcome if one may judge by the great activity manifested lately by local and national engineering organizations in civic and national problems.

Over against these weaknesses of the engineer must be placed certain inherent qualities that strengthen his claim to industrial leadership. He is as a class essentially honest. His entire training and professional experience are such as to demand honesty of thought and purpose in all of his transactions. It is true, of course, that here also there are exceptions, but they are comparatively rare ones. Engineers as a class are honest, and if anything is needed today in management more than anything else it is this ancient virtue.

The engineer also often occupies a strategic position in industry which is of great importance in controversial matters. As the designer and planner of industrial enterprises he stands between capital and labor, and he is, not infrequently, better informed of the real difficulties at issue than are either sides of the controversy.

Furthermore, human progress must rest to a large extent upon a knowledge of the experiences of the race. This is true in all lines of human activity, and particularly true of a civilization that rests upon scientific achievement. The hope of the future lies largely in making accessible to all the great mass of accumulated experience that has come down to us. The engineer, of all men, has stood out preëminently in this respect as one who knows and uses classified knowledge to the fullest extent of his ability. The great leaders of the past had, for the most part, no conception of the importance of recorded experience. With few exceptions they took their knowledge and experience with them. The modern engineer has been the first to endeavor to reduce to written form the basic principles of industrial leadership, and his work in this field has already commanded worldwide attention.

And last, but most important, the engineer has command of the scientific method of attacking problems. With this he has practically solved the problem of production and is now rapidly rebuilding the field of administration. Is it unreasonable to suppose that he cannot make a great contribution to the problem of the distribution of wealth if he attacks this problem in the same wholehearted manner that he has applied himself to these other fields of activity? There is indeed very good reason to believe that if he makes proper preparation he will bulk large in the industrial leadership of the future.

A New Form of Industrial Leadership Needed

All thinking men who know anything about industry agree that we are sadly in need of a new form of industrial leadership, but the source of this new leadership does not seem to be clear. And it should be noted that future industrial leadership will be closely associated with political leadership, so closely are the problems of industry linked with political administration. History gives us an idea of what has occurred in the past and gives us some basis from which we can draw conclusions as to the leadership of the future. The first form of national leadership was the military type, the rule of the strong man. This extreme form of leadership still prevails in some countries, though it is hoped that it has seen its day and will soon disappear from the earth. It was natural that the military form of government should be adopted in the first factories and large industrial enterprises. And this principle has certain inherent advantages that will undoubtedly prolong its use, though the modern tendency is to modify its more extreme features. The complexities of industry and the dependence that must now be placed upon expert advisers render any form of autocratic industrial government almost impossible.

In modern democracies military rule has been succeeded by what may be termed legal government. Today our social, political,

and industrial activities are governed by a very comprehensive code of legal regulations that rest upon precedent and upon the opinions of eminent jurists sometimes affirmed and reaffirmed many times. These legal restrictions are a valuable guide since they embody the experience of the race with conditions that have occurred. The lawyer has always rendered and is still rendering a great service to humanity in collecting public opinion and codifying it for our guidance; and for this reason the lawyer has always been prominent in public affairs as an interpreter of justice as prescribed by precedent and usage. The legal method and the legal mind, however, are for the most part backward looking in their processes. They aim to correct abuses as they arise in the body politic or in industrial life, and while the legal mind is of immense value to society, it cannot be said to have developed any philosophy of industrial life that holds out hope of a solution of these problems. An excellent illustration of our modified point of view as affecting the legal government of industry is to be found in our modern compensation laws. For many years all courts have held that a workman could secure compensation for injuries only if he could prove that he had not been guilty of negligence and that his fellow-workers had not been guilty of contributory negligence. Or in other words, the burden of proof was upon him to show that the blame lay upon the employer. This legal ruling had been confirmed repeatedly and it should be noted that, in general, the worker had to have recourse to law to secure compensation. Suddenly, almost, these old laws were swept from the statute books and the modern compensation acts passed which provide that workmen and their families shall not be made to suffer because of the dangers of industry. They practically affirm that accident compensation is a proper charge upon production and should be borne by the community interested and not by the unfortunate workman and his family who, usually, are not in a financial position to assume this load. This is clearly a step toward universal well-being and indicative, I believe, of other similar changes. There is, therefore, good reason to believe that the legal type of mind is not likely to produce the much needed new industrial leadership. In fact, it is more than likely that the legal regulations of the future will not rest so much as heretofore upon ancient usage, but will be greatly modified in their viewpoint by the new industrial conditions.

There remain for consideration two other types of mind from which a new industrial leadership may come, namely, the business or financial type, and the scientific type. The business type of mind with the aid and counsel of the legal and engineering fraternities has built up modern industry as we now see it. There can be little doubt as to the ability of this type of mind to plan and direct the larger aspects of industry along existing lines. One weakness of this type of mind lies in its apparent inability to appreciate or rather to acknowledge that a new industrial day has dawned in which industry is being viewed more and more as the support of human life and not as a means of producing private, corporate, or state profits. It is rather reluctant to admit the philosophy of universal well-being as defined in the foregoing. Whether it can be made to appreciate this view is an open question.

Another weakness of this type of mind is its lack of technical knowledge of modern industry. As industry becomes more and more complex the business man is compelled to depend more and more upon the engineer for advice and knowledge. It is this very phase of modern industry that is rapidly forcing the role of industrial manager upon the engineer. The truth of these statements is shown in considering complex industrial problems like the twelve-hour shift, which is partly at least a technical problem. The best report upon this subject that has as yet appeared is the report of the Committee appointed by the Federated American Engineering Societies. It is the best because it is based upon accurate technical knowledge of the industry and not upon speculative hearsay as most of these industrial reports are. The futility of any other kind of report is well illustrated in the Muscle Shoals controversy, which could be settled quickly and accurately by a properly chosen engineering commission. If the new industrial leadership comes, therefore, from the business world, the business type of mind, I believe, will have to be greatly modified.

Dean Inge, the noted London divine, reasoning along lines similar to the foregoing, comes to the conclusion that the only hope for new industrial leadership lies with the business type of mind on the ground that the scientific type of mind is somewhat visionary or theoretical and not practical enough for the solution of this great problem. With all respect to the learned dean, I would point out that workers in the field of science are of two well-defined types, and this distinction holds true probably for all fields of human activity. In science, as in philosophy, there are minds that may be described as *minds of the first order*. These are the minds that blaze the way by seeking out new truths whether of science, philosophy, religion, or what not. At no one time in the history of the world has there been a large number of such minds as compared to the total population, and the entire list of such great prophets, poets, philosophers, and scientists is insignificant when one considers the vast number of people that have lived on this globe. It is true that this type of mind is usually visionary and impractical, for which Heaven be praised! but upon it rests all hope of future progress. The true scientist who is interested only in discovering new truths or the man whose mind is even strongly drawn in this direction is usually not capable of directing the energies of others. But the engineering type of mind (which may be described as belonging to the class of *minds of the second order*) is interested in applied science and is for the most part eminently practical when brought into contact with practical problems. It is a mind capable of high development along business and financial lines, while yet retaining in its background the powerful scientific methods of attacking problems which have made modern industry possible. And this is the great contribution that the engineer can bring to this problem of universal well-being. The one great thing we are all seeking is justice; but there is no justice where there is no knowledge, and the engineer, again using this term in its widest sense, alone possesses an accurate and intimate knowledge of industry.

No one would presume to say that the engineer alone can solve the industrial riddle, but it is clear that he can make a very great contribution to the solution. But it becomes increasingly clear that hope of a solution rests with the two groups just discussed. The National Department of Education has for some time been advocating strongly that engineering students be taught more of the fundamentals of business and that young men preparing for the field of business and commerce be instructed in some of the outstanding features of engineering. And it may be that we shall yet develop a combination of these two fields that will produce the new type of industrial leader. But whether the new leadership comes from one field or the other, or from a combination of the two, the problem of universal well-being offers a challenge and a call to duty that the engineer may not refuse. The primary conditions and responsibility for universal well-being now rest upon his shoulders, and the engineer does not like to be concerned with a half-finished "job." There is good reason to believe he will do his share of work in attaining the ultimate results desired. Already there are significant signs that he has accepted this duty. The activities of city, state, and national engineering societies in all manner of civic problems in which they are competent to express an opinion need no rehearsal here. A few years ago it was unthinkable and unbelievable that an engineer should hold a high political office. Yet today we see with great satisfaction two engineers occupying gubernatorial chairs, one of them also an inventor of note, a Past-President of this Society and possessing a mind approaching at least that of the first order. More encouraging still we see an eminent engineer chosen, for the first time, to sit in the Presidential cabinet. These are pioneer adventures in a field that hitherto has been considered the exclusive territory of the lawyer and the politician, and their experiences are being watched with great interest by all thinking engineers. They are undoubtedly the vanguard of a larger invading army.

Whatever the result, we may be assured of one thing. Unless we can in some manner change our industrial system so that we can more nearly attain universal well-being and distribute the fruits of our industry more equitably, we have no reason for believing that our civilization shall endure, and its bones will full surely strew the shores of time along with those of the great civilizations that have preceded us. But if we can solve these problems, and I believe we can, there is hope that there may arise in America a civilization fairer than any that this war-weary world has yet seen, where universal well-being shall be a reality, and not a dream, and where liberty and justice shall prevail.

Making Goods and Making Money

By Wesley C. Mitchell,[1] New York, N. Y.

Engineers and economists, according to the author, have always had a common interest in production, but they have worked on different parts of the problem and have used dissimilar methods. Recently, however, the two sets of workers have come into closer touch, because economists have begun to use quantitative methods and engineers have begun to study the whole organization of the processes of production.

Quantitative analysis of production may run in terms of money, goods, or some index of welfare. As a community we are more interested in welfare than in goods, and more interested in goods than in money. But in practical affairs the business enterprise is forced to subordinate its interest in promoting welfare and in producing goods to the necessity of making money; for if it does not make money it will cease to produce.

The system of economic organization which presents this contradiction between our deeper and our more superficial interests seems, nevertheless, to promote the production of goods and material welfare more efficiently than any other plan which men have so far devised. It is a highly flexible system, offering free scope to the inventive genius of both engineers and economists.

Among the improvements needed at present are methods of stabilizing the monetary standard, controlling the business cycle, allowing production to be organized in units large enough to attain maximum industrial efficiency while safeguarding the community against high prices, etc. Engineers are equipped to make constructive contributions toward the solution of many of these problems.

BOTH engineering and economics have been concerned with the production of wealth since their beginings. But they approached the problem from such different angles and with such different aims that at the outset they scarcely came into touch. Adam Smith and James Watt were friends at the University of Glasgow when Smith was delivering the lectures which grew into the Wealth of Nations, and when Watt was making his experiments upon Newcomen's engine. Both of these Scotchmen had a plan for increasing the efficiency of production; but one plan centered in freedom for individual initiative, and the other in a separate condenser. It was not at all apparent at the time that this economist and this mechanical engineer could contribute to each other's work.

One hundred and sixty odd years have passed since Adam Smith and James Watt started their careers in Glasgow. In this interval the industrial revolution, which was getting under headway in the 1750's, has produced a new world. Looking backward, it is now clear that this new world is a joint product of engineering and economics. Adam Smith's ideas could not have influenced the reorganization of economic policy as they did without the development of steam power. James Watt's engine could not have run its conquering career without an opportunity for individual initiative. The mathematical instrument maker of the University of Glasgow and its professor of moral philosophy have been more intimate co-workers than either dreamed.

Meanwhile engineering and economics themselves have been growing. The engineer has begun to busy himself with other things than machine designing. He sees his problem as one which takes in all phases of the process of producing goods. He is interested not merely in his mechanical equipment but also in the choice and training of the personnel, in the planning and routing of work, in the purchasing and storing of materials, in the distributing agencies which handle the product, in the methods for winning markets, even in questions of financing. Thus the engineer has begun to attack many of the problems which concern the economist.

Although it must be admitted that the progress of the economist has been less rapid, he is to be credited with trying to practice the quantitative methods characteristic of engineering. Adam Smith had "no great faith in political arithmetic." His successors, blessed with better data and knowing more mathematics, are coming to have great faith in statistics. By the development of this technique they hope gradually to establish their science upon a quantitative basis.

This expansion of the engineer's problems and this improvement in the economist's methods are bringing the two sets of workers into closer touch. Today they are conscious of their common interests, as Adam Smith and James Watt were not. They wait no longer for a later generation to perceive that they are co-workers.

Fundamentally their common problem is still what it was when Smith was lecturing and Watt experimenting. The industrial revolution which was beginning then is continuing still. Every decade since 1750 has witnessed important advances in engineering and important changes in economic problems, if not in economic solutions. The need for further progress in the technical arts of production is not one whit abated by all the marvels of electricity and automatic machinery. Nor is the need for further progress in the arts of economic organization less pressing than it was in the generations of Adam Smith, Ricardo, or John Stuart Mill. The common task is to carry forward the industrial revolution through this generation—to carry it forward in such fashion as to make it yield our race still greater benefits.

It is not likely that economists can contribute to the further perfecting of machine design, though they may render help in problems of industrial organization. On the other hand, engineers no doubt can and will contribute greatly to the solution of economic problems. To those problems they bring a special type of training, an organized method of attack, which should enable them to see many things wanting or awry in the economists' conceptions. By constructive criticism they may make the economists' contribution more efficient, and in working with economists they may learn some things of advantage to themselves.

The Three Levels of Economic Analysis

All that I have said so far is exceedingly general in character. May I go on to matters somewhat more definite? My aim is to set our common problem of production in a perspective useful alike to engineers and economists.

The process of producing goods has been viewed in three ways. Subjectively it has been treated as a process of seeking to gratify wants. Industrially it is a process of making goods. From the business viewpoint it is a process of making money.

Corresponding to these three ways of viewing one and the same process of production, there are three levels of economic analysis—the level of satisfactions, the level of goods, and the level of prices.

Economic theory long cherished the ambitious design of penetrating to the satisfactions level of analysis. It sought to explain most economic phenomena in terms of a balancing of subjective sacrifices against subjective satisfactions. In so doing it became itself subjective. So long as it followed that tack it was not possible for economists to use quantitative methods. For, despite much searching, no satisfactory units have been found in which to reckon either men's sacrifices or their satisfactions. And without units, of course, one cannot cast up totals or strike averages. At best this level of analysis yields but a dubious explanation of why men behave in certain ways—"dubious" because modern psychologists have discarded for the most part the notion that our conduct is a calculated pursuit of satisfactions.

Gradually dropping this inefficient type of speculation, economists have recently begun to develop a more objective type of work—a descriptive analysis of economic behavior, as opposed to a subjective explanation of choices. It is this shift which enables them to use quantitative methods in their theoretical inquiries. We cannot measure sacrifices and satisfactions, but we can count goods and reckon in money. Within a limited range of problems we can also go behind commodities and prices to something more fundamental and yet susceptible of measurement—not sacrifices or satisfactions, but some objective index of physiological conditions or some objective record of behavior. For example, it is possible to investigate fatigue, to grade men by intelligence tests, to study the reaction of certain occupations upon health, and so on. It is true that

Address at a joint session with the American Economic Association at the Annual Meeting, New York, December 4 to 7, 1922, of The American Society of Mechanical Engineers. All papers are subject to revision.

these efforts to carry quantitative analysis into the realm of physiology and psychology are still in the pioneering stage, but does not the success already attained suffice at least to justify faith in future progress in this direction—progress to which not only engineers and economists but also physiologists and psychologists must contribute? For convenience of reference, let us say that this type of work runs on the welfare level of analysis.

The quantitative economist, then, and the engineer who attacks economic problems are concerned with money values, with goods, or with some objective index of welfare. As between these three levels of analysis there is no question but that the welfare level is the most significant and that the money level is the least significant. Indeed, money and goods get whatever significance they possess only in so far as they represent a contribution to welfare. We rate the goods level of analysis as more significant than the money level because a bushel of wheat has a more direct and unambiguous relation to welfare than has $1.25, which may be the price of wheat on some given day.

To illustrate the practical importance of these distinctions, let us refer to the national income. We should like to reckon this income in terms of common welfare, but we cannot conceive of welfare as a magnitude. So we do the next best thing and think of the national income as an aggregate of commodities and services obtained by the nation within a year. Such an aggregate we can conceive in bushels of wheat, tons of coal, board feet of lumber, ton-miles of transportation, months of schooling, and so on. When we come to measure this magnitude, however, we are forced to express the different classes of goods in terms of money values. That is, we make our computations on the most superficial level of analysis and state the national income in billions of dollars.

We are not forced, however, to stop short with so superficial a result, for we can work back again from money to goods. Thus, when our money estimates of the income of the American people show an increase from 33 billions in 1914 to 45 billions in 1916 we can analyze this nominal gain of 37 per cent into the part due to the rise of prices and the part due to the increase of physical output between a year of severe depression and a year of great activity. By applying appropriate index numbers of prices to the various sections of the data we can get revised estimates of the national income in "dollars of constant purchasing power." These revised figures come out as 33 billions in 1914 and 40.7 billions in 1916. That is, the estimate of the two-year gain in national income is cut down from 37 to 23 per cent.[1]

For most purposes this lower estimate of the increase in the national income in which the fluctuations of prices have been cancelled as accurately as may be, strikes us as more significant than the unrevised estimate. It is easy to increase the national income to any limit by monetary inflation—easy and harmful to welfare.

Where, then, do we stand in our efforts to treat economic problems by quantitative methods? What we seek to promote is welfare, but welfare we cannot measure except in certain details where objective indexes of physiological or psychological conditions are available. So we work on the assumption that an increase in commodities and services generally brings with it an increase of welfare. It is on that assumption that we seek to promote efficiency in producing goods. But we have to measure the progress of efficiency in money values whenever we are including goods of many different kinds. While we can afterward correct our figures for changes in the price level, they still remain in money terms—a hypothetical money of constant purchasing power. And the meaning of these monetary aggregates is exceedingly difficult to interpret except when we are comparing one such aggregate with another.

The Money Economy

The various levels of analysis in economic investigation are matters of profound and practical concern to the engineer as well as to the economist.

In considering the national income it is obvious, as previously stated, that money is important because it represents goods, and that goods in turn are important because they contribute to welfare. But in the process of production as now organized these relations are reversed in large measure. Production is carried on more and more by business enterprises, and business enterprises must make money if they are to keep going. The men in charge of a business enterprise may be filled with zeal for public service, but they must make enough to pay expenses and something over or they will have to find some other way of serving the public than running a business. The men in charge of another enterprise may be engineers interested primarily in perfecting their processes and products; but they must keep their passion for technical perfection within the limits set by money profit or they will be eliminated from the ranks of business managers.

It is no disparagement of business men to say that in business they subordinate the making of goods to the making of money. They are compelled to do so by the system of which we all are parts. If they fail to get their profits they cannot go on making goods. And it is to the interest of all of us that business men should get their profits, as every period of business depression proves. For when business promises losses instead of profits, production falls off and the national income is diminished, in extreme cases perhaps by 10 per cent.

But while it is silly to blame any one for this situation, it nevertheless bristles with economic contradictions. From the national viewpoint money making is a means toward making goods; from the individual viewpoint making goods is a means toward making money. From the national viewpoint the engineer is the central figure in production; in practice he takes orders from the business man. A community is well off in proportion to its efficiency in producing a current supply of the necessities, comforts, and amenities of life; an individual is well off in proportion to his efficiency in getting a money income.

This practical subordination of our common interest in making goods to our individual interest in making money produces grave consequences. But before enumerating them, it should be emphatically stated that the money economy is doubtless the best form of economic organization for promoting the common welfare which men have yet devised. This opinion is based on the fact that the money economy has developed out of simpler forms of economic organization in all the most progressive nations of the world, and that, broadly speaking, this development has been spontaneous. No one forced our forefathers in America to give up raising their own food, making their own clothing, and cutting their own fuel. They changed from the practice of making goods for their own families to the practice of making money incomes and buying goods made by others because they liked the results of the more elaborate plan better. In medieval times the king of England traveled around the realm with his court subsisting on the produce of the royal manors. When the king began to commute the labor services of his villeins and their dues in kind into money payments, the villeins shared with the king in the advantages of a better arrangement. So almost all the elaborate machinery of the money economy has grown up by slow degrees because men thought they got more goods or better goods when they worked for money than when they produced for themselves. The villeins have been converted into wage earners, the craft guilds have given way to the merchant and the factory, the weekly markets where neighbors met to barter have been superseded by retail shops, banking has evolved from small beginnings into an ubiquitous business, the joint stock company has become the dominant form of business organization, all because on the whole these changes recommended themselves on trial to large and growing sections of the population. Of course most of these changes were accompanied by grievous hardships to many individuals, but if the new organizations had not filled demands numerous enough to make them pay they could not have broken through "the cake of custom."

It must also be set down to the credit of the money economy that it is a marvelously flexible institution. It has been developed in a dozen ways undreamed of by the medieval money lender. Its capacity for further development and adaptation to human needs has no visible limits except the limits of man's capacity for invention. With that thought in mind let us consider some ways in which the money economy serves us ill, in the hope that the engineers and economists may invent practicable devices for bettering its operations.

[1] Income in the United States. By the Staff of the Bureau of Economic Research, vol. i, pp. 64 and 72. Harcourt, Brace and Company, 1921.

Some Developments Needed in the Money Economy

To begin with an obvious point, our dollar is not a stable unit. It is subject to continuous and wide variations in purchasing power, and these variations introduce uncertainty into business plans, cause undeserved losses to some and confer undeserved gains upon others. Various plans for stabilizing the dollar have been proposed—plans which merit critical study. But this whole topic is so familiar and its challenge to our inventive power so clear that this mere mention is sufficient.

Scarcely less obvious is the problem of controlling business cycles. Economic history shows that when any nation develops the money economy to such a point that a large part of its people get their livings by making and spending money incomes, its industry becomes subject to more or less regular alternations of feverish activity, financial crisis, and industrial depression. Of late years these business cycles have been the subject of quantitative investigation, so that our knowledge of the phenomena, while still far from complete, is yet sufficient to suggest various methods of exercising control over the cycle—methods such as the systematic scheduling of business operations with reference to anticipated changes in demand, the long-range planning of construction work, the launching of new products and increase of advertising when business is dull, more circumspect granting of credit in periods of activity, the improvement and wider use of business barometers, various schemes of unemployment insurance to reduce labor turnover and sustain the purchasing power of wage earners in periods of depression, and the like. Most of these plans emphasize the policy of "prevention rather than cure;" that is, they seek to diminish the wasteful excesses of booms as the best means of diminishing the severity of crises and depressions. All these plans are in the experimental stage. Engineers by virtue of their scientific training and their intimate relations with business men are likely to take an active share in testing these schemes and perfecting the best among them.

Another problem presented by the money economy is the clash between our desire for efficient production and our fear of being exploited by very large corporations. At present the work of production is systematically planned and controlled within the limits of each independent business enterprise. But we have no systematic plan for industry as a whole. Our industrial army is like a collection of military units of different sizes each efficiently led—squads under sergeants, companies under captains, regiments under colonels, a few brigades under generals—but an army without a general staff and without a general plan of campaign. However well the separate units are disciplined and led, there is loss of efficiency through lack of coöperation among the units. Under such circumstances, every increase in the size of the independent units extends the area within which careful organization exists and lessens the area in which no planning is possible. But as the companies combine into regiments and the regiments into brigades, we are afraid that the larger units will levy upon us a tribute which exceeds the savings from heightened efficiency. How, then, can we unite the efficiency of large-scale production with safety to the consumer? To that vexed issue of economic policy the organizing genius of the engineering profession may address itself with excellent results.

Other problems might be discussed—the possibility of cutting down the overhead which business needs impose upon industry, the possibility of raising the efficiency of Government service, the elimination of all methods of making money that are detrimental to public welfare, the advantages of investment in improving the personnel of industry as compared with the advantages of investment in plant, conflicts in interest arising from the immortality of nations and the short span of individual lives, what constitutes waste and how it may be minimized, the effect of changes in the standard of living upon production, the relations between the distribution of income and production of income—all matters of concern to engineers and economists alike. But enough has already been said to illustrate the main contentions, and illustration is all that is possible in treating so wide a topic in a brief paper.

To sum up, the industrial revolution has been marked by changes in economic organization as well as by changes in engineering technique. To keep this beneficent revolution going will require further changes of both types, economic and engineering. We should not be less alert to note the imperfections of economic organization than we are to note those of mechanical methods. In one field as in the other our best hope of constructive accomplishment lies in developing scientific analysis in quantitative terms.

How to make production for profit turn out a larger supply of useful goods under conditions more conducive to welfare is a problem that gives scope for the most diverse abilities and training. It is a problem that can be broken down into manageable parts which can be attacked by quantitative methods, and the advances made by one discoverer can be made the starting point of his successor.

The Human Problem in Industry[1]

By E. M. Herr,[2] East Pittsburgh, Pa.

That the human problem in industry is not a new thing is shown by the author's review of labor conditions in the Roman Empire, England, France, and this country, from ancient to modern times. With the increase in manufacturing and decrease in agriculture, however, new elements have been brought into the problem. A much smaller percentage of the population is now working and living conditions have greatly changed. The larger scale of industry places a greater degree of responsibility upon the manager, who must win the confidence of his employees and take every step known to scientific management to secure their coöperation, both for his own benefit and for theirs. According to Mr. Herr, shop representation, fair wages, security of employment, and means for education are among the demands of workers and merit the earnest consideration of all managers.

We are perhaps inclined to consider the present industrial problems as new and peculiar to this day and age and it is somewhat surprising to find how closely the labor problems and conditions of twenty-five hundred years ago approach those of today, in spite of a total change in background.

During a thousand years of ancient times, for the most part before the Christian era, self-supporting and self-regulating organizations of workmen existed, which were remarkably similar to the trade unions of today. They were publicly acknowledged and legislative enactments made to control them, notably the Roman laws of Numa Pompilius, who succeeded Romulus as emperor, and the Greek laws of Solon (about 700 B.C.). These laws, liberal for a time when the slave element entered so largely into industry and held up even today as models by labor advocates, were to the benefit of the state as well as the workers. (The tribune Tiberius Gracchus was their able supporter.) They were weakened however, under the reigns of successive tyrants. (Caesar, under the conspiracy laws of 58 B.C., broke up all the "unions" except those which were very ancient) and finally they were lost with the Christian massacres of Diocletian in the early part of the fourth century and the subsequent feudalism of the dark and middle ages.

The immediate cause of the destruction of these far-reaching labor organizations seems to have been the coveting of their wealth and power by the rulers of the day, together with their association with the persecuted Christians. Nevertheless the Christian movement early became a helpful factor in labor conditions, although it was first opposed by the unions because of its interference with the production of idols and other supplies for pagan temples.

The records of these workers' associations (Collegia) are fragmentary, but fully authenticated as including from century to

[1] In the preparation of this paper acknowledgment is made particularly to the authors quoted in the text, to Messrs. C. Osborne Ward (The Ancient Lowly) and W. L. Chenery (Industry and Human Welfare), and to Mr. Tracy Lyon for suggestions and valuable data, as well as for information made available by the National Industrial Conference Board.

Address at a joint session with the American Economic Association at the Annual Meeting, New York, December 4 to 7, 1922, of The American Society of Mechanical Engineers. All papers are subject to revision.

century most of the trades and crafts of the day. Numa formally recognized nine and Constantine, a thousand years later (337 A.D.), thirty-five, of which the following list may be of some interest: Architects, brass and copper smiths, blacksmiths, carpenters, decorators, doctors, founders, fullers (cloth), furriers, glaziers, goldbeaters and gilders, goldsmiths, ivory workers, joiners, looking-glass workers, lapidaries, masons, marble cutters, plasterers of various kinds, pearl and filigree workers, potters, painters, plumbers, pavers, sculptors, silversmiths, stonecutters, statuaries, veterinaries, wagon makers, workers in mosaic.

Even professions are included, but there are evidences of the existence of many other early organizations, notably of the armorers and iron workers, shoemakers, musicians, and gladiators.

Inscriptions found in the ruins of Pompeii show that the unions furnished members to be voted for as candidates to municipal offices, and what is more remarkable, these candidates then included women. As a historian puts it, "The inscription reads like some caucus slate of a New York ward Tammany club." The eight-hour law was also an issue of the times and every seventh day was observed as a day of rest. There were many strikes, usually called historically, when they attained sufficient proportions, "servile wars." The greatest and last of these was the uprising led by the gladiator Spartacus. Practically all ended disastrously, and it is authentically stated completely extinguished all hopes of the workers for the achievement of liberty by violent means.

And so the tide of the human element in industry has ebbed and flowed through the centuries, with its vital effect upon the welfare and happiness of all civilized peoples—through the feudal and medieval times with their greater or less industrial activity, when all mechanics and traders were organized into gilds possessing important legal powers and often exercising great political influence, to the time of the so-called English (industrial) revolution in 1760, which marked the beginning of the factory system and a departure from isolated craftsmanship under oppressive landlordism.

The vicissitudes were many. Under a Statute of Labor, issued in the fourteenth century at one of the times of plague in England, it was decreed by Edward III that thereafter labor should be given no greater wage than that received before the "Black Death," about 1350.

After the French Revolution all associations of either merchants, manufacturers, or laborers were forbidden.

Early Labor Problems in this Country

To come to our own country, at the beginning of the last century there were very few factories, and those then existing had only a small number of employees. We were a rural and agricultural people—as late as 1820 less then five per cent of the American people lived in cities with a population of 8000 and over. Today we are the greatest manufacturing nation in the world and over half of our population are city dwellers.

Farmers were of many classes—the richest, masters of principalities, and the pioneers, each with but a few acres of poor clearing. Manufacturing was a home industry, carried on chiefly by farmers and their wives, children, and servants, and by wandering mechanics. The artisan was sometimes a freeman but often an indentured or "redemptioner" servant. Many of these people were imported as late as 1835, their services being bought and sold.

The hours of labor in nearly all industry were from sunrise to sunset, even in the early New England textile mills, in which women and children did most of the work. It seemed entirely right in those times that little girls of ten should work fourteen hours daily, receiving about a cent and a half an hour.

Wages were certainly not high. In Massachusetts, for instance, from 1800 to 1815 laborers received from 35 to 75 cents a day; carpenters and blacksmiths about \$1.00; millwrights, machinists, painters, coopers and foundrymen about \$1.13; a mason as much as \$1.66; tailors and shoemakers about \$6.00 a week, and women employed as domestic servants their board and 50 cents a week.

In such a world the foundations of modern industry in America were laid. From the beginning of the 19th century the factory system steadily grew with the accompanying human struggles. About 1825 occurred the first strike for a ten-hour day. "Sweat-shop" methods had then begun, but there was as yet no method of reducing the labor cost of production by the use of labor-saving machinery, outside of the textile industry.

Local trade unions sprang up more or less intermittently early in the century, principally in the shoemakers' and printers' trades, both for mutual benefit and insurance, and for the reduction of working hours and the increase of wages, but it was not until the fifties that national organizations began to take effective form. These were pretty well shattered by the depression preceding the Civil War and did not really come into being until the seventies and eighties.

With the constant growth of the factory system and the continued development of machinery, the value of all manufactured product in the United States, estimated at about \$170,000,000 in 1812, increased to more than \$60,000,000,000 in 1919, or approximately three hundred and sixty fold, while the population had increased sixteen fold.

In this comparison the consideration of relative commodity prices would reduce the output of 1919 by perhaps one-third. Prices were very high immediately succeeding the World War and accurate comparable figures of the early period are not available.

The Colonial manufacturer was the mechanic or artisan who had gathered about him a few journeymen and apprentices.

Increase in Size of Manufacturing Plants

Reference has been made to the effect on the human problem in industry of the great increase in the size of manufacturing establishments, as with this increase personal contact between employer and employed necessarily becomes more difficult.

Judging from the trend of public sentiment, it might be assumed that the factory system is practically dominated by the so-called interests or trusts, but as shown by the United States census of 1920, by far the greater number of manufacturing establishments even now are small—over eighty per cent with twenty or less hands and nearly ninety-five per cent with less than one hundred—although it is true that nearly forty per cent of the wage earners are concentrated in what might be called large establishments, and upward of seventy per cent of those having above one hundred employees. A summary of the figures is as follows:

Distribution of Establishments		Number of Wage Earners	Distribution of Wage Earners	
Number	Per cent	per Establishment	Number	Per cent
235,881	81.3	20 or less	943,586	10.3
37,795	13.0	21 to 100	1,725,683	18.9
13,661	4.7	101 to 500	2,831,456	31.2
2,768	1.0	Over 500	3,595,647	39.6
290,105	100.0		9,096,372	100.0

It may be mentioned that according to a recent authority the number of existing monopolistic "trusts"—that is, combinations controlling in the neighborhood of three-quarters of the national supply of their respective outputs—probably does not exceed one hundred, and practically all of these came into being between 1887 and 1903, nearly twenty years ago.

Under our liberal incorporation laws, perhaps too liberal in their lack of uniformity, corporate management is increasing. The proportionate number of employees and the value of the product of manufacturing corporations, as distinct from industries managed by individuals or partners, comprising nearly seventy-five per cent of the whole fifteen years ago, has increased to nearly ninety per cent.

Racial Composition of Workers

An important element in the human problem in industry of today is the racial composition of the workers. According to a report of the United States Immigration Commission on conditions before the war, the distribution of industrial workers at that time was about as follows: Native-born Americans of native father (5 per cent of these colored), 25 per cent; native-born Americans of foreign father, 17 per cent; foreign born, 58 per cent.

It is interesting to note that the first-mentioned class, or more purely American, was employed most extensively in railway transportation, the manufacture of cars and locomotives, electric supplies, firearms, knit goods, gloves, collars, shoes, cigars, tobacco, etc.

With industry dependent to such a large extent upon foreign-

born workers, the recent immigration laws threaten, for lack of "common" labor, the return to and maintenance of normal production, and it is to be hoped that these laws will be made reasonably liberal and that restrictions will be based on fitness instead of as at present without regard to the immigrant's character or qualification to become an American citizen.

Decrease in Percentage of Workers

As has been pointed out, in the early days of this country almost everyone was an industrial producer, including the housewife and children above the age of seven. It is rather surprising to find that, according to the United States Census of 1920, about forty per cent of the inhabitants of the United States support the entire population, directly or indirectly, according to the following distribution:

	Per cent	
Persons Engaged in Gainful Occupations:		
Manufacturing and mechanical industries (including building trades)	12.1	
Agriculture	10.3	
Trade and clerical	7.0	
Transportation	3.0	
Mining	1.0	
Public and professional	2.8	
Domestic and personal	3.1	39.3
Not Engaged in Gainful Occupations:		
Over ten years of age	38.9	
Under ten years of age	21.8	60.7
		100.0

Although our Government has from its inception fostered manufacturing industry, largely by tariffs and patent laws, there has been since the time of Alexander Hamilton a public feeling and belief that agriculture was the backbone of the nation and manufacturing a supplementary source of wealth. To this belief may be attributed no small part of public indifference to the ills of working conditions.

The Human Problem in Industry

Let us now turn our attention more directly to this problem in an endeavor to ascertain at least some of the directions toward which its solution trends.

There is a human problem in industry because human nature is as we find it and as it always has been. This problem, as we have seen, is as old as humanity and will in all probability continue throughout the ages to come. It has varied and will continue to vary in intensity and in character. A study of the past and present conditions, however, gives promise of a continued and steady improvement in the relations of those who make up this problem. How, then, can this improvement in industrial relations be best continued?

The principal new thing about the human problem in industry is that industry is now conducted on a large scale—larger than ever known before—and that the problem has been intensified not only by factory employment and all that goes with it, but by the greatly increased size of manufacturing establishments, by the concentration of population in cities having a large foreign element of often radical tendencies, and by the insecurity of employment, in which business cycles play a large part. Furthermore, a very large number of people are now entirely dependent upon industrial operations, as those employed in manufacturing in early days were not.

These are concrete things and all conspire to produce conditions which cause what is perhaps the greatest problem in the industrial relations of today, that is, the underlying labor unrest and distrust, born of fear and misunderstanding—fear of coercion, unemployment and sickness—and a lack of mutual confidence as between employer and employed. There is more liberty and consideration for the workers than has ever been known before, and with it has come to the workers the greater vision of what they believe should belong to them in welfare and happiness. The social responsibility of management is being emphasized as never before.

Of first importance is the responsibility of management in its broadest sense. The awakened worker of today, more sensitive than his predecessors, intelligent, critical and perhaps irritable, must be convinced of the ability of management as well as its good faith, and in extreme cases even of the necessity of its being. It is said that democracy without management reverts to despotism on the mere ground of its inefficiency, and that the fundamental error in the recent Russian failure to provide for its people was confiscation of the factories and the expulsion of the managers, with the resultant breakdown of discipline and credit, on a false theory that labor alone creates wealth, whereas management, with credit and good faith, is of the first importance in the process of production.

"Effort in itself" says King in Industry and Humanity, "is of little value; it is only effort intelligently directed that counts." The Bolshevik dictators are reported to have been compelled, as a means of existence, to resort to despotism in the name of labor in the prohibition of strikes enforced by the army, to proposals of "scientific management" at any expense, and to offers of high salaries to the old managers if they would return.

It is the duty and responsibility of the management of today to prove its "reason for being" and that the collective result of the combined efforts for managers and workers is a fine and great thing. If they can feel that this is the case, most men will toil cheerfully as subordinates.

It is management's problem to obtain the confidence of their employees, to give them every reason to believe and convince them by their experience that their treatment is fair and honest and without "bluff." Since men are naturally distrustful it takes time to establish such confidence, and they will discover very quickly if the "boss" is not square. It must be established as between man and man for the good of humanity as well as the individual that labor and management are not foes, but that their interests are in every practical sense identical.

The personnel department is now often the means of establishing, that contact with employees which is so essential, governing employment, education and welfare, as well as shop representation. Its intelligent extension still has far to go and it is regrettable that some companies have seen fit to curtail this activity in times of depression when they and their men need it most.

These relations should not be handled and directed by the personnel department alone. The active heads and real managers are the ones on whom this responsibility must rest and who must handle it with their employees, not occasionally nor spasmodically but regularly and continuously, for work of this kind requires a great deal of time and patience. This effort on their part will gain the confidence of the employees and instil a spirit of coöperation throughout the organization, and it must be exerted on those directly in charge of the daily work of production. Anything less than this is futile and doomed to failure.

Boards of directors must keep in mind this relation and work with the officers in determining policies which the managers can carry out without destroying valuable relations established only after long and patient work and almost impossible to renew.

Shop-Representation Plans

One very large organization cites good practical results of some five years' experience with a plan of joint representation of men and management "along simple, plain lines that can be lived up to." They find that if the men are free to make suggestions to the management they will not ask an outsider to do it for them, and that most questions are settled by local boards. They find that workmen are anxious to learn if given a chance, and encourage the study in factory schools of the work of other departments. This broadens their perspective and increases their interest in their own work. They want to see every worker a capitalist, with an interest in the company's stock or with a savings account. In view of the justice and importance of steady work, their personnel department has special instructions to obtain advance notice of necessary layoffs so as to provide other jobs, if possible—this for the benefit of the company as well as of the men.

It is credibly stated that at present there are in the United States more than 300,000 employees working under shop-representation plans created to give them a voice in the conduct of the shops in which they work, and that in by far the larger number of cases considerable progress has been made in establishing the most cordial relations between management and employees.

Reference has been made to fears on the part of labor, such as fears of layoff or discharge, of arbitrary exactions and reductions in wages, of unfair discipline, of ill-health, and until unnecessary fears of this sort can be removed by a better understanding and

assurance, labor is obviously incapable of devoting its best energy to production. It is consuming time in organization against ills that are feared and thereby losing its just and full reward for effort in wages and opportunity for wider employment, which would be provided by greater public confidence in the investment in industry, as well as the elimination of the enormous waste in the joint effort which such mutual fears entail.

As put by W. L. Mackenzie King:

> Consideration of how best to eliminate fears respecting the distribution of output touches the crux of the industrial problem. How is the just share of each party to industry to be determined? And how is each to be guaranteed its right to share progressively in increasing productivity, and be held also to the corresponding obligation to see losses proportionately shared?

Wages

The last-mentioned obligation is often overlooked. Nominal wages have increased enormously; according to the United States Bureau of Labor Statistics, the average hourly rate increased seven fold from 1840 to the peak in 1920, and it is safe to assert that real wages have also augmented despite the high cost of living and the fact that in the early days of industry few workers depended entirely upon their wage but were "found" many things which must now be purchased; also the employment of young children was considered proper and the mother bore an undue part in family support, both practices which are now recognized as wrong, although not as yet adequately provided against by law.

Manufacturers naturally wish to see their employees receive a wage, with reasonable working hours, which will support them in comfort. This, of course, is only possible when economic conditions will permit, as wages are not and cannot be based on the cost of living. If this condition is to obtain, the employee must live in accordance with his income and responsibilities and exercise frugality and care in his expenditures. Unless this is done, the real interest of the employer and employee will not be conserved because wages would be lifted to the point of throttling the industry. The employer must also see to it that restrictive regulations, which weaken organization and curtail output, are not employed, either generally or for the benefit of any group or class of employees. Dr. W. I. King, in Wealth and Income of the People of the United States, states this principle very clearly as follows:

> The grim fact remains that the quantity of goods turned out absolutely limits the income of labor and that no reform will bring universal prosperity which is not based fundamentally upon increasing the national income.

Scientific Management

Scientific management—which is in fact little more than getting rid of confusion and perfecting adjustments, or in other words, good management—has entered largely in recent years into the human problem in industry. Its use may be abused, of course, but as helping to avoid undue strain on the part of the worker, under modern mechanical methods, and waste of time and materials in many directions, it should be of benefit to all concerned in industry as well as to the community. It should be a part of such management to remove the cause of any hostility to the broadest application of scientific knowledge of the conditions of maximum labor efficiency, to the gain of all parties to production. The scientific management which dealt in the earlier stage with individual output in an engineering way must now deal with men collectively and develop that scientific breadth of imagination and application which is becoming a vital necessity for the welfare of a modern civilized community.

In the introduction to the last edition of Trade Unionism and Labor Problems, Professor Commons says:

> Fifteen years ago insurance and unemployment were placed last, now they are placed first in this book.

Further on he says:

> The psychology of labor, both in good and hard times, is fundamentally the psychology of a class of people whose life is insecure, who are subject to rough methods of discipline. We cannot understand the problem of dealing with labor unless we understand that fundamental fact of insecurity of employment.

The accident-compensation law has accomplished the first little step toward giving security to the job. It has shown that the only way to establish safety and security is by making it financially profitable to do so. And so shall we make it financially profitable to business to eliminate to a large extent the wage loss due to unemployment on account of sickness, on account of changes in seasons, and on account of fluctuations in business. Labor can never accomplish this result. The only possible accomplishment of it will come when the employer arranges to cover unemployment from sickness by some adequate form of insurance, to the expense of which the employee will contribute, indemnifying the employee against loss of employment from this cause (accident is now covered by our compensation law), and to lessen unemployment on account of the fluctuation in production because of changes in seasonal demand by the proper use of stocks of finished product so as to smooth out these fluctuations and also those due to abnormal variations in business activity. The latter are much more difficult to provide against as they are irregular and often of large magnitude. When very great they cannot be entirely smoothed out but can always be lessened and are a real problem worthy of the effort of any manager.

Not only do increased security and continuity of employment greatly lessen the human problem in industry but on account of lessened labor turnover and uniformity of production they also reduce the cost of the product.

Many progressive industrial organizations have gone far beyond the requirements of the accident compensation laws and the safety of the worker, incurring large expense in providing liberally for free life insurance for their employees, advantageous savings and loan opportunities, housing, service pensions, and education. This education provides employees, at nominal or no expense, with almost every curriculum desired, from the teaching of English to foreigners to a vocational or technical course, the education of trades apprentices and the training of college men for service in the manufacturing, engineering and sales departments.

Education of Workers

There are other phases of helpful education which might well be prompted by the conditions of modern industry. One of these is in pointing out how to make repetitive work, in itself monotonous, interesting. A knowledge of the "why" of their product and the use of it and of related products of other departments has been found to materially broaden the operator's perspective. Then, too, workers can be encouraged to exercise their ingenuity in devising means to lighten and quicken their work and thereby incidentally increase their earnings. With shorter working hours there arises the question of what to do with idle time. Any one who investigates the use to which the average employee devotes his leisure undoubtedly will be convinced that such employee would be much better physically, mentally, and morally if he had less idle time, for it is generally used in loafing or in amusements which consume a material part of his earnings without corresponding benefits.

The question is often raised, "Is there not a great source of satisfaction in attainment?" Work well done and with a knowledge of progress is a source of enjoyment and with many takes the place of the recreation others find necessary to their happiness. Education of both sexes in ways in which to use leisure time profitably yet pleasantly is needed. The tendency toward shorter working hours makes the training of the young to use their leisure profitably more and more important. They should be taught thrift, for a thrifty person will not uselessly waste his leisure time.

The human problem in industry cannot but be largely affected by example. H. G. Wells, in some articles written about ten years ago on the labor unrest in England, which are unfortunately quite applicable to our conditions of today, speaks of the disturbing influence of "the obvious devotion of a large and growing proportion of the time and energy of the owning classes to pleasure and excitement" and the way in which this spectacle of amusement and adventure is being brought before the eyes and into the imagination of the working man. "We have, in fact," he says, "to pull ourselves together and make an end to all this slack extravagant living. I believe that in making labor a part of every one's life and the whole of nobody's life lies the ultimate solution of these industrial difficulties."

The human problem in industry, as has been pointed out, is very complex and can never be entirely solved. We will do a great

and valuable service to humanity if we can measurably improve the feeling of confidence of the employee in the employer and gain his hearty coöperation. To obtain this much, however, in addition to our educational work in its broadest sense, we must always and fundamentally be absolutely honest in our dealings, not only honest in our actions but also in our thoughts and intentions. Unpleasant facts necessary to be told to employees should be given them as honestly as the others and very promptly so as to give them all possible time to adjust themselves to difficult or distressing conditions.

Finally, is it not clear that at least one direction of the solution of this human problem in industry is along educational lines? First, education of ourselves, the employers, to a more general understanding of the spiritual, personal, economic, and physical relations involved; and second, education to encourage and aid in every proper way the general and vocational training of the employees in thrift, especially the younger boys and girls, but also the mature but still impressionable group of young men and women who are keen to learn how their position in the workaday world can be improved. Example in this effort to educate and train the employee is especially effective. Such educational effort should establish confidence and encourage coöperation. It should also be directed so as to develop individuality in each workman and woman. The sense of individual progress and freedom was the controlling motive with the founders of this great country. By keeping this characteristic strong in our young people we will perpetuate, strengthen, and develop the true American spirit in our land.

Let us therefore substitute the rule of reason and intelligence for force and so endeavor to restore in America the freedom of the individual, be he employer or employee,—"that freedom which enables the young man to look into the future with confidence, knowing that the only limitations to his achievements are the boundaries of his intellect and the measure of his energy."

Discussion at Engineering and Economics Session

AT THIS session of the A.S.M.E. Annual Meeting, held in the auditorium at 8 p.m. on Wednesday, December 6, under the joint auspices of the Management Division of the A.S.M.E. and the American Economic Association, two papers were presented: namely, Making Goods and Making Money, by Wesley C. Mitchell, Director of Research, National Bureau of Economic Research, Inc.; and The Human Problem in Industry, by E. M. Herr, President, Westinghouse Electric and Manufacturing Company. The texts of these papers appear on the pages immediately preceding.

President Kimball, in calling the meeting to order, said that the occasion was undoubtedly unique in the history of professional organizations. The American Society of Mechanical Engineers had long been interested in many joint activities having to do with a wide range of affairs, engineering, scientific, humanistic, but so far as he was aware, this was the first time that engineers and economists had gotten together in joint session to see what one might learn from the other.

Later, in opening the discussion, President Kimball said that Dr. Mitchell had brought forward probably the most important problem that engineers have before them today, namely, how are they to obtain this knowledge of economics to which he has referred? Colleges of engineering began some years ago in an endeavor to have all students taught the elements of economics, and the largest institutions now require a certain amount of instruction in that subject. It is not an easy thing to secure the attention of the students, however, for to them it seems a strange subject. That is natural, because we all are afraid of the things we do not understand, and just as the engineer was afraid of economics, others are afraid of engineering.

We are in need of some common basis, some common denominator of thought, and one of the first changes which has to be brought about is the simplification of the language which the engineers and economists speak. When we get to the point that we can write the elementary principles of engineering and economics so that he who runs may read, there will be some hope of a mutual understanding.

Discussion by Prof. H. R. Seager[1]

I find myself in such full agreement with both Dr. Mitchell and Mr. Herr that instead of criticising I will ask you to consider another application of the clarifying distinction Dr. Mitchell made between the money, the goods, and the welfare aspects of our economic relations. He called his paper Making Goods and Making Money. Perhaps the best title for my remarks would be Making Men and Making Goods, for I wish to direct attention to a problem which has its money aspect and its goods aspect, but which can be solved satisfactorily only by reference to its welfare aspect. It is in weighing against each other gains that can be stated in terms of goods and gains that can be stated only in terms of welfare that economists and engineers have their most difficult task. Or perhaps I should say that it is in connection with the goods plane that engineers should be able to render their greatest service to economists, and in connection with the welfare plane that economists should be able to repay some of their debt to engineers. But, as Professor Mitchell pointed out in dealing with welfare problems, we lack the exact means of measurement which we have when considering monetary or goods problems. Argument must take the place of demonstration, and in the end equally intelligent men must often agree to disagree.

Let me illustrate by reference to a practical problem that is sure to receive an increasing amount of attention during the coming year, the problem of the restrictions that should be imposed upon immigration. If this problem were to be decided as a problem merely of making goods, we should all have to agree that the present restrictions, the virtual exclusion of Chinese and Japanese immigrants and the limiting of immigrants from other countries within a year to three per cent of the number from each country who were shown to be here by the census of 1910, are obstructing the material progress of the country and should be repealed.

As a result of the war that steady stream of immigrants, averaging a million a year from 1910 to 1914, which used to recruit our industries, was largely checked. The net gain in our foreign-born population from 1910 to 1920 was thus only 3 per cent as contrasted with 31 per cent in the preceding decade, and from constituting 16 per cent of our total in 1910 they had come to constitute only 14 per cent in 1920. In 1921 wholesale misery in Europe was balanced by widespread depression and unemployment in this country. There was danger that immigrants would seek our shores again in large numbers when our industries were unable to afford employment even to our own citizens. It was to meet this situation that Congress in May, 1921, passed the per centum limit act which in May of this year was extended for another twelve months.

Our industrial situation is now quite different. In all parts of the country our industries have revived and in place of unemployment we have at present a real scarcity of many types of workers. It happens that this scarcity is most acute in the case of unskilled laborers, the very type that predominates among our European immigrants.

The arguments for letting down the bars and allowing the hundreds of thousands of laborers we could undoubtedly employ to enter are, from a business point of view, very strong. By maintaining or even advancing our standards of admission as regards physical fitness we could undoubtedly secure in large numbers just the type of sturdy and docile workers for which our industries are now clamoring. Accustomed to much lower wages than prevail in this country, these men would accept with enthusiasm current rates of pay, and the trend of wages upward which is proving embarrassing to our reviving iron and steel, copper mining, and other industries would be checked. Moreover, immigrant labor from a national point of view is always cheap labor. Other countries have borne the cost of rearing immigrants during the unproductive years of childhood, and in admitting them in early manhood we reap the full benefit of this investment without having to contribute anything to it.

There can be no question, then, that a return to our more liberal

[1] Professor of Political Economy, Columbia University.

prewar immigration policy would enable us to increase substantially our output of goods, and of this large output a goodly share over the wages we should have to pay for immigrant labor would remain as profits to employers and investors and constitute a net addition to our national wealth.

Notwithstanding these certain material advantages, economists very generally oppose a return to our former liberal immigration law and for reasons with which we are all familiar.

In this matter there is much more at stake than our national wealth. It goes to the very heart of our national welfare. Although most of us did not realize it, the admission of an average of a million immigrants a year before the war came dangerously near to wrecking our country, politically, socially, and economically. In saying this I do not intend to assert that our native Americans are demonstrably superior to the immigrants who come to our shores even from Southeastern Europe. What is certain is that they are more familiar with our institutions, more generally convinced that these should be maintained, and better trained in their operation.

When we admit an immigrant we admit not merely another pair of hands for our industries, but another potential citizen to strengthen or weaken our vital national institutions. Under the present 3 per cent restriction 357,803 immigrants may enter the country during the current year. The number who will actually come in will be substantially less because the countries of northern Europe will not send us the quotas to which they are entitled and which we should gladly welcome, while the countries of Southeastern Europe will be permitted to send us only a tithe of those who eagerly desire to come. But though the number may not exceed 250,000, or a quarter of the prewar average, economists generally feel that that will be quite as many as we can wisely undertake to assimilate in these troublous times.

The truth is that we have on our hands a highly difficult problem in trying to educate our present one hundred and eighteen million people to a better understanding of some of the elementary facts of economics and government, and cannot afford to complicate this task by admitting too many whose ideas and standards are already fixed. According to a recent writer,[1] the maximum population which the continent of the United States can support is about 200,000,000 and to maintain even this number it will be necessary to import nearly if not quite one-half of our food supply from abroad. Moreover it will take less than 200 years for us to multiply to this extent even if we make no net additions to our foreign-born population in this period. These estimates may be exaggerated, but they emphasize forcibly the truth that our population will multiply quite rapidly enough without any immigration, and that our great concern henceforth must be over the quality rather than the quantity of our people.

According to one of our leading biologists,[2] owing partly "to the great influx of foreigners of low mental capacity," but even more to the relatively larger families of our less intelligent natives, "our average intelligence has probably been declining for the past twenty-five years at least." Just what this means was brought out in startling fashion by the results of the intelligence tests applied to the 1,700,000-odd drafted men during the war. According to the same writer these tests indicated that 45,000,000, or nearly half of our population, "will never develop mental capacity beyond the stage represented by a normal twelve-year-old child, and that only thirteen and a half millions will ever show superior intelligence."

Clearly we need a respite from adding further to the number of our population of the routine manual laboring type and should concentrate all the time and attention we can spare upon means by which we can prevent the 45,000,000 at the bottom of the intelligence scale from further multiplying while we increase the thirteen and a half million of superior intelligence until they become the predominant American type. Unless we thus deliberately subordinate our goods or wealth interests to our national-welfare interests the rights to life, liberty, and the pursuit of happinesss, which we still consider our most precious national inheritance, will lose their only certain sanction, a representative government responsive to an intelligent as well as independent citizenship.

Discussion by Ernest F. DuBrul[1]

In the first part of his paper, Dr. Mitchell comments that engineer and economist today are conscious of their common interests and perceive that they are co-workers. This comment is of course evidence that they have not been collaborating in the past to any great extent. In his presidential address to the American Economic Association last year, Dr. Hollander brought out the costliness of this lack of contact during the war, how the neglect of economics led to misguided policies in labor adjustment, price fixing, revenue provision, and banking administration. He showed that on the one hand economists failed to mobilize as other scientists did, and on the other there was no instinctive recourse to the economist on the part of public authority, as there was to other scientists.

It is truly regrettable that instead of economics being recognized as the human, humane science that it really is, instead of it forming a valuable part of the business world's working knowledge, we find it considered, and for the most part still taught, as some form of esoteric mental gymnastics for college students. It is high time that both the economist and business man take effective steps to bring economics into its own proper place.

Dr. Mitchell has said that "engineers no doubt can and will contribute greatly to the solution of economic problems, to which they bring a special type of training which should enable them to see many things wanting or awry in the economist's conceptions. By constructive criticism they may make the economist's contribution more effective and in working with economists they may learn some things of advantage to themselves." As one working with both elements I can add a hearty "Amen" to that statement. More than that, I would appeal to both elements to give sympathetic attention to what each has to offer in the way of constructive criticism.

I do not lay all the blame for lack of collaboration on the economists; the greater part rests properly on the shoulders of the business men and the managing engineers. Measuring the great economic progress of the world, we may jump to the conclusion that economics cannot be of much value since so few of the business men who brought about this progress know anything of economic theory. But measuring the human element we find that very few people in all the world ever undertake a business enterprise, and of those few who do, a very large proportion fail, and the failure are not all small ones by any means.

It is not illogical to presume that more knowledge of economics would make far more successful business structures, just as more knowledge of other sciences and their better application has made more successful mechanical structures. We no longer leave the design of costly and important mechanisms to men who disclaim and even disdain the worth of education in physics and mathematics, because we have found the percentage of failures to be less when we had those mechanisms designed by men trained in theory as well as practice. The engineer's function is to consciously coördinate practice and theory, and to do this he must have a knowledge of both.

In puzzling out reasons for the lack of contact between business and economics, I have concluded that it is because, in sales terms, business has not been "sold on economics." To the suggestion that economic science deserved being "sold" to business, an economist of the academic type gave me the shocked response: "Why, that would commercialize the science, and destroy its cultural value in our course." To my unacademic mind economics, like engineering, is essentially commercial. I think it could be made decidedly more cultural than it is now if more teachers taught it as a science of living humans instead of as though it concerned on economic specimen preserved in academic embalming fluid. Far from shrinking at the fling of commercialism, I am for selling economics to the business world, as we have sold chemistry, physics, mathematics, geology, and other organized divisions of human knowledge.

We business men have learned that to procure consumer acceptance for our goods we must hunt out, run down, coax, stimulate, and manipulate our demand. We have learned that such acceptance depends—

1 On the sales effort made, its attractiveness and effectiveness

[1] General manager, National Machine Tool Builders' Assn.; Mem. Am. Economic Assn.; Assoc-Mem. Am.Soc.M.E.

2 On the service we give our customers to keep them sold after we have reached them
3 On the effective utility of the goods we have to sell
4 And least, perhaps, on the price we ask.

In analyzing a sale we business men have also learned the four steps through which we must lead our customer's mind to accomplish the desired transfer of our goods to him and his money to us. These are: attracting attention, arousing interest, creating desire, and inducing action.

Wherein have purveyors of economic science failed in these? As to attracting attention, many of the best of our economists seem to prefer academic retirement—and ease—to the hard work necessary to popularize the science. They may have a mistaken notion that it is unscientific or unprofessional, or undignified to make a science so popular as to promote effectively its application to every-day life. If any science ought to be and can be made popular it is economics, the one that deals with getting our living.

The opportunity of arousing interest in economics is ever present. Business men are always interested in the question, "How is business?" Their wives often talk about the domestic labor supply. Workingmen think a lot about jobs and wages; politicians and citizens think about taxes, and the gathering and spending thereof. Even professors worry at times about the cost of living and whether the latest drive for endowments will be successful enough to increase their own salaries. It would seem very noble to do everything possible to direct this general interest toward constructive rather than destructive action.

Economists have evidently not created much desire, much appetite, for economics; and Dr. Hollander gives testimony that in the great war crisis they did not induce good economic action. Perhaps it is because they have not presented their wares in an attractive, appetizing manner. Dealt out as dry, unpalatable brain fodder, economics cannot have as strong an appeal as if served in the form of a sparkling beverage to quench a human thirst for knowledge. Because it has been subjectively treated, as Dr. Mitchell has said, it seems to me that the quality of the wares has been defective. It is a fatal defect in economics to assume as true for the whole what business experience proves to be true only for a part, or to assume as true at all times things that are actually true only a part of the time.

Men of course think only as they know, and of course they write as they think. Few writers of economic texts have had business experience. They mostly have but limited knowledge of fabrication and exchange. Their personal exchange experience is limited to purchasing the most evanescent of all goods—food, clothing, shelter. So they subjectively formulate laws of supply and demand from that consumer angle, and apply that formulation to a mere abstraction, the economic man, buying and selling goods and services in a perfect economic market. But this method takes no account of the human element swayed by caprice and favoritism, and hampered by ignorance and folly. According to this theory the seller always extracts the last penny of profit from every sale. It must be the engineer's function to constructively criticize such a formulation of theory.

Take the absurd expressions, "normal price," "normal wage," "normal profit," "normal business." The "normal price" notion leads people to chasing price-fixing rainbows, meanwhile baying the word "profiteer." The "normal wage" notion leads unions to attempt to level up wages regardless of efficiency. The "normal profit" notion leads to envy of superior capacity that can make two healthy blades of grass grow where most competitors can only get one sickly sprout. The silly "normal business" notion leads men to run their business craft aground when the tide of demand goes out. That fallacy of a "normal business" has destroyed much wealth and wasted much human effort. Men have complacently considered a boom quite the normal thing, only to bewail the abnormality of the succeeding depression that their complacency brought on.

Striving for a fallacious simplicity of statement, economists have sacrificed clarity of thought in formulating so-called "economic laws." The subjective method developed a formalism that led men to believe that the so-called law of supply and demand was something external, universal, and automatic in its operation like the law of gravity, and that business simply consists of fabricating goods and making a price that takes the goods into consumption. The business world never could and never will recognize that sort of purely imaginary market.

Every business man knows that fabrication is not difficult but that sale at a profit is. It is not impossible to start a new automobile factory and make a better car at a lower cost than the "flivver," because the limit of invention is not yet in sight and Mr. Ford is still a human being, in spite of all attempts to deify him. Suppose such a factory were started, and its owner, counting on the automatic operation of the law of supply and demand, were to make a lower price than Ford's, and just wait for customers. Would he find Emerson right, that clamorous buyers would beat a path to his door, elbowing each other out of line to secure one of the new cars? Personally, I would wager that the Ford sales organization would put more "flivvers" on the road, and at a higher price.

Again the usual generalization is fatally defective when a depression comes on, when nobody wants to buy at low prices; or when a boom develops, when every one wants to buy at high prices. The usual explanation of these things is, "Well, that is abnormal; it just cannot be explained by the formula." Another important fact is that the relative elasticity or inelasticity of demand in its response to price movement is vitally different for different commodities at all times, and is different for the same commodity at different times. Economic theory has concerned itself but little with the effects of this inelasticity in different businesses.

England's leading economist, Alfred Marshall, seemed to think that only in the case of a coffin maker working for a local poor house would it be impossible to stimulate demand by lowering prices and that with this limited exception, the law as formulated by him is universally true. Yet manufacturers of industrial machinery of all kinds, whose yearly sales amount to hundreds of millions of dollars, are precisely in the same boat with this coffin maker, and unless they manage their business craft according to actual facts and not by generalized errors they are sure to lose their ventures. The whole mechanical engineering profession is largely effected by this little considered but very important characteristic of inelasticity of demand for some goods.

Making plant equipment of all sorts constitutes a very large part of total production from year to year, and each year it constitutes an increasing part. How many engineers recognize that such a business cannot be continuously operated according to the notion of a "normal," because of the nature of its demand? Demand for production machinery is entirely secondary, dependent on the demand for the product of the machine, and becomes effective in orders from three sources:

1 From wear-out
2 From expansion in the market for the machine's product
3 From improvement of the machine reducing the cost of the product.

Unlike demand for food and fuel there is little recurrent demand arising from wear-out or consumption of machinery. Well-built machines are relatively long-lived so that actual wear-out is slow, and as improvement is always proceeding there is a diminishing market each year for old types of machines. Expansion demand comes on only when the machine builder's customer is starting a new shop or is making additions to his capacity to take care of prospective increases in his own demand. This is done only well along in the prosperity stage of a business cycle, and it stops before the boom is over, as soon as the user sees his own temporary satiety point looming up. Obsolescence or improvement demand is largely an expansion demand, since it involves greater production per machine. Expansion demand comes on late in the cycle because most men lack both the money and the courage to expand their plants during depression. The consequence is that a machine industry's order curve would show relatively sharper peaks and wider valleys than consumer goods demand would show. For good reasons, until the particular cycles of the machine-using industries are controlled, buyers will mostly continue to place their orders in that fashion, and will not be tempted by the low prices made in a depression to do otherwise. The machine builder and his employees can feast only as the buyer spreads the feast.

Not knowing much of the practical effects of this inelasticity, but assuming that all demand can be made to respond in the same theoretical way to a reduction in price, Prof. John R. Commons

gravely proposes an absolutely uneconomic scheme, falsely but attractively labeled "unemployment insurance." It is not insurance at all, because it does not distribute the risk of unemployment over a considerable base or over a considerable time. It concentrates the risk on the last employer unfortunate enough to be compelled to lay off a workman at a time when jobs are scarce in his locality and industry.

Certainly conditions of demand and supply for machinery are decidedly different from those for butter. So even though this scheme which it is proposed to apply to all employers alike, might work no great hardship on a butter manufacturer, that is no good premise for a conclusion that its effects would be beneficial in the machine industry. Such superficiality is coupled with a praiseworthy desire to do a really constructive thing—to provide a reserve out of which workers can better support a business depression. But the good motive does not cure the bad logic that is being used to further this uneconomic legislation in Massachusetts and Wisconsin at this time.

Is it any wonder that business is not "sold" on that kind of economics? Can business be blamed for scoffing when such manifest fallacies are gravely put out for public consumption by an economist of some standing without much, if any, criticism from this confrerès? Unfortunately it is just such economic stuff-and-nonsense that attracts the attention of the unthinking mass and arouses their interest. It is easy to create desire for something that looks so easy to get—at some one else's expense— and to induce legislative action regardless of logic and real economics. And so the sale is made—here and in Russia. Then, when private initiative is so hampered that industry withers, the public finds—too late— that it was "sold" —in the sense the bunco man uses the term "sold."

Good economics does need selling of the right kind, to replace the spurious goods mostly current on the market. To do that sort of selling will require men of the engineer type, who are now preferred to the superficial hand-shaking type where any project of importance is under way. The engineer salesman with a professional, scientific background knows his goods and their application, and knows how to engineer the sale. I believe that when the engineer takes up economics seriously he will want to "sell" it to business, and he will keep business "sold on economics" in the proper way. As the engineer is essentially one who carries out the application of other sciences in the furtherance of human welfare, perhaps we would call this class of man an Economic Engineer.

Discussion by President-Elect Harrington

There is being carried out before us today one of the greatest experiments the world has ever known in the endeavor to level all standards of living to one common standard, to be applied to all the people. A large portion of the Russian people, however, have been disillusioned in regard to the possibility of doing that. The theoretical governments that have been set up in like fashion have all failed whether on a large scale or small scale, and their endeavor to level the standards of living and to adopt uniform production and consumption has failed.

The support given to these ideas has resulted from reasoning from the particular to the general—the endeavor to establish general laws from a theoretical consideration of individual cases. The economist must, of necessity, establish his general laws in that fashion. The result has been that in this country recently a number of pronounced errors have been perpetrated in the endeavor to apply to the nation as a whole deductions made from a few individual cases, without regard to locality or local conditions.

The organized workmen have sought vigorously to reduce all wages and all returns for labor to a common standard. And during the late unpleasantness with Germany, when our Government was concentrated in the hands of a few, and operated in a very arbitrary manner for the sake of winning the war, advantage was taken of that situation to establish by law certain uniform standards of payment, not standardizing the living, but standardizing the payment.

Out of that condition there has arisen the idea on the part of organized workmen that a standard of living could be established that should be adopted and used throughout the country. And it has further been contended that something like $2000 a year is necessary to sustain in reasonable American fashion the theoretical family of five of the workman, and various endeavors have been made to extend the view that that rate of payment is essential in probably our greatest industry, that of transportation.

It therefore has been brought about that in some portions of this country today the standard wage fixed by law or by the regulation of a commission is double in that particular industry what it is in corresponding industries in like localities. It is an absurdity to apply the same rule in those portions of the country where food and living conditions are comparatively cheap as in those portions where they are comparatively dear, for excess wages paid to any group in any community are paid at the expense of the other members of that community.

It would seem, therefore, that in studying the welfare conditions in this country we have got to consider very carefully the question of differences in locality. For example, it is very difficult to convince the southern tenant farmer, who has never received as much as $500 a year and has a poor little house to live in, that his fellow in the same community employed on a railroad is entitled to three or four times that wage. He knows that a rank injustice is being done by law.

It would be very simple if we could only reduce all of the general laws to a common formula, applicable to anybody and everybody: it would avoid thought and effort. But we must deal with the narrow, with the individual case and bring up the standards of living in some portions of our country, which are entirely too low at the present time—too low for a wise government and for the wise development of our people; while in others there must be repressed the tendency to secure more than rightfully belongs to them.

It is high time that we addressed ourselves carefully to a broad consideration of the differences in the living conditions of the people of the various parts of the United States, and the rightful compensation which they should receive. We cannot possibly afford to let living conditions go on as they are and have been going on in certain portions of the United States where they are so low that the character of the population is far below the American standard. These conditions, strange to say, do not prevail so much in our larger cities as in the poorer agricultural districts, where education is scanty, where it is difficult to train the people to think about their own condition or to reach them, where the citizenship is widely scattered and it is hard to bring them into a common condition for their own benefit, and where organization is out of the question. The city problems have had many times the study put upon them and are in course of solution, but the problems of our scattered and backward agricultural population are not receiving the consideration their importance warrants, and more attention should be given to them by economists and engineers.

Discussion by Past-President Fred J. Miller

In the development of our modern economic and industrial life we have gotten in some way too far away from the conditions that obtained in the earlier and more attractive forms of industry. The nearer we can get to a simpler ideal in the development of industry, the nearer we shall get to solving many of the difficulties that now confront us in our industrial civilization. I believe in the conditions of economic freedom with a natural leader of the shop to mass the helpers or employees, so that they can, as a group, do better work—and with more profit—than they could do working as individuals, each applying his labor to the materials of nature for the support of himself, working for himself and devoting all his efforts to his own benefit.

Our modern system develops leaders of that sort to a great extent, but at the same time we have drawn into the development of our industrial life certain restrictions around that very association that would not take place under simpler conditions, and I believe that it would be desirable to find some way of doing away with these restrictions, so that these natural associations would come about more readily. The leader, even under those conditions, would be adding to the value of the labor of every man under his direction and would thereby receive the larger reward that is due, and properly due, those capable of directing large operations, who should be liberally paid for their services. There would then be no doubt that each man working under such a leader was receiving what was his due, and that the man who did the leading was receiving what he should fairly and rightly expect.

Developments in Stoker Practice

ONE of the outstanding features of the 1922 Annual Meeting of The American Society of Mechanical Engineers was the well-attended and closely followed joint session of the Fuels Division of the Society and the Stoker Manufacturers' Association, held on Wednesday, December 6. At this session three papers were presented dealing with the various types of stokers that have been developed for the firing of boiler furnaces: namely, The Development and Use of the Modern Chain Grate, by T. A. Marsh; Overfeed Stokers of the Inclined Type, by Geo. I. Bouton; and The Design and Operation of Underfeed Stokers, by H. F. Lawrence. A Chronological History of Stoker Development to the Present Day, by A. H. Blackburn,[1] was also presented at this session. Extended extracts from the three papers dealing with stoker practice immediately follow.

The Development and Use of the Modern Chain Grate

By T. A. MARSH,[2] EAST CHICAGO, IND.

After discussing the need of progressive combustion of the several constituents in coal, and the variations in grate designs to handle different coals, the author takes up the improvement of chain-grate practice as regards air-tightness, cooling, size of combustion space, etc. He shows how a greater boiler capacity can be obtained by increasing grate size or by more intense natural or forced draft (0.50 to 0.60 in. for a combustion rate of 40 to 45 lb. per sq. ft. of grate per hour), but states that high and sudden overloads are best met by forced-draft chain grates burning 55 to 60 lb. of bituminous coal per sq. ft. per hour, with air at 2 in. pressure distributed through compartments between the runs of chain. He describes such equipment, and states that 200 per cent of rating can be reached in 8 min. from a short-banked fire, or in 52 min. from a cold grate. The paper concludes with a table of results obtained in a number of stations equipped with chain grates.

ANY STUDY of the adaptability of various stoker types and their proper functioning as fuel burners must start with an analysis of four constituents in coal, namely, moisture, volatile, fixed carbon, and ash; or roughly, water, tar, coke, and dirt. These constituents are so dissimilar that each must be differently treated in the combustion process, and specific means for burning them in proper sequence must be provided in stoker and furnace design. These facts at once determine as fundamentally correct those types of stokers embodying the principles of progressive combustion, by which is meant in practice a continuous movement of coal through the furnace and the providing of definite treatment at proper time and place for the burning of each constituent of the fuel.

Chain grates embody the principles of progressive combustion. As coal is fed into the furnace, the moisture is vaporized; then the volatiles are distilled and burned in suspension, followed by the burning of fixed carbon. Finally the ash is discharged over the rear, and the air space of the grate is automatically cleaned for a repetition of the process.

Variations in the proportions of these constituents are seen in coals from different sources. Some coals are more free-burning, others tend toward coking. Some have high percentages of ash, others less. Differences as to clinkering or non-clinkering are noted. Such variations at once emphasize the fact that no one stoker and furnace can be suitable for all coals. Stokers and furnaces adapted for progressively burning certain coals must be modified if they are to be used for burning other coals having widely different proportions of characteristic constituents.

Free-burning coals burn best when the fuel bed is undisturbed; coking coals demand fuel-bed agitation. High-ash coals demand continuous scavenging of refuse from the grate; with low-ash coals this is not necessary. Clinkering coals must not be agitated, or clinker formations will result. With non-clinkering coal, agitation has a less detrimental effect.

Chain grates were first developed to burn high-volatile, free-burning, high-ash, clinkering coals. For such coals they offer in best form the specific combustion treatment demanded by their characteristics. The fuel bed is undisturbed, making this stoker type suitable for free-burning and clinkering fuels. The ash is continuously discharged from the grates, which is necessary for continuous operation with high-ash coals.

The development resulting in the modern chain grate has been gradual but definite, and has involved the successful burning of many coals having far different characteristics. All successes, however, have been dependent upon the application of the principles of progressive combustion. Coal burning in any practical process involves some losses: a total conversion of the heat in coal into heat in steam is impossible. Costs of operation must also be considered. These facts determine that every combustion process must finally operate with a common-sense balance between the three important factors in steam-generation economy: namely, maintenance, efficiency, and capacity.

Maintenance and Efficiency

Maintenance and reliability are closely related. The chain grate, with two-thirds of the grate surface out of the furnace and with a simple driving mechanism, was always low in maintenance costs. In the earlier designs, however, some parts were exposed both to heat and wear. Parts necessarily exposed to wear or strain often did not have sufficient resistance.

The chain, which is the fuel-carrying part, is now subjected to but slight heating as a result of adequate ventilation. Stoker frames are not subject to wear and are not exposed to heat. When exposed to heat or wear, replaceable parts are provided.

The high fuel costs of recent years, combined with a broader knowledge of combustion principles, have led to the development of features for improving efficiency. Inasmuch as chain-grate stokers have always involved very low auxiliary power consumption—about 0.5 hp. per stoker—all results obtained are practically net, and little improvement could be hoped for in that direction. Efforts were therefore directed toward the elimination of other losses, such as excess air, and to the reduction of furnace and ashpit losses.

Improvements in Grate Design

Air Leakage. A grate surface moving through a furnace presents the problem of air seals along the sides of stoker and at the rear. The reduction of air leakages at these places has contributed materially to modern economy.

Overhanging bridge walls and water backs are necessary. All attempts to approach efficient combustion without water backs have failed. Many designs of water backs were tried, resulting finally in the modern water back connected into the pressure circulation of the boiler. Water backs are successful only to the extent that they close the openings and eliminate air leakage between the bridge wall and the fuel bed.

Ledge plates or seals along the sides of the stoker went through a similar development, resulting in the modern adjustable ledge plates for making a proper rubbing seal with the stoker chain, and including means for adjustment to keep this seal intact.

The development of the ledge-plate flange adjustable against the side of the upper chain made it possible to raise and lower the stoker to vary the discharge opening under the water back in order to meet broad changes in fuel conditions. The improved results thus obtained indicated the desirability of a water back adjustable as to height, and several designs were developed. These were for the most part difficult to construct or to maintain. From such designs the modern fuel retarder was developed. This is an adjustable member in connection with a fixed water back and bridge wall.

[1] Chief Engineer, Under-Feed Stoker Co. of America, Detroit, Mich. Mem. Am.Soc.M.E.

[2] Chief Engineer, Green Engineering Co. Mem. Am.Soc.M.E.

The fuel retarder can be raised or lowered to make a definite air seal with the fuel bed.

Sifting of coal through the grate often amounted to from 5 to 10 per cent of the coal fired. The use of longitudinal skids to carry the chain in place of cross-rollers has reduced the siftings to 1 or 2 per cent, and in addition to labor saving a more uniform fuel bed results.

Furnace Design

Simultaneous with the development of the stoker has been that of furnace design. Furnace volumes have been quadrupled during the last 10 years. Modern chain-grate furnaces have 2 cu. ft. of furnace per developed horsepower. Losses due to unburned hydrocarbons have been greatly reduced. Formerly a rating of 150 per cent was exceptional. However, modern high-set arches with ample draft and adequate furnaces permit high combustion rates and high ratings from boilers.

Improved furnaces, proper draft, longer arches, water backs, and fuel retarders have all contributed to the reduction of ashpit losses. High stoker and furnace efficiency is dependent, not on a minimum of any one loss, but on a minimum sum of the losses due to excess air, ashpit loss, and unburned hydrocarbons. The modern chain grate and furnace permit adjustment and continuous operation, with the aggregate of these losses a minimum.

Chain grates are ideally adapted for producing smokeless combustion, due to the uniform feed, uniform fuel bed, and the arch. With modern furnaces and proper air control, smokelessness within the capacity of the furnace can be assured even with the high-volatile smoky coals of the Middle West.

Capacity

Modern steam turbines called for greater capacities from boilers. This demand was met in the chain-grate field by development along three general lines: namely, higher drafts, larger grate surfaces, and forced draft.

Higher Drafts. Chimney heights for natural draft were increased to 200, 250, and even in excess of 300 ft. Many plants installed induced-draft fans. Furnace drafts of 0.50 to 0.60 in. were obtained, and combustion rates reached figures of 40 to 45 lb. per sq. ft. of grate surface per hour.

Larger Grates. This rate of combustion seems to be about the limit of natural-draft performance. Efforts to obtain higher ratings have led to larger stokers. Stokers were built up to 18 ft. long, with ratios of grate to heating surface increased to 1 to 30. With such grates and high draft, boiler ratings up to 200 per cent were possible.

Forced Draft. The need of still higher ratings, particularly with low-grade coal, brought the application of forced draft to the chain grate. Early installations applied forced draft at uniform pressure under the entire grate surface. This increased capacity but did not control excess air. Forced draft under a fuel bed with the slightest tendency toward thin spots caused excess-air losses, chilled the furnace, and reduced capacity.

The logical development for air control was to divide the stoker into compartments and control the air supply to each compartment.

The forced-blast chain-grate stoker has been in commercial use for some twenty-five years, and in successful use for approximately ten or twelve years in the anthracite-coal regions, but it was not until five or six years ago that any really successful installations were made for burning bituminous coal.

This stoker consists of a continuous or endless chain of links or grate bars traveling over front and rear sprockets. Side girders are used in some cases, but in others are entirely omitted and transverse members forming compartment sides and wall supports substituted therefor. Above the front sprockets is a sizeable coal hopper, and at the back of this hopper a stoker gate which can be raised or lowered to vary the thickness of the fuel bed on the grate.

The stoker is usually set in an extension or Dutch-oven furnace the arch of which radiates its heat on the incoming fuel under the stoker gate and causes i to ignite, the fire gradually burning down through the fuel bed until it reaches the grate. The thickness of the fuel bed is governed by the character of the coal burned, the length of the stoker grate, and the capacity at which the stoker is to be operated. With the same grate, and with different grades of coal or different capacities the fuel bed may vary between 5 in. and 9 in. in thickness.

Size of Forced-Draft Stokers

The length of the stoker, which should be taken as the distance between the inner face of the stoker gate and the sealing plate of the rear blast compartment, is varied somewhat to conform with the type of boiler under which the stoker is installed, and with the rate of combustion which is desired. Very few forced-draft chain grates are less than 12 ft. in length, but only in exceptional cases do they exceed 20 ft.

The width of the stoker is usually made slightly less than the boiler-furnace width, so as to afford column protection. Single stokers practically the full width of the furnace have been built, even for the wide central-power-station boilers now so popular. There are forced-blast chain-grate stokers in operation today that are 24 ft. in width, and widths of 27 ft. to 30 ft. are under consideration.

Various types of links are used with the forced-blast chain-grate stoker. Regardless of the type, however, the design of the link is such that relatively fine jets of air are admitted through the grate, and a uniform air distribution is applied to the fuel bed from any given blast compartment.

The forced blast is usually admitted into five or six compartments formed between the runs of the chains. These compartments are sealed from one another, and dampers or slides are arranged so that the blast to any one compartment may be regulated independently of that in any other. Some designs are so constructed that any compartment can be operated on forced or natural draft, or closed off entirely, and so that the change from one to either of the other conditions of air supply can be made simply by the operation of a single adjustment lever.

As the coal is burned, the resistance of the fuel bed decreases toward the rear end of the grate, and the air pressure is varied in the different compartments to meet the requirements and effect proper combustion at any given point with the least excess air. It is possible to use only half or three-quarters of the grate length when operating the stoker at low capacities and still maintain a comparatively high rate of combustion on the front portion of the stoker.

The blast pressure in any one compartment rarely exceeds 2 in. water pressure, even at a combustion rate of 55 to 60 lb. of coal per sq. ft. of grate surface. Low-pressure designs obtain similar combustion rates with about one-third of this pressure. The highest pressure is usually carried in the second and third compartments from the front of the stoker, as it is at these points that the fuel bed on the grate is completely ignited and the maximum rate of combustion takes place.

The blast to each compartment is regulated by heat control. The amount of blast used under the grate and the speed at which the stoker chain travels are the factors that usually determine the capacity at which the stoker may be operated with a given thickness of fuel bed.

Combustion Arches

Stokers installed for the burning of the Central States high-volatile coals have ignition or combustion arches set about four feet above the grate at the front end, and somewhat higher at the inner end. These arches cover approximately 50 per cent of the length of the stoker, are of the suspended type, and are made from high-grade refractory material.

Stoker installations for the burning of the low-volatile high-carbon bituminous coals of the Eastern States use a shorter arch, covering about 30 per cent of the stoker length but set at practically the same height above the grate as for the high-volatile coals. Arches set at this distance above the grate require a short ignition arch, 12 to 18 in. in length, at the stoker gate, and set 18 to 24 in. above the grate. The increased rate of combustion obtained with forced-blast chain grates necessitates a better grade of refractory for the entire furnace lining.

Various schemes are being considered today for cooling the furnace side walls of all the different types of stokers operating at high rates of combustion, with the purpose of reducing furnace

maintenance costs. Of these various schemes those employing water-cooled members will undoubtedly prove the most successful, because of positive functioning.

Prevention of the formation of clinkers at the fire line on the side walls is a problem separate and distinct from reducing side-wall maintenance. Some manufacturers are using specially designed firebrick blocks at the fire line, through which blast from the blast duct enters the furnace. The air passing through these blocks keeps them cool and prevents clinker from adhering to them. Other manufacturers are using side-wall water boxes at this point, some of which are connected into the boiler circulation, while others are independently connected.

The bridge-wall water back is a part of the standard stoker equipment with several of the forced-blast chain-grate stokers. This water back is carried transversely across the rear end of the stoker 3 to 7 in. above the grate, and acts not only as an air seal at this point but protects the bare links of the stoker from the reflected heat of the bridge-wall brickwork.

TABLE 1 FUELS USED AND RESULTS OBTAINED IN ELEVEN BOILER PLANTS EQUIPPED WITH CHAIN GRATES

[1] Part of the stokers in this plant are forced-draft units.
[2] All of the stokers in this plant are forced-draft units.

Results Secured

The forced-blast chain-gate stoker is particularly adapted to the use of free-burning coals that require agitation of the fuel bed to break the crusting or caking action so often encountered with the slower-burning coking coals.

With free-burning coals, which usually run high in sulphur and have an ash with a low fusing point, results are being obtained, with uninterrupted operation, that equal the results obtained with other types of stokers using the low-volatile high-carbon coals.

When burning No. 3 buckwheat or coke breeze, fires 3 to 6 in. in thickness are carried on the grate and sufficient blast is carried in the first and second blast compartments to cause a gentle boiling or dancing of the fuel bed. Care must be taken, however, to regulate the thickness of fire and the blast so that excess carbon monoxide is not produced and continued combustion carried through the boiler to the chimney.

The forced-blast chain grate may be operated at continuous high overload capacities for days at a time with only slight variations in the steam output of the boiler. This operation is made possible by the uniform thickness of the fuel bed, the uniform blast pressures carried, and the uninterrupted disposal of ash and refuse from the grate. Such stokers may be operated efficiently under natural draft when burning as little as 10 lb. and as high as 35 lb. of coal per sq. ft. of grate per hour. Forced-draft combustion ratings reach 55 to 60 lb. of coal per sq. ft. of grate per hour.

The forced-blast chain grate is simple to operate and flexible in handling varying load conditions. If properly handled it can be brought from banked fires to full load in time to meet any ordinary power-plant requirements. A cold boiler can be put on the line in 45 min. from the time of lighting the fires. The boiler can be operating at 150 per cent of rating in 5 min. from the time it goes on the line, or it can be operating at 200 per cent of rating in 7 min.

With the ordinary short-banked fire, which consists of a bed of coal three to four feet in from the stoker gate, the remainder of the grate being bare, the boiler can be brought up to 200 per cent rating within 25 min., while with the long bank, in which 50 per cent of the grate is covered with fire, the boiler can be brought up to 200 per cent rating within 6 to 8 min.

Automatic control has been successfully applied to both natural- and forced-draft chain grates. With natural-draft chain grates the usual control is by means of a steam-pressure or steam-flow regulator controlling the boiler damper and the speed of the stoker engine or motor. With forced-draft chain grates several control systems are in successful service. The electrical control is applicable on motor-driven installations. The steam-flow regulator controlling the air supply to the stoker and the speed of the grate is giving successful results.

The steam-pressure regulator controlling the air supply to the stoker and speed of the grate is also giving excellent service. In case constant furnace draft is desired, the balanced control can also be applied, as is frequently done with the two latter-mentioned systems.

Natural Draft vs. Forced Draft

Whether natural- or forced-draft chain grates should be installed depends upon the conditions in the individual plant. The station load, banking periods, boiler absorption with or without economizers, as well as the limits of the draft available, are all involved.

Natural-draft chain-grate stokers, within the limits of the draft available, produce cheap steam. Low auxiliary power requirements, low maintenance, and controlled loss in the combustion process, make low cost of steam inherent.

Natural-draft stokers should be installed:

a Whenever the capacities demanded to meet the station load are within range of the natural draft available

b Whenever the load demand is steady or where peaks can be anticipated sufficiently far ahead to permit building up furnace conditions to meet them

c Within the limits of the above two conditions, whenever induced draft and economizers are used.

In Table 1 the author submits some long-period operating figures from chain-grate power stations. While the compiling of such figures by power stations is subject to variations in the methods employed for that purpose, the figures in question nevertheless must be accepted as part of the operating records of large and reliable companies having engineering departments competent to compile such records.

Overfeed Stokers of the Inclined Type

By GEO. L. BOUTON,[1] DETROIT, MICH.

In this paper the author discusses the development, present construction, and method of operation of the front- and side-feed types of inclined overfeed stokers. Several side-feed stokers are described, with an illustration of a Dutch-oven type of setting. It is stated that 200 per cent of boiler rating can be obtained with 0.3 in. to 0.5 in. draft loss through the fuel bed, and that when forced draft is applied, it should be done with proper regard to air circulation and the maintenance of suction above the fire. Front-feed stokers are also described, with an explanation of combustion control by varying the stroke of the coal pusher and the angle of rotation of the bars. The effect of the flux content of ash in determining the fusion temperature is also discussed.

STOKERS of this type are of two general classes, the side-feed double-inclined or V-type, and the front-feed or single-inclined stoker. The early development of these stokers was along natural-draft lines, because that was the draft available and because it was possible to readily burn all the coal required to meet load conditions. As the steam plants have increased in size, the boilers and stokers have also increased in size until this type has apparently reached a limit in a stoker having a projected grate area of 100 to 110 sq. ft. in a single unit, capable of burning sufficient coal, under forced draft, to develop about 2000 b.hp. as a maximum.

The double-inclined side-feed stoker was the first to make its appearance in this country, Thomas Murphy fathering this particular line of development, commencing about 1875. His first attempt, which was hand-operated, was placed in the firebox of a marine boiler and had inclined grates, every second grate being movable. It was provided with a revolving toothed cylinder or clinker grinder extending from front to rear along the bottom of the V, for the removal of clinker and ash.

In 1879 Murphy moved this device forward into a Dutch oven for use in connection with a return-tubular boiler, and added magazines and stoker boxes for feeding coal to the upper end of the grates. He placed a firebrick arch above the entire grate surface, with a second arch enclosing an air space above the arch and with provision for circulating air for combustion over the firebrick arch and through openings in the arch plates immediately above the fire, at the point where the volatile gases are distilled from the coal. About 1880 he provided an engine drive, placing a reciprocating bar across the front of the stoker, with arms and links to operate the stoker shafts which moved the stoker boxes back and forth, and the rocker bars which raised and lowered the movable grates, and with a ratchet which rotated the clinker grinder. In all essential features this stoker is the stoker of this class of the present time, as represented by the Murphy, Detroit, and Model stokers, although there are many minor changes in the stokers as built today.

About 1885 the front-feed inclined stoker was developed, the Roney and Brightman stokers being brought out at that time. The Brightman stoker was apparently not a financial success and it gradually disappeared; a modified form of it, however, still remains in the Wetzel stoker.

Originally the grates in the side-feed stokers were set at an angle of 35 deg. with the horizontal. As the size of the stokers was increased this angle was increased to 40 deg., and later to 45 deg., which is the present standard. Grates at this angle are suitable for bituminous and semi-bituminous coals. With non-coking coals a much flatter grate is desirable, and when coals of this sort are to be burned it is advisable that the stokers be designed particularly for the coal in question. The grates in the Roney stoker are at an angle of 35 deg. with the horizontal, and this stoker will burn anthracite and bituminous coal and lignite. The grates in the Wetzel stoker are also set at the same angle.

Where wood refuse or spent tanbark is used, this is usually burned in connection with bituminous coal, enough coal being burned to keep the grate surface covered. Wood refuse is spouted to the stoker through an opening in the stoker front, or dropped through openings in the arch directly on to the fuel bed. Tanbark is usually mixed with the coal and fed to the stoker in the regular way, that is, through the magazine or hopper. Spent tanbark will run about 60 per cent moisture, and when a half-and-half mixture is used about 85 per cent of the heat supplied to the boiler will be from the coal, the remainder from the tanbark.

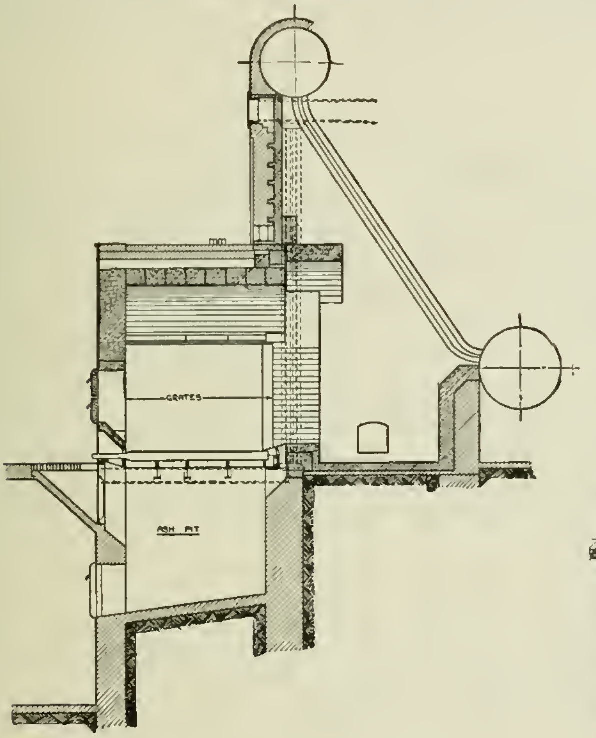

Fig. 1 Typical Dutch-Oven Setting for Side-Feed Double-Inclined Overfeed Stoker under a 500-Hp. Stirling Boiler

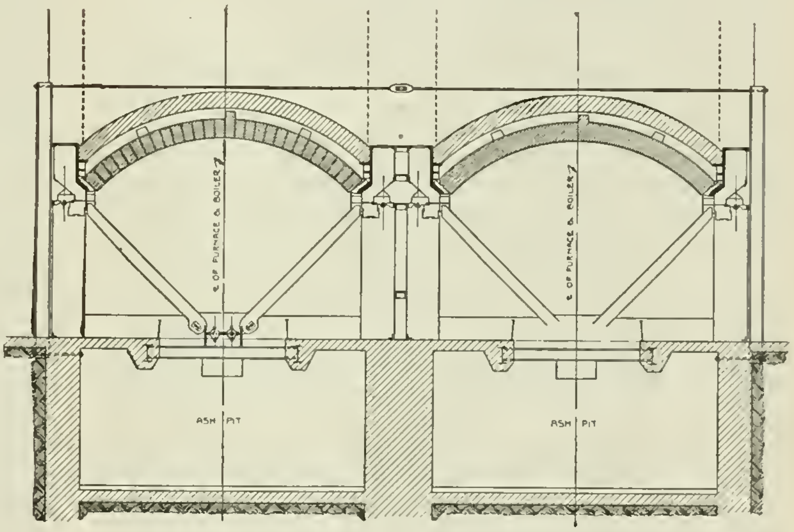

Fig. 2 Typical Dutch-Oven Setting for Side-Feed Double-Inclined Overfeed Stoker under a 500-Hp. Stirling Boiler

Side-Feed Double-Inclined Stokers

The side-feed double-inclined stoker may have either a flush-front or Dutch-oven setting. The flush-front setting is limited to the smaller return-tubular boilers and horizontally-baffled water-tube boilers. On the larger return-tubular boilers, vertically baffled horizontal water-tube boilers, and boilers of other types it is advisable to place the stoker in a Dutch-oven setting. A Dutch-oven setting materially simplifies the matter of supplying coal to the stoker, and where desirable an eight or ten-hour supply of coals can be stored on top of the stoker. A typical Dutch-oven setting is shown in Figs. 1 and 2.

[1] Chief engineer, Murphy Iron Works. Mem. Am.Soc.M.E.

These stokers are made in various sizes, both as to width and depth, varying from a stoker with a grate surface 4 ft. wide and 3 ft. deep to one having a grate 12 ft. wide and 9 ft. deep. In the larger stokers 1 sq. ft. of projected grate is provided for each 6 1/4 rated horsepower of the boiler, and in the smaller stokers 1 sq. ft. for about each 5 rated horsepower. Where the stokers are set with a Dutch oven they extend in front of the boiler about the depth of the grate surface of the stoker, this being varied to suit local conditions and the details of the boiler. The overall width of the stoker is roughly the width of the boiler setting. The head room required will vary with the width of the stoker. The boiler should be set sufficiently high so that the front header or the sill of the tube-door opening clears the top of the arch about 3 in. This would mean a height of about 6 ft. on a 100-hp. boiler, 7 ft. 9 in. to 8 ft. 3 in. on a 300-hp. boiler, and 11 ft. 3 in. on a 600-hp. boiler. Where vertical water-tube boilers are used, such as Wickes, Rust, or Erie City vertical, it is advisable to place a combustion space between the rear of the stoker and the tube surface of the boiler. This can be made of somewhat greater cross-section than that of the stoker. The distance from the rear end of the grate surface to the tube surface should be 6 or 7 ft.

Stokers of this class are usually driven by a small steam engine operating the reciprocating bar through a chain of gearing. Where for any reason it is desirable to do so, a motor, either a.c. or d.c., can be used in place of the engine. An engine is preferable to a motor, however, as the exhaust steam which it supplies is useful under the clinker grinder.

As far as the author knows, the most convenient and effective means of chilling clinker so that it can be readily handled is by means of low-pressure steam discharged under both the clinker grinder and the lower ends of the grates.

It is desirable that the fuel be fed as uniformly as possible to the stoker. The fuel bed is about 8 to 10 in. thick at the upper end of the grates, thinning down gradually toward the clinker grinder. Minor fluctuations in load should be taken care of by minor variations in the draft over the fire. Where the load changes into a decidedly higher or lower range, the coal feed should be increased or diminished to meet this range, the draft over the fire being regulated to take care of the immediate needs of the boiler.

The draft loss through the fuel bed will vary with the amount and kind of coal being burned, the high-volatile coals requiring less draft than the lower-volatile coals. The amount of draft required is also affected by the amount and kind of ash which the coal carries. Where proper draft is provided, stokers of this class will take care of various loads readily up to 200 or 225 per cent of boiler rating, although the draft available usually limits the capacity to 200 per cent of boiler rating or less. Where there is a shortage of draft it is possible to compensate for this in part by increasing the amount of "rousting" or hand manipulation of the fuel bed. At two per cent of boiler rating the draft loss through the fuel bed will vary from 0.3 to 0.5 in. water gage, depending on the kind of coal and the amount of rousting.

Where it is desired to obtain more capacity than can be obtained with the natural draft available, it is sometimes possible to do this by adding forced draft. Where forced draft is applied to a stoker of this class, it is advisable to see that all the necessary items for its proper installation are taken care of. The air should be admitted to the space beneath the grates, either at the front or the rear, in a line parallel with the clinker grinder; two inlets being used, placed symmetrically with reference to the center line of the stoker. Instances have been found where a blower has been placed through each side sheet, discharging air directly against the grates, and troubles have quickly resulted from such practice. Under natural-draft conditions the amount of air reaching the furnace through the openings in the arch plates increases as the capacity increases, and provision should be made so that this same condition holds good under forced-draft conditions.

The limit of capacity under forced-draft conditions will be that point where the draft over the fire is so reduced that fire is blown out of various openings. This will be when the draft over the fire is reduced below 0.10 in., probably to about 0.05 in.

With forced draft properly installed and skilful firing it is possible under favorable conditions to get in the neighborhood of 300 per cent of boiler rating. The fires are rather thin for forced-draft work and it requires closer attention to the fuel bed to keep the grates covered than in the case of stokers using a much thicker fuel bed.

Where these stokers are operated under natural-draft conditions the proper method of regulating the air supply is by adjusting the damper at the outlet of the boiler. This can be done by hand where necessary. There is no objection to using a damper regulator provided it reproduces the action of a skilled fireman as closely as possible and shifts the damper slightly with varying steam pressure.

Front-Feed Inclined Stokers

Of the many forms of front-overfeed inclined stokers which have appeared, the Roney and Wetzel are still being built. The Roney is a natural-draft stoker only. It is made up of an inclined grate with transverse bars. Each bar is supplied with sectional grate-bar tops so arranged that they allow a uniform distribution of air through the whole grate area. At the upper end of the furnace, flat fuel plates are provided on which the coal can coke, and this prevents sifting of the green coal until the coking process is well under way; by this time there is no further trouble with siftings. There is an agitation given to the grates by a rotary motion of the transverse bars. This motion feeds the refuse and fuel uniformly toward the lower end of the grates. At this point and immediately above the dump grates there is an agitator for the purpose of breaking up clinker that may form in this zone; it also serves the purpose of preventing the avalanching of the fuel bed down the grate while the dump grates are open and the fire is being cleaned. The dump grates are slotted, thus providing active fuel-burning surface in this zone.

The angle of rotation of the transverse bars can be varied from nothing to a maximum. The stroke of the coal pusher can also be varied. The ability to control these motions without changing the speed of the engine provides a very wide range of flexibility. It is customary practice to operate Roney-stoker driving units at constant speed, and take up the fluctuation in the rate of feeding coal by means of the variable adjustments on the stroke of the coal pusher and grates. Motors or reciprocating engines are usually supplied for driving Roney stokers. The whole stoker-driving mechanism is extremely simple, as a multiplicity of stokers can be driven from one shaft for both the feed and grate motion.

The thickness of the fuel bed on a Roney stoker is uniform for a given grade of coal and does not vary for different ratings. The best practice is to control the rating on the boiler as desired by means of the boiler damper and not by thickening or thinning the fuel bed.

The Roney stoker is applicable to any type of boiler. It is set with an arch to ignite the incoming fuel and burn the volatile gases. This stoker is suitable for burning anthracite and bituminous coals and lignite. For burning anthracite and lignite a slight change is made in the grate-bar tops so that they will overlap in any position and thus prevent the fuel from sifting through. There are a number of installations where hog fuel has been burned very successfully in conjunction with coal. This is done by using an extension furnace and cutting a hole through the arch so that the hog fuel can be dropped through the arch and on the fuel bed.

The Wetzel stoker is somewhat similar to the Roney, the principal difference being in the form of grate used. Instead of being made up of bars extending across the furnace and rocking, the grate is made up of a series of bars extending from front to rear. These bars are ribbed to prevent sifting; the upper end of the grate is supported on a short rocker arm so that is has a slight forward-and-back motion, and the lower end on an arm placed at a somewhat different angle, so that the motion of the lower end of the grate is practically at right angles to the grate surface.

Ash

Most coal ash has a fireclay base with various kinds and amounts of foreign materials which act as fluxes, such as iron, lime, magnesia, and sodium and potassium oxides. An ash low in fluxes is desirable because it will be an ash of high fusing temperature and one which can be handled in a stoker more readily than an ash high in fluxes. It is also desirable when the maintenance of the stoker and boiler brickwork is considered, as small particles of ash impinge on the brickwork, and the iron, lime, etc., in the ash form an active flux for this firebrick at furnace temperatures.

The Design and Operation of Underfeed Stokers

By H. F. Lawrence,[1] Philadelphia, Pa.

This paper describes briefly the distinctive features of the single- and multiple-retort types of underfeed stokers, giving particulars regarding their operation and results that have been obtained. Emphasis is laid on the importance of proper adjustment of the secondary coal feed, to prevent clinker and ash depositing at the lower end of the retorts, and on draft control not too responsive to momentary variations in boiler conditions. Underfeed stokers are said to be particularly adapted to bituminous and semi-bituminous coals, and for carrying sudden overloading. Clinkers are a necessary result of the high temperatures secured, and different means for preventing their adhesion to the side walls are discussed. The relative merits of various fans are considered, and a table of setting heights is given.

Underfeed stokers are so designed that coal is fed from beneath the burning fuel. This is accomplished by feeding through retorts with adjustments so that the fuel bed is replenished throughout the length of the retort. The main feed from the coal hopper is accomplished with rams of fixed displacement so that the amount of fuel fed per stroke is a definite amount for a given coal, and therefore the amount fed per hour is accurately controlled by regulating the speed at which the rams are operated.

Single-Retort Stokers

The first development of this type was the single-retort underfeed stoker. This consists essentially of a horizontal retort, into which fuel is fed from the hopper and distributed throughout the length of the retort. Tuyeres are placed around the edge of the retort and through these air is supplied to the fuel under pressure from a fan. Dead plates or dump plates are placed on each side of the retort, from which the ash and refuse are removed. For wider furnaces, intermediate inclined movable grates or tuyeres are placed between the retorts and the dump plates. These serve the purpose of providing more grate surface and also of depositing the ash and refuse on the dump plate.

Single-retort underfeed stokers do not require large ashpits and ash tunnels below the boiler-room floor. They are cleaned of ash and refuse by dumping into shallow ashpits which are depressed slightly below the floor line, and withdrawing the ash and refuse through doors in the boiler front at floor level, or by withdrawing the ash from the dead plates through doors in the boiler front.

These stokers are also particularly adaptable to installations in which more than two boilers are placed in a battery, since side doors are not necessary to their operation. Boiler plants may then secure the advantages of the underfeed type of stoker without the expense of excavation and without being limited as regards arrangement of boilers.

Multiple-Retort Stokers

The multiple-retort stoker is a development of the single-retort and consists of a number of single retorts placed close together and inclined with the ash discharge at the rear. As the coal is burned the ash is formed on top of the fuel bed and is floated to the rear and deposited on dump plates or into crusher pits from which it is readily removed. The continuous ash discharge consists of rotary toothed crushers placed at the rear of the stoker and set low so that a large, deep pit is formed for receiving the ash and burning out the last of the combustible material.

The secondary coal feed, that is, the feed from the retort to the fuel bed, is obtained in various ways. The Taylor stoker uses additional rams similar to the coal-feeding ram, which are placed in the bottom of the retort. The retort inclination is such that the rams are reciprocated horizontally. The Westinghouse and the new Frederick stokers have a lesser inclination, and the secondary coal feeding is accomplished by large wedge-shaped castings placed at the bottom of the retort. These are reciprocated on an inclination corresponding to the slope of the bottom of the retort.

The Jones and Detroit stokers have similarly shaped retorts, and the secondary coal feed is obtained by small wedge-shaped pushers which are reciprocated horizontally in the bottom of the retort. The Riley stokers accomplish the secondary feeding by reciprocating the retort sides and the tuyeres. They also vary in the angle at which the tuyeres are placed—from horizontal in the case of the Detroit to 25 deg. in the Taylor stoker.

Tuyeres are placed between the retorts, and serve to convert the static head of air into velocity and direct the flow of air through the fuel bed. The tuyere designs naturally are different in each stoker.

All designs are for forced draft and cannot be operated at any appreciable capacity with natural draft. The air for combustion is circulated beneath the furnace parts and thereby cools these parts before being discharged through the fuel bed.

Operation of Underfeed Stokers

The operation of underfeed stokers is essentially as follows. The incandescent burning fuel is on top and is replenished throughout the entire retort length from beneath. As the coal emerges from the retort it is coked and spreads over the tuyeres, forming a homogeneous fuel bed across the entire furnace width. As the fuel approaches the surface the volatile matter is completely distilled off and the fuel completely coked. The surface consists of a layer of incandescent burning coke. The air for combustion is introduced near the point where the fuel emerges from the retort. As the volatile gases are liberated they are thoroughly mixed with air. As the mixture passes up through the fuel bed, higher-temperature zones are reached and complete combustion of the volatile gases takes place when they pass through the white-hot coke at the surface.

Smokeless combustion is obtained without the use of special mixing of ignition arches or special brickwork construction. As the fuel bed is replenished from beneath the surface, the burning incandescent coke which is on top is slowly moved toward the dump plates. As the ash is formed it is floated on the surface and is eventually deposited on the dump plates.

The control of the fuel bed is obtained by adjustments of the secondary coal-feeding arrangement. For good operation it is essential that the fuel bed be so controlled that the replenishing coal emerges from the retort through its entire length; the lesser amount being fed from the rear end of the retort.

With low-grade western coals more fuel must be discharged from the rear end of the retort than with the high-grade eastern fuels. In general, the greater the quantity of ash in the coal, the longer should be the stroke of the secondary fuel-feeding mechanism.

If insufficient coal is fed from the lower or rear end of the retort, the ash, instead of being carried on to the dump plates, is deposited at the lower end of the retorts, and as high fuel-bed temperatures are always obtained the ash is clinkered, and when deposited at this point it blocks the air discharge. After a short interval, fuel from the upper part of the retort, which is not coked, is deposited over this clinker formation and then avalanches on to the dump plates. With this condition of fuel bed it is impossible to secure good results or good operation. With proper strokes of the secondary coal-feeding mechanism this condition can be eliminated, as with the proper amount of coal being fed from this section of the retort the ash and clinker can never be deposited at this point. This is really the important adjustment to be made for various grades of coal, and it probably receives less attention from plant operators than any other variable. When properly adjusted the fuel bed is automatically maintained clean, and high rates of combustion can be obtained.

With the underfeed stoker properly adjusted, fresh fuel will be fed up throughout the full length of the retort. Green fuel moving upward with respect to the tuyeres tends to keep them buried, and consequently the ironwork is in the comparatively cool zone of the fuel bed. For this reason the maintenance is low on underfeed stokers.

With the underfeed system of combustion the excess air re-

[1] Mechanical engineer, American Engineering Co. Mem. Am.Soc.M.E.

quired can be reduced to a minimum, which means that high fuel-bed temperatures are obtained. The fuel-bed temperature will probably always exceed the ash-fusion point of any of our coals. This means that clinker must be formed in order to secure the best combustion results.

Results Secured

These stokers are particularly adapted for burning bituminous and semi-bituminous coals. However, with only slight modifications lignites and coke breeze are also burned with excellent results.

With the thoroughly coked thick fuel beds carried, this apparatus is very quick in responding to load demands. Under running

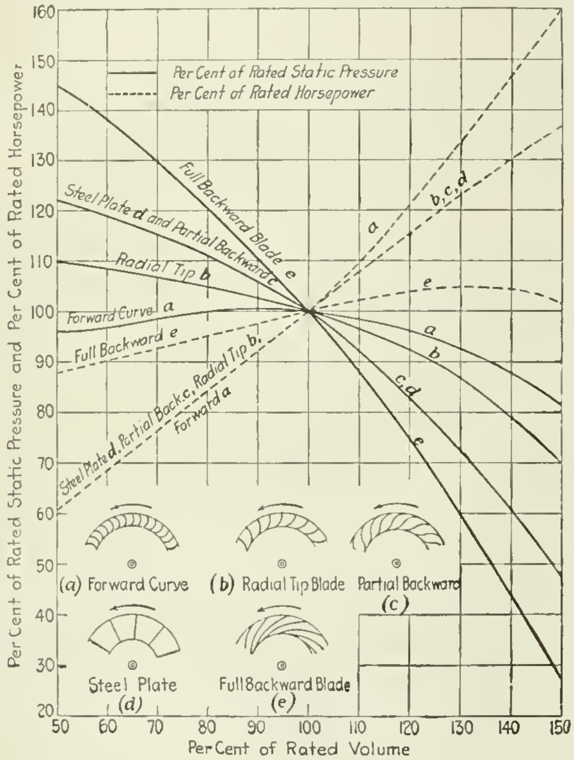

Fig. 3 Fan Characteristics at Constant Speeds

conditions the boiler capacity can easily be doubled almost instantaneously. From a banked-fire condition loads equivalent to 200 per cent of boiler rating and over can be picked up in a few minutes.

Many times the stoker manufacturer is handicapped by being forced to meet space limitations of the boilers. It is recommended that stokers be selected first, of the proper size and type to obtain the desired results, after which the boiler should be selected to meet the furnace requirements of the stoker.

Regulation

Automatic regulation is receiving a great deal of attention at the present time, and improved equipment has been developed which is giving good results. It is doubtful, however, whether regulating apparatus will ever be developed to the point where adjustments will not be required from time to time. These adjustments, it may be said, should only be made by an expert observer or fireman.

An ideal equipment would control all the variable elements in the proper proportion, thereby obtaining a constant steam pressure. It would, in addition to controlling the fuel, air supply, and drafts, be required to control the feedwater in proportion to the load.

Practically all regulating systems in use at the present time are controlled by variations in the steam pressure. The damper regulator is very sensitive to slight changes in steam pressure, and unless its action is retarded by some means, hunting will take place, causing rapid and wide variations in the air pressure. Much better fuel economy is obtained by eliminating the rapid fluctuations in air pressure. This is accomplished by damping the regulator so that a greater steam-pressure variation is required to operate it through its complete stroke.

The Jones fluid-operated rams are controlled by a Cole automatic valve for each cylinder. This valve is operated from a power source, usually driven from the fan or the fan engine. It is possible to obtain a number of different adjustments for the rate of turning this automatic valve, so that the rate of feeding fuel can be varied for each retort; in fact, all the retorts can be arranged to feed at one speed or at eight different speeds. Furthermore, each valve can be operated by a hand crank, so that the coal can be fed into the retort in very large quantities at any time it is required.

Fans

There are several types of fans used in stoker service, each of which has different characteristics.

The full-backward-curved fan with long blades, Fig. 3 (*e*), which is also a high-speed fan, has the best characteristics for stoker service. It has a very steep static-pressure curve, together with a comparatively flat horsepower curve, and has the additional characteristic that after reaching the maximum horsepower any further increase in volume due to reduction of static pressure, will reduce the horsepower required. The smallest-sized motors can be used safely on this type of fan, and it also has the highest efficiency.

For a fan operating against a constant resistance the power varies as the cube of the speed, the static pressure as the square

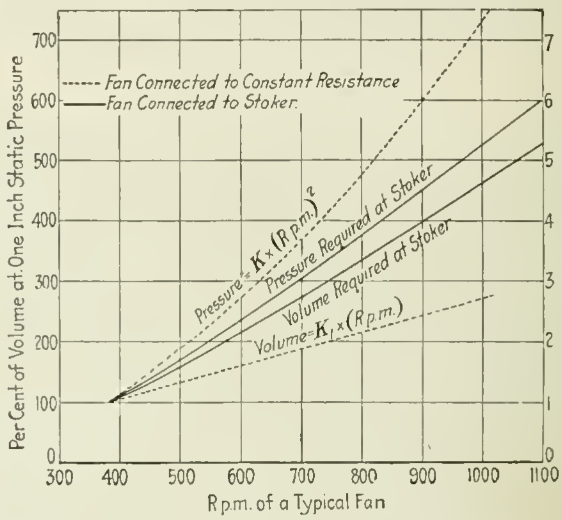

Fig. 4 Relation of Volume and Pressure of Air to Fan Speed

of the speed, and the volume directly as the speed. In underfeed-stoker practice, however, the resistance is not constant, so that the fans do not follow this law.

Fig. 4 shows in the dotted curves the volume and pressure characteristics in accordance with the constant-resistance law, while the full-line curves show the volume and pressure characteristics at the stoker connection. These curves have been plotted from data obtained in actual stoker tests.

Clinker Prevention

The most serious operating difficulties are caused by clinker adhesion to the side walls of the furnace. There are several successful methods for preventing this, the most popular one probably being that in which perforated firebrick blocks are located along the clinker line, through which the air is blown from the stoker air duct. Care must be used in locating these blocks so that no free air is discharged above the fuel bed.

Another method of preventing side-wall clinker uses special high side tuyeres through which air for combustion is discharged, these tuyeres extending high enough along the side walls to prevent the clinker adhesion to the brickwork.

Still another method which has been very successfully applied in a number of plants, is one in which cast-iron side-wall air boxes are used. These faces of the boxes toward the fuel bed are made of small overlapping ribbed plates. These plates are solid so that no air is discharged through them. Air enters one end of the box from the stoker air chamber and is discharged under the tuyeres from the other end of the box; this air circulation being sufficient to prevent burning of the plates and the ad-

hesion of clinker. These boxes should not be less than 10 in. wide.

Carborundum bricks are satisfactory for this purpose with some coals. However, when the ash contains much iron, carborundum brick is rapidly eaten away.

TABLE 3 DEFINITIONS OF SETTING HEIGHTS FOR VARIOUS TYPES OF BOILERS

Type of Boiler	Setting Height
Water-tube, horizontal	Floor line to bottom of header above stoker
Water-tube, inclined	Horizontal mud drum: floor line to center of mud drum
	Vertical mud drum: floor line to top of mud drum
Water-tube, vertical	Horizontal mud drum: floor line to center of mud drum
	Vertical mud drum: floor line to top of mud drum
Horizontal return tubular	Floor line to under side of shell.

Setting Heights

The Stoker Manufacturers' Association, in conjunction with the American Boiler Manufacturers' Association, have adopted minimum setting heights for all types of boilers which are given in Table 2. Setting heights for the different types of boilers are defined in Table 3.

A number of recent large boiler units have been set considerably higher than as specified in Table 2. The boilers of the new Hell Gate power station are set 21 ft., giving a furnace volume of $16^1/_2$ cu. ft. per sq. ft. of grate surface, or 390 cu. ft. of furnace volume per 1000 sq. ft. of boiler heating surface.

Frequently the combustion space required is stated as a function of the coal-burning capacity. This is misleading since it leaves out of consideration all conditions imposed by the arrangement of the boiler baffles and stoker in relation to one another.

It is desirable to keep the velocity of the rising gases in the furnace as low as possible, but a larger horizontal furnace section, with consequent large volume, may not necessarily do this.

Ample height of the boiler above the stoker should be secured in order that combustion of the gases may be completed before they enter the tubes.

High setting heights impose a more severe service upon the brickwork. Extreme care must be used in designing the furnace walls, so that they will stand not only the high furnace temperatures, but also the load. It is common practice at the present time to expose all of the first few rows of boiler tubes to the radiant heat from the fuel bed. This gives lower furnace temperature and greater life to the brickwork.

No arch construction or special brickwork is required in the application of underfeed stokers, and in fact it is preferable not to have arches. On account of the differences in the coefficients of expansion of different kinds of brick, however, only one kind should be used in the furnace.

Proper provision must be made for taking care of the expansion as the setting heats up. The brick should be carefully sized so that thin joints can be obtained. Each brick should be dipped in a thin fireclay wash and tapped into place with a wooden mallet until it touches the bricks next to it.

Walls should never be so constructed that they overhang or lean toward the furnace. Walls which slope outwardly from the furnace will give much longer service.

Discussion on Stokers at Fuels Session

ALEX. D. Bailey[1] submitted a written discussion in which he said that Mr. Marsh's statement that "modern steam turbines called for greater capacities from boilers" was not the whole story. Turbine development had been in a way parallel with boiler development, and along with the development of these two major pieces of equipment had been the coincident development of all plant equipment. So far as the boilers themselves were concerned, the demand for higher capacities had been occasioned by increased fuel costs and increased equipment costs, partly due to higher pressures and partly to economic conditions.

That the boiler proper had shown itself capable of taking care of these higher rates of heat absorption without materially decreasing its efficiency was evidenced by the very marked development of stokers and other coal-burning equipment during the past few years. The chain grate, which was probably one of the oldest forms of mechanical stoker known, had had to fulfill its part in this development in order to justify its existence, and the development of the forced-draft chain grate was the result.

Just as the natural-draft chain-grate stoker had made possible the use of coals which were unsuited to existing types of stokers which were consequently cheap, so the forced-draft chain grate had made available not only low-grade fuels, but also coke breeze and smaller sizes of anthracite, which had not been previously considered suitable for power production. This economic saving alone justified the improvement in chain grates.

John M. Drabelle[2] wrote that in the Central West, particularly in Iowa, there was a rather peculiar type of fuel available, namely, one low in heat value (8500 to 9000 B.t.u. per lb. as screenings) and having a high ash content (20 to 35 per cent), the ash being easily fusible. To burn this it was necessary to have an undisturbed fuel bed, a large furnace volume, and a high ignition rate. The chain-grate stoker, judging from several years of actual operating experience, was the only stoker successful in handling this type of fuel.

In judging stoker performance it was necessary to bear in mind that it was the total cost per 1000 lb. of water evaporated and not percentage efficiency that must be dealt with. The maintenance problem was a serious and important one, also the amount of operating labor required and the item of investment, the latter in turn determining fixed charges.

The ideal chain-grate stoker, Mr. Drabelle believed, would be a combined natural-draft and forced-draft stoker operating under

[1] Chief engineer, Stations 1 and 2, Commonwealth Edison Co., Chicago, Ill. Mem. Am.Soc.M.E.

[2] Mechanical engineer, Iowa Railway & Light Co., Cedar Rapids, Iowa. Mem. Am.Soc.M.E.

the normal operating conditions of the station on natural draft and over the peak load with forced draft, thereby reducing the amount of auxiliary power required to the absolute minimum, and resulting in a lower cost per 1000 lb. of water evaporated.

J. R. Fortune[3] submitted a written discussion in which he said that there ought to be some way of designating stokers other than by the terms "underfeed" and "overfeed." There was but one type of stoker that, in his opinion, could truly be described as overfed, and that was the sprinkling stoker, which was not very well known in this country but which was quite commonly used abroad. This was the only stoker in which the fuel was fed on top of the burning fire. The fuel in the stokers of the Murphy, Roney, and chain-grate types was always, in effect, underfed. In other words, there was a layer of fuel unignited close to the grate bars near the stoker hopper, and this was overlaid with fuel which was burning almost all the way to the feed opening of the stoker. The unignited fuel close to the grate bar might extend halfway down the grate.

A. H. Blackburn[4] wrote that in drawing attention to the many types of underfeed stokers Mr. Lawrence had omitted to mention the lateral-retort stoker brought out by The Under-Feed Stoker Company of America during the present year. The novel feature of this stoker was that it fed the coal in through a main retort extending from the front wall of the furnace to the bridge wall, with lateral retorts branching off the main or central retort at right angles. The front and back walls of the furnace were protected by high air-cooled tuyeres, the stokers having been designed for working continuously around 200 per cent boiler rating. The design of the stoker enabled it to be installed without a basement and under low-set boilers that might be already installed.

Walter N. Polakov[5] in a written discussion said that, quite apart from the excellence of design and construction of its mechanism, and altogether independently of its adaptability to fuel used, the success or failure of a stoker depended largely upon the mode of its use.

The Stoker Not an Automatic Device

Sometimes it was claimed that a mechanical stoker was an automatic device and that by virtue of its so-called automatic action the plant owner could "forget his power plant." A stoker, however, was automatic only in so far as it replaced a certain amount of physical exertion by the substitution of mechanical power. For this reason alone the stoker attendant was no longer interested in how he could spare himself the pain of shoveling unnecessary coal into a furnace, and unless he had other stimuli he would let the stoker feed as much coal as it could and make as little steam as it might. Again, when supplementing a mechanical stoker automatic regulating devices were introduced, they as a rule controlled only one or few detached factors, but never the operation as a whole. Worse yet, in many cases these automatic controllers operated either a little behind time or made adjustments of conditions by steps, the consequence being that losses were increased coming and going. Even with oil firing he had on record cases where automatic regulators of merit had to be discontinued and manual control introduced in order to improve the evaporating efficiency.

The foregoing was neither theory nor generalization, but a summary of facts which had come under his observation during the last twenty years.

Wm. R. Roney,[6] who in recognition of his pioneer work in stoker design and construction had been asked by Chairman Breckenridge to share the platform and open the oral discussion, spoke briefly regarding troubles encountered in stoker operation, and said it was his experience that the human element was the most important factor in the satisfactory handling of such equipment.

David Moffat Myers,[7] agreed with Mr. Roney as to the importance of the human element. He further called attention to the fact that nothing had been said in the papers regarding marine applications of stokers. Here was a wonderful field for effecting economy; less coal would be used, thus leaving more space for carrying revenue-producing cargo. He was desirous of learning the attitude of stoker manufacturers toward automatic regulation. He thought that in specifying heights of boiler settings the figures should be related to the capacity rating expected from the boilers.

Later in the discussion Mr. Myers said that during the war, in the course of an investigation of the possibilities of stokers and Scotch boilers, he had come across a stoker that had been used extensively and successfully on locomotives. Locomotive practice was similar in some respects to marine practice, both having to deal with very cramped fireboxes and very small combustion space. The stoker in question involved also the use of a screw conveyor which brought the coal from the tender to a point at the footboard of the locomotive. From that point screws inclined at about 60 deg. carried the coal up to two points on either side of the fireboard and above it, from which points it was distributed over the fire by steam jets. In case of a breakdown on board ship, it would not be necessary to discard such a stoker, because it could be fired by hand without any difficulty.

Furnace Volume Essential for Good Design

J. E. Woodwell[8] said that one of the principal essentials of stoker design was furnace volume, for in running on high ratings at peak load it cost money to replace furnace linings, brickwork, etc., and to have boilers out of commission while such repairs were being made. Accordingly, in his last central-station design, he had installed stoker capacity 15 per cent in excess of anything that had been done in the Hell Gate and other new stations, simply as a reserve against furnace repairs and so that the boilers would be in service 100 per cent of the time.

As to automatic control, he did not agree with Mr. Polakov. Manual control could never equal automatic control under proper supervision.

Theodore Maynz[9] called attention to the fact that in operating chain-grate stokers it was necessary to watch the carbon in the ash. With some coals, running with 35 to 40 per cent air would give good carbon, but with others the air would have to be raised to 60 or 70 per cent before the total loss was a minimum.

One of the most important things in operating forced-draft and natural-draft chain-grate stokers was to have uniform coal. This was difficult, for even when it was mixed in advance, by the time it got to the coal hoppers it was segregated, the coarse going through the center and down the sides while the fine coal packed about a foot from the wall to about within a foot of the center. His company had had some success in obviating this by employing tilting and split gates in order to maintain a more even fuel bed.

The rear end of the stoker should be sealed either by banking coal against the water back or by means of ashes between the lower portion of the grate and the ash pit. With a forced-draft chain-grate stoker, the dirt coming out from the front made a boiler room almost uninhabitable, especially when there was, say, only about 0.05 in. draft in the furnace. He believed with Mr. Polakov that instruments were absolutely necessary, no matter how small the plant, and that the men appreciated them.

Edwin Lundgren,[10] replying to the questions propounded by Mr. Myers, said that one reason why stokers had not been applied extensively in marine practice was that while fuel obtained in one port might burn satisfactorily, the next fuel bunkered might give a great deal of trouble.

Another difficulty was the limited space between the tubes of the boiler and the bottom of the ship, which made it necessary to install a horizontal type of stoker. The company with which he was connected had applied that type of stoker to several ships in Europe and had reported in most cases very successful operation.

As to automatic regulation, speaking as a stoker manufacturer he would say that there were so many varying factors that must be compensated for that it could not be other than unsatisfactory. It had been his personal experience that the best control was that which an intelligent fireman would give when provided with proper

instruments for his guidance and means whereby he could easily adjust the factors that varied.

Albert A. Cary[11] called attention to a previous statment he had made to the effect that when a fuel carrying combustible gaseous matter was charged upon a hot fire bed, the first thing that happened was the distilling of the gaseous matter, this gas going up into the combustion chamber and being burned there. It was only the coke or fixed carbon that remained behind that was really consumed on the grate. Therefore, if it was desired to specify the capacity of a stoker by the rate of combustion, the latter should be expressed in pounds of fixed carbon burned per square foot of grate area per hour, not in pounds of fuel. Rousting and hand manipulation of the underfeed stoker was something that needed to be done away with in order to get the best results.

Alfred B. Carhart[12] said that he was very strongly inclined toward regulation by intelligent operators as against automatic control beyond the reach of the operator. Automatic control gave an average, but only through the intelligent operator could there be obtained adjustment to varying conditions which would be in control of the actual results of the moment, instead of historical records afterward to show what mistakes had been made.

C. G. Spencer[13] called attention to the fact that the coal now supplied to the East had entirely different characteristics from the fuels for which stations in that section had been designed. There was no reason to believe that the industrial war in the coal fields was ended, and that being the case, the pressing need was for a stoker that would handle effectively a variety of coals.

H. C. Heaton,[14] discussing the stratification of coal in bunkers, said that unless bunkers were properly designed the coal would tend to pile up and stick together on the sides of the bunkers, with the result that it would avalanche and supply successively different sizes to the grate. He had seen coals that would stand almost vertically on the sides of the bunker, which of course, was impossible to overcome. He believed that the best way to handle coal out of the bunker to the grate was with a spout that would swing and spread the fuel uniformly over the grate.

Smoke Abatement

O. P. Hood,[15] at the instance of Chairman Breckenridge, spoke briefly of the chaotic situation regarding smoke abatement in the various sections of the country. Most of the smoke ordinances, he said, were largely concerned with matters of administration. There was need for a simple statement of the technical requirements —what kind of smoke could be allowed, and for how long, etc.— and such a statement was now being drafted by a committee fathered by the Fuels Division of the Society and having in its membership representatives of the Heating and Ventilating Engineers, the Stoker Manufacturers' Association, railroads and other interested bodies. The matter of administration, it was proposed, should be left to each community for settlement. Mr. Hood, it should be stated, is chairman of the committee in question.

Henry M. Burke[16] said that as the operator of a 5000-hp. industrial plant he had found that the automatic control of the entire plant was impossible from the standpoint of efficiency, as was also control by manual means where a bonus scheme of payment obtained, because in that case the firemen were anxious to do more work and took care of too many operations to operate the plant most efficiently. He had therefore worked out standards according to the loads carried by the plant and had sectionalized the control, taking up the peak loads with manual control and carrying along the regular load by the automatic control. The plan had worked satisfactorily, not only on the stoker boilers but also on the boilers fired with fuel oil.

J. B. Crane[17] said that in his opinion the best plan was to set as many boilers in a plant as possible to carry a steady load and employ automatic regulation to keep steam pressures up to the remainder. As to furnace volume, his company had started in 1916 to put in boilers with $4^1/_2$ cu. ft. per rated hp., and the results had fully warranted that action. It was known now that instead of the melting point of the brick being the factor, it was the point at which it began to compress. Consequently, if combustion chambers were designed so that the load on the hot zone would not be more than 25 lb. per sq. in., were inclined away from the grate upward, and were provided with some means for overcoming the slight tendency of the brickwork to fall into the center of the combustion chamber, he believed that no further trouble would be experienced with combustion chambers, no matter how heavy the loads that were carried on the boilers.

Jos. J. Nelis,[18] speaking of the problems of marine men, said that the sea had not attracted the technical man as yet, and until it did, he did not think there would be a very general adoption of improved machinery.

Another matter to consider was the space available. Tests recently made by the Bureau of Mines and the Shipping Board had shown that with practically one-quarter of the volume used ashore, the Scotch boiler gave over 80 per cent efficiency, so that this boiler had been adapted for marine service because it had been found to be the best boiler; but it was passing, not because it was not the best boiler, but because pressures were coming up. Stokers had been tried on the Scotch boiler, principally the underfeed types. They would not get rid of the clinkers, however, so that they had been finally abandoned.

The marine man had one thing in his favor that the shore man did not have, namely, an absolutely steady load factor. It was therefore possible to design for a marine power plant closely, and to get higher efficiency than in the case of a shore plant with fluctuating load. There was a chance now to install stokers on ships, provided a low, flat boiler to get the furnace volume became available.

Fewer Coal Sizes Suggested

Lester C. Bosler,[19] said that anthracite coal operators thought that there should be a reduction in the number of sizes. They would like to eliminate the rice and two sizes of barley now produced and combine them into a size called bird's-eye, which would mean a size through $^1/_4$ in. and over $^1/_{16}$ in., and preferably through $^1/_4$ in. and over $^1/_{32}$ in.

M. Alpern,[20] representing the Stoker Manufacturer's Association, spoke briefly of its work in correcting evils that had cropped up, in improving the design of all stokers, and in creating a wider market for such equipment.

Chairman Breckenridge said that he did not subscribe to the idea that the furnace volume was a function of the horsepower of the boiler. He believed that it was a function of two variables: the rate at which coal was burned in the furnace and the volatile content of the coal that was being burned. In other words, the amount of volatile combustible material leaving the grate was the determining factor of furnace volume.

R. Sanford Riley,[21] in reply to a question raised by Mr. Myers in regard to fusion on the surface of the underfeed stoker because of the fuel working upward to the higher-temperature zone, said that clinkers were the logical result of thoroughly burning out ash if the ash had the proper chemical elements. As to the troubles encountered from these clinkers, which were inherent in certain kinds of coal in general, in underfeed stokers he desired to avoid arches because of the reverberatory action under them, which raised the temperature and made the clinkers still more liquid, causing them to run and make more trouble. In general this led up to the utilization of the maximum amount of radiation, using radiation as the means of transferring heat from the fuel bed to the boiler. By making this transfer as direct as possible there would result a cooler fuel bed, less trouble with brickwork, higher efficiency, and less trouble with clinkers.

[21] President, Sanford Riley Stoker Co., Worcester, Mass. Mem. Am. Soc.M.E.

As to automatic regulation, the difficulty heretofore had been in getting operators with intelligence enough to regulate the fire directly, that is, the various drafts and the feed of the coal. It took a little higher grade of intelligence to regulate a regulator than it did to regulate the drafts and the coal feed directly; but he believed that before long regulators would be much more generally used, which was equivalent to saying that the grade of fire-room operators was being raised.

Regarding setting heights, it was not claimed that the specifications adopted were perfect, but it was certainly a great advantage to all to have some standard established by which some of the most serious mistakes made in the past might be avoided.

W. J. Wohlenberg,[22] discussing automatic control, said that in the case of parallel operation of a number of forced-draft stoker-fired boilers, the device first to respond to the load would be one that would be actuated by a change in pressure. That device would operate a throttle valve or an electric control governing the fan used to drive air through the fuel bed. If a similar change was desired in all parts of the equipment, every device and fan would have to have similar characteristics and then the right condition would be obtained only provided the same kind of fuel bed with the same kind of fuel was under every boiler. That, it would be seen, made parallel operation automatically very difficult.

W. G. Freer[23] said that he had spent 20 years at sea and knew what had to be accomplished in order to operate stokers on shipboard. The stoker being installed in nearly all the locomotives built by his company, he believed, could be adapted for such service. It distributed the coal evenly over the fire by means of a pair of mechanically actuated firing shovels.

J. C. Percy,[24] thought that stoker manufacturers could do away with much of the trouble experienced by their customers if they would manage in some way to furnish proper instruction to the men who were to operate their equipment.

Closures

T. A. Marsh, in closing, said that the real thing in efficiency was the cheap production of steam. Sometimes it was possible by burning a cheaper coal with low efficiency to make cheaper steam. He agreed with Mr. Riley, that automatic control was coming, for he knew of a number of installations working very successfully under such regulation in the West.

Answering Mr. Maynz on the tightness of forced-draft stokers, he would say that there were types on the market today that were very tight and would not blow out. He took exception to Mr. Cary's statement that on the grate we burned fixed carbon. We did not. It rested on the grate until it was thoroughly burned; but the only thing that we could possibly burn was gas. As to Mr. Cary's question regarding caking coals, he would say that they were not suitable for chain grates, and chain-grate manufacturers were not attempting to burn them today.

H. F. Lawrence, in summing up the comments on his paper, said, referring to Mr. Polakov's discussion, that the mechanical stoker was more than a coal-feeding mechanism. In addition to putting the coal into the furnace, it had to deposit the ash into some locality from which it could be easily removed, and also furnish the air at such places and velocities and directions as to accomplish the burning of the fuel in the best manner.

As to Mr. Myers' references to the clinker on top, the under feed stoker of course formed its ash on top. It was the feeding of the coal from the retort that flooded the ash on the fuel bed. The coal, in addition to rising up, was pushed forward so that the ash was carried forward toward the grate wall with the fuel. There was a comparatively small amount of ash, and the main feature to avoid trouble of this kind was to get the secondary coal-feeding mechanism—that which controlled the issuance of the coal from the retort—in such relation to the particular fuel and the amount that it would carry the clinker on beyond the end of the retort before depositing it.

With reference to burning different coals, the underfeed stoker was built with adjustments, the principal one being this control of the coal from the retorts, which was what made it possible to burn a wide variety of coals on the underfeed stoker.

As regarded cinders, it could be said that the higher setting heights were reducing them, and that the lower air pressures and lower velocities of air which would come as designs were improved, would also reduce them.

With reference to slag on the tubes, they were reduced by the high settings. With some fuels this slag was much worse than with others, and provision should always be made in the boiler setting to get at it and remove it.

Improving Power-Plant Efficiency

There are three ways of improving power-plant efficiency—maintaining the efficiency of the operating cycle, selecting the proper equipment, and improving the equipment by changes in design. Although in coal-burning plants over-all thermal efficiencies of about twenty per cent have been obtained under favorable conditions, even in the largest plants the average for a year is far below this figure. Fifteen per cent is about the best that the average large station is doing, with many plants, having ratings for twenty thousand to thirty thousand kilowatts capacity, operating at ten per cent or less. Instead of producing a kilowatt-hour on seventeen or eighteen thousand British thermal units, the average figure will be from twenty-three thousand to over thirty thousand.

There are many conditions in plant operation that tend to reduce the average over-all efficiency; some of them are controllable and others are not so readily handled. Load factor undoubtedly has an effect, but cases are on record where, in plants of considerable difference in size, the smaller plant operating at about forty per cent and a larger one at sixty per cent load factor, the smaller plant showed thirty per cent less coal consumption per unit output than the larger station. Even though these conditions may exist, taking two plants that are alike as to equipment, if both are operated with equal proficiency, the station with the highest load factor will develop the highest over-all average efficiency.

For years it has been possible to obtain an over-all boiler-and-furnace efficiency of over eighty per cent with large stoker-fired boilers without the use of economizers, yet the average in many of the large plants is down around sixty-five per cent or less. There are a few exceptions to these figures where efficiencies up to about seventy-seven per cent have been obtained without the use of economizers. The maintenance of equipment has a marked effect on over-all efficiency and is very largely under the control of the operating force.

The wide difference in average operating efficiencies of two plants under similar conditions can be attributed to operating methods and the selection of the kind and size of equipment to serve the load. When selecting equipment, it is not always possible to obtain the arrangement that will give the highest over-all efficiency, or engineers have not felt justified in doing so. All electric drives for the auxiliaries and bleeder turbines for feed-water heating will give a higher over-all economy than using steam-driven auxiliaries. The possibilities of the station going dead have deterred power-plant engineers from taking full advantage of benefits to be obtained from this arrangement. Then again there is the matter of cost. Will the installation of equipment that will reduce the coal consumption reduce the kilowatt-hour cost at the switchboard?

Present indications are that in the near future no radical improvement in efficiency may be looked for in the design of power-plant apparatus, although the substitution of a regenerative cycle for the Rankine and higher steam pressures offer possibilities that are encouraging.

While power-plant engineers are waiting for the higher economy to be obtained from new designs, the present differences between the average over-all plant efficiency and that which can be obtained with present design of apparatus offers a fruitful field for careful study and improvement. (*Power*, Dec. 12, 1922.)

Tests of a Large Type W Stirling Boiler

Particulars Regarding Extensive Tests Recently Conducted by The Detroit Edison Company, in Which Various Baffle Arrangements and Different Grades of Coal Were Used

By PAUL W. THOMPSON,[1] DETROIT, MICH.

This paper deals with extensive tests conducted during 1921 on a large Type "W" Stirling boiler at the Connors Creek power house of The Detroit Edison Company. Four different arrangements of the boiler baffling were employed and the results obtained with each are shown. Separate tests were made using four different grades of coal in order to determine which was most suitable. Several operating tests were made to obtain data on different methods of banking, the effect on the temperature of flue gas of varying the time interval between the blowing of flues, and different methods of operating boilers during the low-load period at night.

From the results of the tests with different baffle arrangements, seventeen of these large boilers have been rebaffled with a resulting improvement in boiler-plant efficiency and an increase in the degree of superheat of the steam. Additional improvement is expected as more boilers are rebaffled. From the data and results of these tests, the Babcock & Wilcox Company, working in conjunction with The Detroit Edison Company, have developed a new design of this type of boiler. Four boilers of the new design have been installed in the Marysville power house of The Detroit Edison Company, but economy results on the installation are not yet available.

SINCE the original installation of the large Type W Stirling boilers by The Detroit Edison Company in 1911, many improvements have been made and much experience has been gained in regard to bettering the overall performance of these steam-generating units. The results of the first tests conducted on this type of boiler were presented before the Society by Dr. D. S. Jacobus in 1911. Several tests have been conducted since that time with other objects in view than to obtain accurately the efficiency, but none involving the weighing of water and coal.

Several years of experience in operating these boilers had brought about many improvements, both in methods and in design of auxiliary equipment, yet it was felt that there still remained further opportunities for improving the operating performance. The determination of means for obtaining improved performance comprised the main purpose of these tests.

Eight series comprising fifty constant-rating tests were made, during which four different grades of coal were burned and four different arrangements of the boiler baffling tried out. Table 1 gives general data and dimensions of the equipment and Table 2 the names and sources of the coals, together with the quantities burned. Figs. 1, 2, 3, and 4 show respectively the four baffle arrangements: namely, the original baffle, the "A" baffle, the "B" baffle, and the "C" baffle.

Some idea of the magnitude of the test may be gained from the fact that the total coal weighed to the stokers during the entire test was 12,137 tons, and the total water fed to the boilers 101,200 tons. During the highest-rating test the coal consumption averaged 22,550 lb. per hr. A complete record was maintained of the weights of coal and water during periods between tests, including seven firing-up and burning-out periods, from which data an overall efficiency for the entire period up to and including test No. 76 was computed and found to be 77.9 per cent.

The tests were commenced April 7, 1921, and completed August 27, 1921. The full number of observations were taken until August 6 only, after which date operating tests were conducted for the purpose of determining the effects of blowing flues at various intervals of time and also to obtain data on the amount of coal required for different kinds of banks. These tests were conducted with a reduced force, taking only the most essential observations.

During the period from April 7 to August 6 the services of 57 observers working on three eight-hour shifts were required, besides those engaged in analyzing coal and ash, and others conducting special investigations and checking methods.

Facilities were provided for analyzing the flue gases at points as close as possible to the sampling points. There were two sampling groups on each side of the boiler, one at the bottom of the superheater pass and one at the damper. In addition to these points at which gas samples were taken and analyzed in Orsats, two different types of automatic flue-gas recorders were installed, one drawing samples from four points on each side at the damper and recording an analysis of an average of these samples, and another from one point on each side at the bottom of the superheater pass.

The points at which the pass temperatures were measured are shown on Figs. 1, 2, 3, and 4. All points on the west side have even numbers and those on the east side, odd numbers. Each location except 15 and 16 represents two couples: one placed in the center C, the other placed in the south half S if it is on the east side, and in the north half N if on the west side. The furnace

TABLE 1 GENERAL DATA AND DIMENSIONS OF EQUIPMENT

Boiler:

Type W Stirling, manufactured by Babcock & Wilcox Company. Total number of tubes, 1564; diameter, 3¼ in.; 9 gage. Net effective heating surface, 23,654 sq. ft. Installed and first in operation October 25, 1920.

Superheater:

Twin B. & W., U-tube. Two superheaters having 102 tubes each. Tubes 8 gage, 2 in. in diameter; developed length, 24 ft. 11⅝ in. Total heating surface, 2996 sq. ft.

Stoker:

Underfeed stoker manufactured by American Engineering Company, Philadelphia, Pa. Two 13-retort, 2-ram stokers; total width, 22 ft. 10½ in.; effective length (both stokers), 12 ft. 5 in. (ashpit not considered in giving effective length). Projected grate area, 284 sq. ft. Width of ashpit, 3 ft. 11 in. Ratio of saturated heating surface to grate area, 83.4 to 1. Drive: variable-speed d.c. motors. Clinker grinders: independent drive by d.c. motors.

Setting:

Height of mud drums above floor	15 ft. 9 in.
Height from grate to top of combustion chamber	33 ft.
Width of combustion chamber	26 ft. 2 in.
Length of combustion chamber over grate	16 ft. 4 in.
Total volume computed above grate	8705 cu. ft.

Forced-Draft Fan:

Double conoidal blower manufactured by Buffalo Forge Co. Capacity, 74,000 cu. ft. at 6.5 in. water pressure. Driven by variable-speed d.c. motors.

Stack:

Height above center of grate	323 ft. 6 in.
Inside diameter of stack at top	15 ft. 9 in.

Dampers at boiler are motor-operated.

TABLE 2 COAL DATA

(1) Name of Coal	(2) Location of Mine	(3) Tests	(4) Coal burned during tests of column (3), lb.	(5) Duration in hours of tests of column (3)	(6) Heating value of coal, B.t.u. per lb.
Shipper "A"	Harlan, Ky.	Nos. 3 to 18	6,785,888	613	—
Shipper "A"	Harlan, Ky.	Nos. 40 to 43	1,744,337	128	12,510
Shipper "A"	Harlan, Ky.	Nos. 60 to 66	2,857,053	242	—
Shipper "A"	Harlan, Ky.	Nos. 70 to 76	3,271,959	266	—
Shipper "B"	Mingo, W. Va.	Nos. 20 to 24	2,304,682	196	13,280
Shipper "C"	Kanawha, W. Va.	Nos. 18–30 to 33	1,668,998	143	12,320
Shipper "D"	Logan, W. Va.	Nos. 50 to 54	1,937,176	154	12,200

Averages for Whole Test:

Coal per hr., lb	11,780
Water per hr., lb	98,600
Per cent rating	145.6
Apparent evaporation	8.37
Equivalent evaporation	10.10
Per cent efficiency	77.9
Weighed refuse in per cent of coal burned	11.30
Computed refuse in per cent of coal burned	13.92
Loss to stack in per cent of refuse	18.8

[1] Technical Engineer of Power Plants, The Detroit Edison Co. Assoc-Mem. Am.Soc.M.E.

Contributed by the Power Division and presented at the Annual Meeting, New York, December 4 to 7, 1922, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS. Abridged. All papers are subject to revision.

temperature was obtained at point F at the north and south ends of the furnace by focusing an optical pyrometer on the closed end of a carborundum tube, the tube being of ordinary test-tube shape and projecting about 30 in. into the furnace. In addition to the observations taken at the points mentioned above, a recording potentiometer was used for recording the temperatures at the two dampers separately, each record being an average of five equally spaced points on either side.

In addition to the four operating draft gages regularly provided

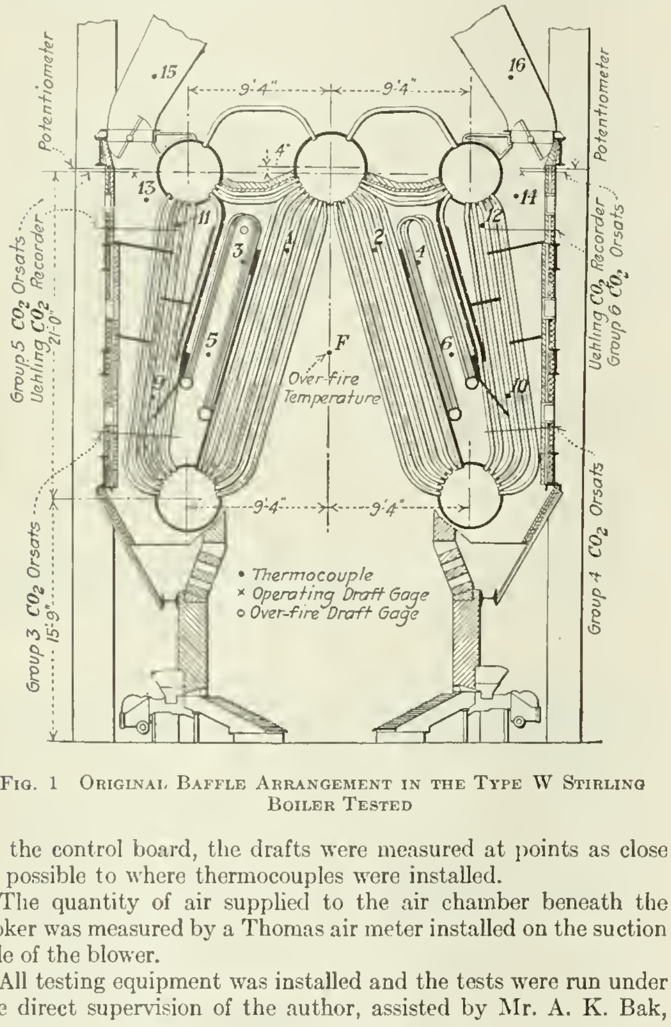

FIG. 1 ORIGINAL BAFFLE ARRANGEMENT IN THE TYPE W STIRLING BOILER TESTED

on the control board, the drafts were measured at points as close as possible to where thermocouples were installed.

The quantity of air supplied to the air chamber beneath the stoker was measured by a Thomas air meter installed on the suction side of the blower.

All testing equipment was installed and the tests were run under the direct supervision of the author, assisted by Mr. A. K. Bak, technical engineer of the Connors Creek station. Coal and water-weighing equipment was installed by the Construction Engineering Bureau of The Detroit Edison Company. The Thomas air meter and thermocouples were made and installed by the Research Department under the personal supervision of Mr. W. A. Carter. The author wishes to express his appreciation to Mr. J. W. Parker and Mr. C. F. Hirshfeld of The Detroit Edison Company, and to Dr. D. S. Jacobus of the Babcock and Wilcox Company for their valuable suggestions and criticisms, and to all those who in any way contributed to make the test a success.

TABLE 3 COMPARISON OF COAL ANALYSES

(Analyses are for dry coal and are made on duplicate samples. Samples Nos. 106, 116 and 126 are Shipper "A" coal; sample No. 138, Shipper "B" coal)

DESCRIPTION OF TESTS

The eight series of tests were made up of 50 constant-rating tests, each series being conducted under different conditions. The first series (tests Nos. 2 to 10) was for the purpose of obtaining the efficiency before making any changes in the boiler or its auxiliary equipment. Shipper "A" coal was used since a regular and uniform

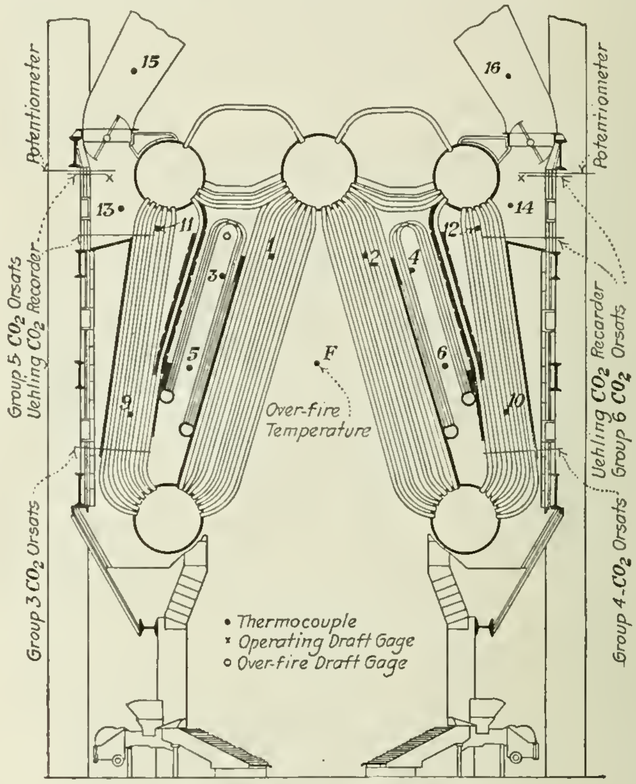

FIG. 2 "A" BAFFLE ARRANGEMENT

supply could be counted upon, and its quality was about an average of the many kinds being received at that time.

At the time the tests were commenced the boiler had been in regular service for six months, and it was decided to ascertain how much the efficiency was impaired by the soot which gradually collects on the tubes and is not removed by the soot blowers. To this end the first series of tests was conducted without specially cleaning the boiler. Then the boiler was given a thorough washing on its exterior surface and a second series of tests (Nos. 11 to 18) was run, also using Shipper "A" coal.

When Dr. Jacobus made his tests on this type of boiler in 1911 he used Red Jacket coal, so for the purpose of comparing results obtained in 1911 with those obtainable now, a series of tests was made (Nos. 20 to 24) using Shipper "B" coal, which, in quality, was as close an approximation to the coal used by Dr. Jacobus as could be obtained. This coal, however, was of poorer quality having a lower heating value and higher moisture and ash than the 1911 variety.

Tests Nos. 30 to 33 were made with Shipper "C" coal to determine its burning characteristics and adaptability for use on this type of stoker. The boiler baffling was then changed to conform to that shown in Fig. 2, called "A" baffle arrangement, and a fifth series of tests (Nos. 40

to 43) was made using Shipper "A" coal. Another series of tests using Shipper "D" coal was also made with this same baffle arrangement (tests Nos. 50 to 54) in order to obtain the burning characteristics and adaptability for use of this coal.

After test No. 54 the baffle was again changed to the "B" arrangement shown in Fig. 3, and a seventh series of tests (Nos. 60 to 66) was conducted to obtain data on the boiler operation with this baffle arrangement.

The last of the constant-rating tests (Nos. 70 to 76) were made with the boiler baffled according to arrangement "C" shown in Fig. 4, during which Shipper "A" coal was burned.

Following the constant-rating tests, additional tests were conducted to determine the effect of blowing the flues at different intervals of time upon the temperature of the gases leaving the boiler. Tests Nos. 80 to 83 were conducted for this purpose, with intervals between blowing flues as follows:

Number of test	80	81	82	83
Interval between blowing flues, hours	4	12	24	8

During these tests the boiler rating was maintained at about 155 per cent.

The following nine days the boiler was banked during the night and over Sundays to determine the amount of coal required for banking. For the first five days a so-called "dead" bank was carried and during the last four days a floating bank. During the day period the boiler was operated at approximately 157 per cent of rating. A dead bank as used here is one in which the coal feed is entirely shut off and the fire is allowed to burn back as far as possible without permitting it to go out entirely. Small amounts of coal, just sufficient to keep the fire, are fed from time to time as required. During a dead bank a boiler will cease to steam, and the pressure will fall to atmospheric if the banking period is of sufficient duration. With a floating bank the coal feed is sufficient to keep the tuyeres well covered and to hold a fire which will maintain full pressure in the boiler. With a floating bank the boiler may even continue to steam at a very low rating throughout the banking period. Each banking test was divided up into overlapping periods with a different proportion between steaming and banking hours. The coal required for banking was computed by taking the difference between the coal actually used during a period and the quantity computed as being required to evaporate the water fed to the boiler during the same period. An average heating value of the coal used during each method of banking was taken as the standard, and all coal quantities were corrected to this standard heating value.

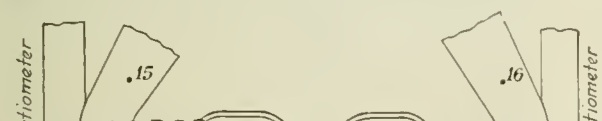

Fig. 3 "B" Baffle Arrangement

The last three tests conducted (Nos. 101–103) were strictly operating tests to determine the results of different methods of operating the boilers during the low-load period. Throughout these tests the steaming rate was varied according to the plant load, the boiler carrying its share of the total load during the day period. Test No. 101 was of 48 hr. duration with the boiler steaming at a low rate during the night. Test 102 was also of 48 hr. duration, but the boiler was subjected to a dead bank at night. Test 103 was of 25 hr. duration and the boiler was steamed at a rating of 90 per cent during the night.

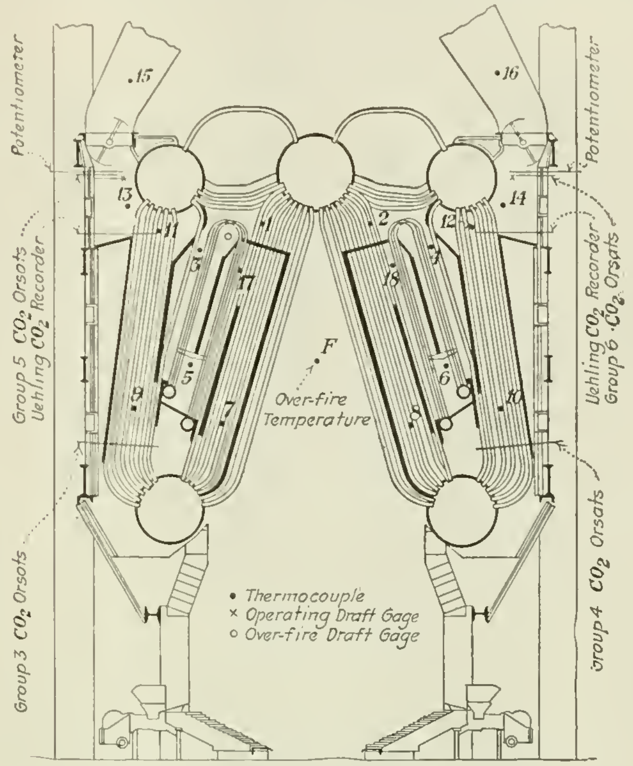

Fig. 4 "C" Baffle Arrangement

Extended tables containing the data and results obtained over all these tests are on file at the Society's headquarters and may be consulted by any one interested in their contents.

Discussion of Results

Baffle Arrangements. Figs. 5, 6, 7, 8 and 9 show the results of all the constant-rating tests in graphical form for the different baffle arrangements. Fig. 5 shows that before any changes had been made to the baffling the efficiency touched 79 per cent at 160 per cent rating. After the boiler was washed the efficiency curve was raised about 0.75 per cent, with a reduction in superheat. With the original baffling, Shipper "B" coal gave the highest efficiencies. These are shown in Fig. 6, in which are also plotted the points as reported by Dr. Jacobus in 1911 for the purpose of comparison. Fig. 8 shows the results obtained with the boiler baffled according to the "B" arrangement. These efficiencies were higher than with the original baffling, touching 83.5 per cent at 106.2 per cent rating. Due to the fact that the extension grates, which will be mentioned later, had been changed prior to this series of tests for others with larger openings, the combustible in the refuse was greater during the high-rating tests than with the original baffle. In order to correct for this loss, which is not chargeable to the baffle, a broken line has been drawn in to show what the efficiency would have been with an ashpit loss the same as during the first series of tests. With the "C" baffle arrangement the maximum efficiency reached was 82.4 per cent at 130 per cent rating. The results of this series of tests are shown in Fig. 9.

Each time the baffles were changed the row of tubes nearest the combustion chamber was partially cleaned by the workmen in making the changes, whereas the other tubes which were not touched

would retain their soot deposit. When comparing "B" and "C" with the original baffling this difference in condition of heating surface should be kept in mind. The "B" baffle shows a lower stack-gas temperature and higher superheat which at its best point gives an efficiency $2^1/_2$ per cent above the efficiency obtained with the original baffling; the best point, however, being

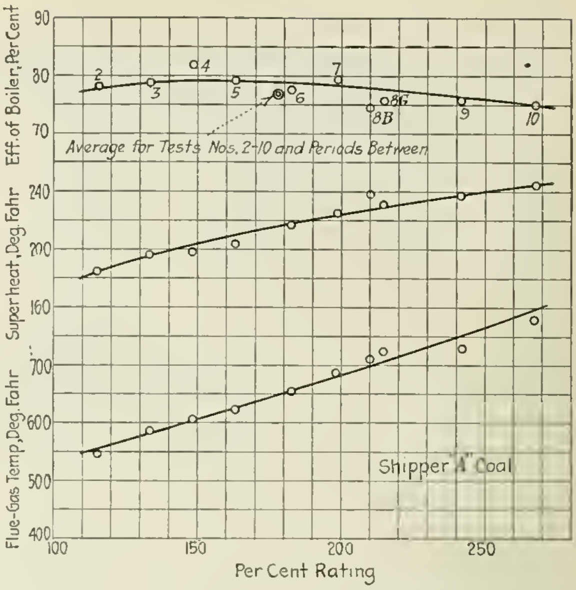

Fig. 5 Results Obtained with Original Baffle

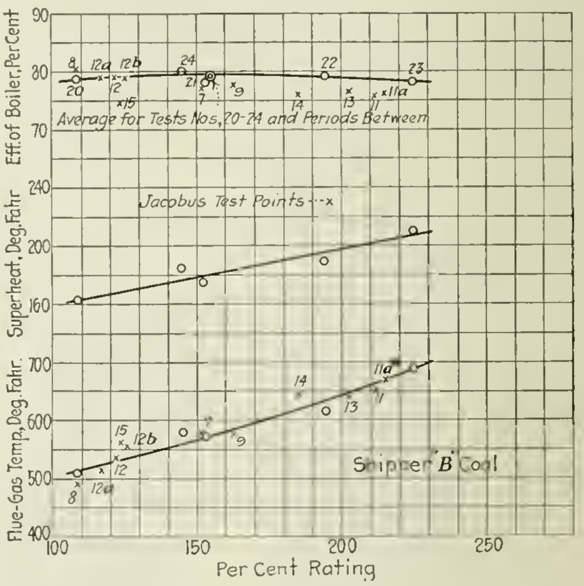

Fig. 6 Results Obtained with Original Baffle

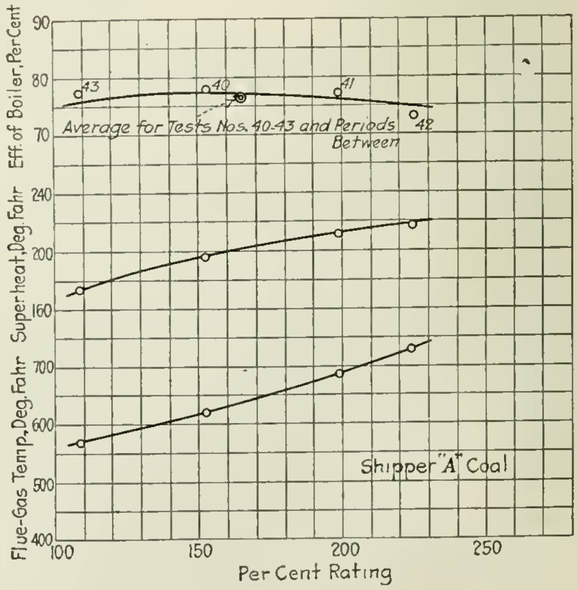

Fig. 7 Results Obtained with Baffle "A"

at a lower rating than before. Comparing the average efficiencies obtained during the entire series of tests on the original baffle before washing with the average obtained during the entire series of tests on the "B" baffle arrangement, we find that the original baffle gave 76.8 per cent at 178 per cent rating and the "B" baffle 79.1 per cent at 145 per cent rating. These results include all periods between the tests of the respective series, and one starting and burning-out period. With the original baffling after washing, the first five tests (Nos. 11–15) gave an average efficiency of 79.5 per cent at 99 per cent rating, and tests Nos. 16–18 gave 79.7 per cent at 122.8 per cent rating. From the results as shown in the

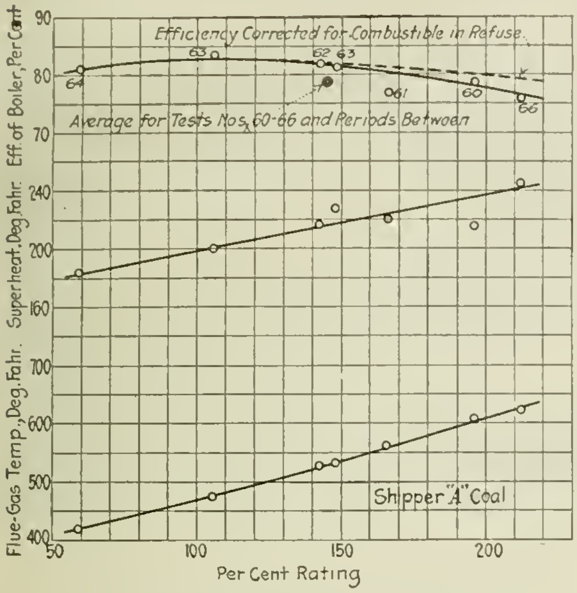

Fig. 8 Results Obtained with Baffle "B"

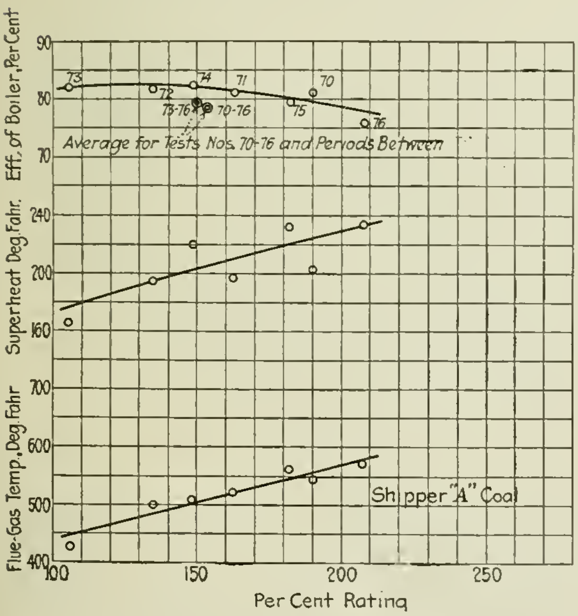

Fig. 9 Results Obtained with Baffle "C"

heat balance (Table 6), it is apparent that these efficiencies are too high.

A comparison between the average results obtained with the "B" and "C" arrangements shows the former to be 79.5 per cent at 145 per cent rating and the latter 79.8 per cent at 157 per cent rating. The gain, however, is not believed to be due entirely to the baffle arrangement, as a separation of the furnace, grate, and boiler losses show that for the "C" arrangement the unavoidable losses were 0.7 per cent lower than for the "B." Granting that a gain of 0.3 per cent in efficiency is accounted for by the "C" baffle arrangement, the fact that the "B" baffle gave a higher superheat makes it more desirable from the standpoint of overall plant economy, due to the effect of additional superheat on reducing the turbine water rate.

Extension Grates. During the tests, extension grates with different-sized openings were installed with the object of reducing the combustible in the refuse by furnishing more air over the grinders. Three different arrangements were made, including the standard grates which were in use at the beginning of the test. These original grates had a total area of openings of 11.76 sq. in. per set. At the completion of test No. 10 new grates having a total area of openings of 17.15 sq. in. were installed. Just before test No. 40 another change was made by increasing the air openings

through the five top bars, leaving the two bottom bars as before. The total area of openings per set was then 25.40 sq. in. The damper control was also changed and improved to give closer regulation of the air to the extension grates. This last change did not give the expected results since the combustible in the refuse increased from 3 to 5 per cent over that obtained with the original grates. Although the ash content of the coal was about 1 per cent greater than during the first series of tests, it is not believed that this could account for the increase in combustible in the refuse, since the average rating carried with the original grates was considerably higher than after the second change. The effect of the second change in extension grates should be determined from tests Nos.

60–67 and 70–76. Comparing the combustible for those tests with that obtained before and after the first change, it is seen that at low ratings the percentage after the second change was only very little greater than after the first one, although from 2 to 3 per cent greater than with the old type, and that the high averages are caused by greatly increased losses at higher ratings. That this increased loss due to combustible in refuse was due to the arrangement of air openings in the extension grates, is verified by the fact that at the completion of all tests the boiler was put back into regular plant operation, and the same difficulty with down blast through the grinders was experienced as during the test. Grates of the old type were then installed and additional observations were made at the same ratings as before, with the result that there was no down

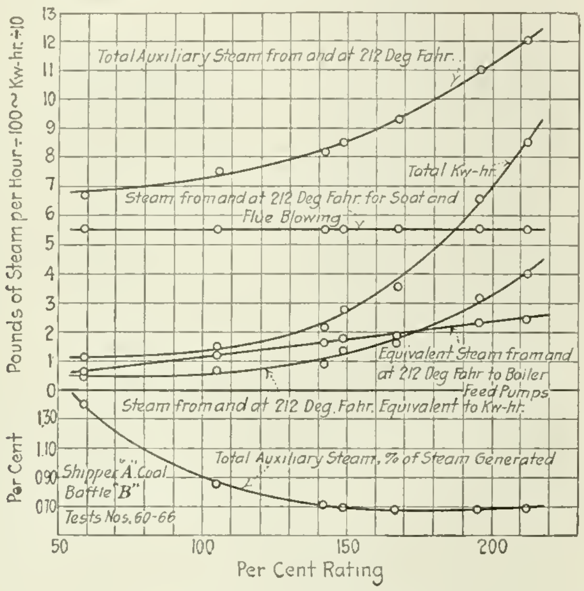

Fig. 10 Auxiliary Energy Required per Hour

blast and the refuse contained about the same percentage of combustible as during tests Nos. 2–10.

Air Supplied to Stoker. It will be seen from the results obtained from the Thomas air meter that this method of measuring the air supplied for combustion was not accurate, due to the leakage of air from the air chamber beneath the stoker. The results indicate that at high ratings the blower supplied over 25 per cent more air than was actually delivered through the stoker tuyeres. The Thomas air meter was checked against a 36-in. orifice with rounded entrance and was found to be an accurate means of measuring the quantities of air supplied by the forced-draft fan, but due to leakage from the air chamber the results could not be used for combustion computations.

Results Obtained with Different Coals. Data on the four different coals used in the tests are given in Table 2. Inasmuch as the different coals were not tested under identical conditions as regards boiler and stoker, the efficiencies obtained are not directly comparable. Except for Shipper "D" the percentage of CO_2 was about the same for the different coals, so the comparison may be made on the basis of the ashpit loss only.

Pass Temperatures. Figs. 1, 2, 3, and 4 show the points on a cross-sectional view of the boiler at which temperatures were taken, and Table 4 gives the temperatures at the different points. The readings of the thermocouples at symmetrical points in the two halves of the boiler have been averaged, and these averages are given in the table instead of the temperatures at each individual point. The over-fire temperature (point *F*) is the average of the two readings taken, one at the north and one at the south end of the combustion chamber. Points 15–16 are the average of the two readings 15 and 16, while every other point is an average of four; for instance, a point marked 3–4 is the average of thermocouples 3*S*, 3*C*, 4*N* and 4*C*. Observations obtained at point *F* are not correctly the temperature in the furnace due to the radiant heat given to the front rows of boiler tubes.

The heating surface as shown in Table 5 was computed on the basis of effective heating surface, assuming the superheater surface to have the same effectiveness in absorbing heat as the remainder of the boiler. Computations were made which showed the superheater absorbs about the same amount of heat per square foot as the average for the boiler.

Heat Losses. Table 6 gives the losses itemized in percentages of the total heat supplied in the coal. The loss due to combustible in refuse is based upon the percentage of combustible in the refuse and is computed by assuming that the refuse lost through the stack contains the same percentage of combustible as the refuse from the ashpit. Presumably the refuse to the stack contains more combustible than was shown by the analysis of the ashpit refuse, so the losses under this heading probably are slightly under the correct values.

In the radiation and unaccounted-for losses are included radiation from the boiler setting, loss due to sensible heat in refuse, loss due to unburned gases other than CO, and all errors involved in observation and analysis. Due to the fact that this item in most cases is small compared with results obtained in other tests, a few words of explanation are given to show that the radiation on this type of boiler is very low. Mr. H. Kreisinger[1] gives the radiation per square foot of exposed surface as 250 B.t.u. per hr. at 100 per cent rating and 350 B.t.u. per hr. at 200 per cent rating. The total exposed surface of this boiler, including steam drums, is 4294 sq. ft., or 1.81 sq. ft. per rated boiler hp., giving a radiation loss per hour per rated boiler hp. of 453 B.t.u. at 100 per cent rating and 634 B.t.u. at 200 per cent rating. The coal burned per rated boiler hp-hr. is practically a straight-line function between 50 per cent and 225 per cent rating, which gives 3.4 lb. per hr. at 100 per cent rating and 6.77 lb. per hr. at 200 per cent rating. This gives the radiation loss per pound of coal as 133 B.t.u. (1.06 per cent) at 100 per cent rating and 95 B.t.u. (0.76 per cent) at 200 per cent rating, assuming a coal of 12,500 B.t.u. per lb. as fired. An effort

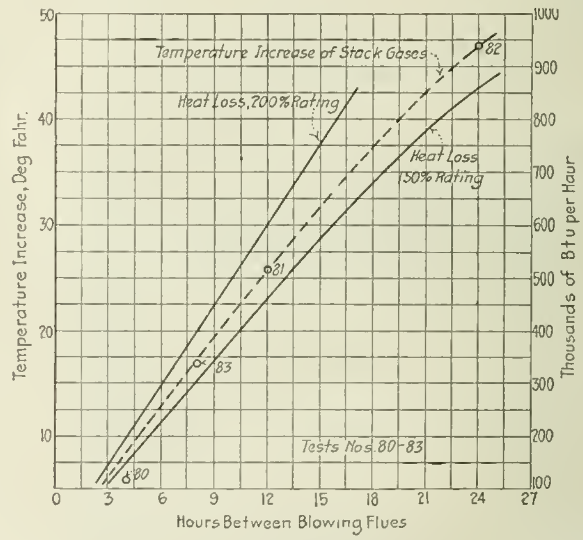

Fig. 11 Effect of Varying Time Interval between Blowing of Flues

was made to check these values by computing the radiation losses on the bases of the exposed surfaces and certain temperatures, some of which were actually measured on a boiler of this type, and some assumed. Conservative values of heat-transmission coefficients were taken, with the result that the calculation gave the radiation per pound of coal as 75 B.t.u. (0.60 per cent) at 100 per cent rating and 40 B.t.u. (0.32 per cent) at 200 per cent rating. With the exception of a few tests which were of too short duration or were otherwise unsatisfactory, the observed radiation losses did not depart from the computed radiation by more than 1.5 per cent of the heating value of the coal.

Energy Used by Boiler Auxiliaries

The stokers, blowers, and grinders were driven by direct-current variable-speed motors, the electrical input to which was measured by watthour meters. This electrical energy was all generated

[1] Boiler Tests with Pulverized Illinois Coal, H. Kreisinger and J. Blizard, Mechanical Engineering, May, 1921, p. 321.

on the auxiliary turbo-generators, the exhaust steam from which is all utilized for heating feedwater.

Fig. 10 gives for tests Nos. 60–66 the electrical energy required per hour for the blowers, stokers, and grinders, the steam equivalent to the electrical energy, and the total steam for all auxiliary uses expressed as equivalent steam from and at 212 deg. fahr.

Flue Blowing Banking—Variable-Rating Tests

Four tests (Nos. 80–83) were made to determine what effect varying the time interval between blowing flues would have on the temperature of flue gas leaving the boiler. In Fig. 11 the temperature increase has been plotted against the time interval between blowing. The B.t.u. loss per hour was computed from the mean temperature increase and is also shown in the same figure for ratings of 150 and 200 per cent.

The banking test included the period from August 13 to August 22. From August 13 to 18, the first period, dead banks were carried at night and over Sunday, and from the 18th to the 22d, the second period, floating banks were carried nights and Sunday. During the daytime the boiler was steamed at about 157 per cent rating. The results of these tests have been plotted in Fig. 12 and straight lines have been drawn through the points representing the two methods of banking. It seems probable that a straight line does not represent the true relation between the two variables, but the lack of sufficient data makes the determination of the exact relationship impossible.

These tests were conducted while the boiler was baffled according to arrangement "C." The two tests with low-rate steaming show practically the same decrease below the efficiency at constant rating (4 per cent and 3.8 per cent), whereas the test during which a dead bank was carried at night shows a decrease of 5.1 per cent.

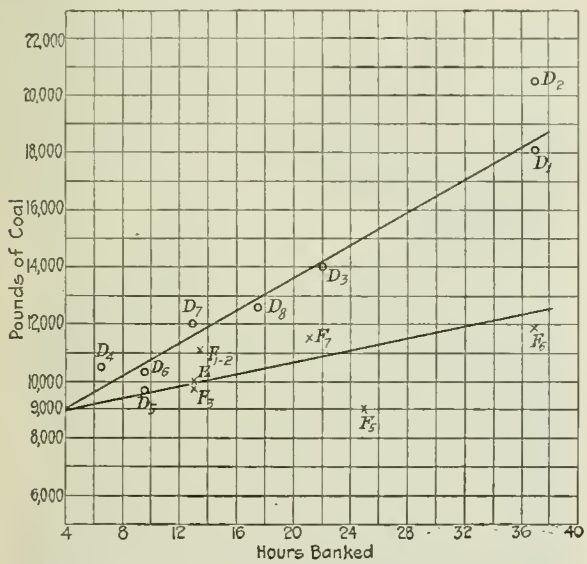

Fig. 12 Coal Required for Banking

When burning out the fires the coal was run entirely out of the spreaders and stoker hoppers, so that this amount of coal had to be added to or subtracted from the weighed coal over the starting or burning-out period. This loss and gain has been plotted against the per cent rating in Fig. 13. The ratings are those carried on the boiler at the end of the starting-up period and the beginning of the burning-out period.

Conclusions

Baffling Arrangements. The "A" baffling arrangement showed no improvement over the original arrangement except that the draft at the damper was reduced about 33 per cent.

With the "B" arrangement an average increase in superheat of over 20 deg. fahr. was obtained and the flue-gas temperature was reduced about 70 deg. fahr. as compared with the original baffling. The draft was also about 38 per cent less than with the original baffling. The results obtained indicated that there was very little difference between the "B" and "C" arrangements, and on account of the simplicity of the "B" arrangement and the fact that a slightly higher superheat was obtained, it was decided upon as the most practical arrangement to install in the present boilers.

Extension Grates. The changes made to the extension grates did not give the desired effect. After both the first and second changes the combustible present in the refuse was greater than with the old-type grates, and resulted from the trouble experienced with down blast which heated the grinders. It is believed that further

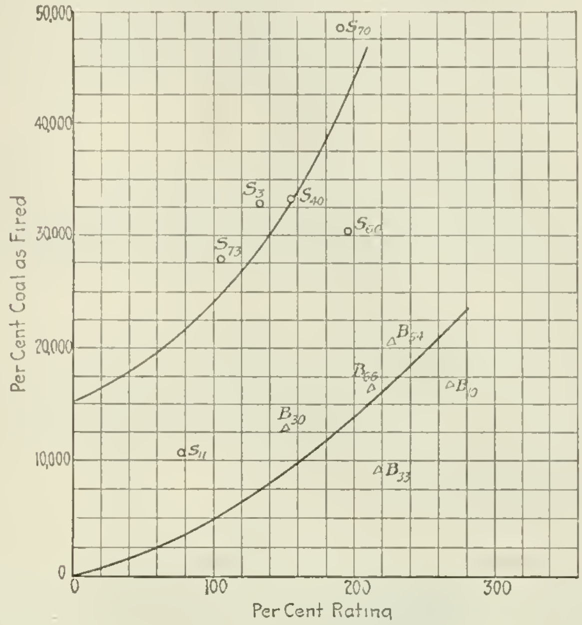

Fig. 13 Coal Lost or Gained in Starting Up and Burning Out Fires

study will develop a better arrangement of air openings, which will make possible a reduction in ashpit loss.

Air Supplied for Combustion. The method employed for measuring the air required for combustion was unsatisfactory, due to air leakage from the air chamber beneath the stoker, although the air passing through the meter was correctly indicated. This leakage amounted to as much as 25 per cent at high ratings.

Comparison of Coals. Shipper "B" coal gave only slightly better efficiency than Shipper "A" coal, while Shipper "C" coal was about 1 per cent and Shipper "D" coal 2.5 per cent lower than Shipper "A" coal. The results obtained, however, are not directly comparable due to the different arrangements of boiler baffling and conditions of the heating surface. A comparison on the basis of combustible lost in the refuse seems to be a better method. Expressed in percentage of dry coal the loss was:

Shipper	"B"	"A"	"C"	"D"
Per cent loss	1.60	2.25	3.68	4.25

Considerable difficulty was experienced with Shipper "D" coal due to the low fusion temperature of the ash, resulting in large clinkers, so that this coal was considered unsatisfactory. The other three burned satisfactorily, so that a consideration of cost f.o.b. plant, together with the relative value as fuel, determined the most economical coal. The results in this case were slightly in favor of Shipper "B."

Energy for Auxiliaries. The total energy consumed by the boiler auxiliaries averaged about 0.7 per cent between 170 per cent and 200 per cent rating, while at ratings near 50 per cent the energy consumed was 1.6 per cent. These figures are based upon the complete utilization of the exhaust steam in the feedwater heaters.

Flue Blowing. Taking into consideration the labor and maintenance costs directly influenced by the frequency of blowing flues together with the quantity of steam required per blow, an economic balance is obtained at 12.5 hr., assuming a constant rating of 200 per cent. Boilers banked at night should be blown only once a day. The foregoing is a literal interpretation of the test results which does not indicate exactly the proper procedure but serves more as a check on present practice.

Banking. Expressed in equation form, the coal required for the two methods of banking is:

Testing Involute Spur Gears

By M. Estabrook,[1] New York, N. Y.

In this paper two new devices for testing spur gears are described: namely, the Saurer gear-testing machine, a Swiss development by means of which the accuracy of the tooth curves, spacing, and eccentricities can be determined with a high degree of precision; and the odontometer, an American instrument for quickly and accurately testing gears for tooth curves and spacing, and which can be used during the processes of manufacture, making it possible to locate troubles in the machines or tools.

In modern machine construction it has been found advantageous to pay close attention to the inspection of component parts, as in this way much time can be saved in the final assembly. Gears, however, being more intricate than most parts, have not been inspected with as much precision as other machine components.

The most commonly used method of inspecting gears is that of rolling them on centers by hand. However, it is difficult to locate the exact trouble with a pair of faulty gears in this way.

The well-known type of gear-testing machine consisting of one fixed spindle and one adjustable spindle is usually employed for testing gears on centers. This indicator will show eccentricity, faulty spacing, or large teeth.

The gear-tooth vernier is commonly used to measure the thickness of gear teeth and accurate results can be obtained with it if the vernier is kept properly calibrated. The gear-tooth micrometer, however, consisting of a straight-sided rack tooth with micrometer adjustment for depth, is superior to the gear-tooth vernier in that the contact points are planes which wear relatively slowly, and it is easier to read than the vernier.

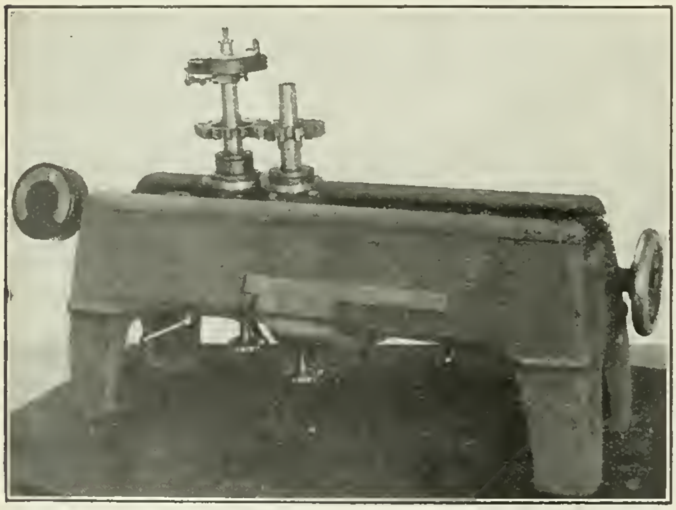

Fig. 1 The Saurer Gear-Testing Machine

An excellent method of testing large gears is to mount them on an arbor in a lathe and then arrange an indicator to bear against a plug inserted between the gear teeth.

The Kayle indicator is frequently used for testing tooth curves and consists of a straight edge arranged to roll on a disk the size of the base circle of the gear to be tested. A dial indicator shows any deviation from the true involute curve.

Projecting apparatus similar to that used for screw threads is sometimes used to examine gears, the tooth curves being compared with a correct profile.

Where large numbers of gears of a kind are to be tested, as in automobile manufacture, it is practical to devise special fixtures for testing the spacing and tooth curves of each gear. However, on account of the expense of making separate fixtures for each gear, this method is not used extensively.

The principal object of this paper, however, is to describe in detail two new devices for testing gears: the Saurer gear-testing machine, which was developed in Switzerland, and the odontometer, an instrument of American origin.

The Saurer Gear-Testing Machine

The Saurer gear-testing machine permits a more detailed study of a pair of gears than any of the devices commonly used, and with it the accuracy of the tooth curves, the spacing, and the eccentricity can be determined with a high degree of precision. The machine, shown in Figs. 1 and 2, consists of two spindles on which the gears are mounted. The spindles are also connected by two friction disks of which the diameters are the same as the pitch diameters of the gears to be tested. On one spindle there is a single sleeve which carries both the gear and its friction disk; on the other spindle there are two sleeves, one of which carries the second gear and the other the second friction disk.

When the first spindle is revolved its friction disk drives the other friction disk with a uniform velocity and its gear should drive the other gear with a uniform velocity if the gears have correct tooth curves and the spacing, etc., is accurate. In this case the two sleeves on the second spindle will revolve together. If there are inaccuracies in the gears, however, there will be a slight slippage between the sleeves. This slippage is magnified by a system of levers and a pen point traces the deviation. The magnification is about 100 to 1 for a 4-in. gear, or, expressed in another way, an angular variation of 1 min. is represented by $^1/_{16}$ in. on the chart. All of this error may be in one gear, or partly in one and partly in another. The chart shows errors in tooth curves, spacing, and eccentricity.

Fig. 2 Saurer Gear-Testing Machine, Showing Chart Being Traced

In any pair of gears there is almost always more than one kind of inaccuracy present, and, therefore, before proceeding to the examination of charts from the Saurer machine, it will be interesting to glance at Fig. 12, showing how the different kinds of errors are shown by the pen point on the chart.

A perfect gear gives a smooth circle or spiral. A spiral is produced when the friction disks are not of exactly the same diameters as the pitch diameters of the gears, but in many ways a spiral chart is preferable to a circular chart as it can be easily seen whether the

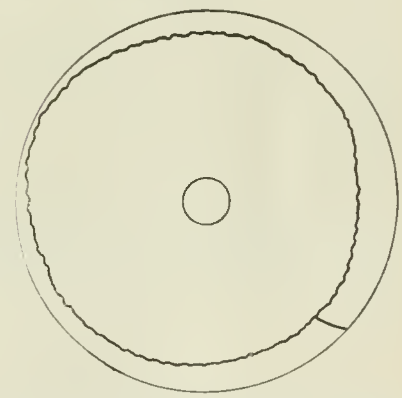

Fig. 11 Chart of a 72-Tooth Hobbed Gear Running with a 24-Tooth Pinion, the Teeth of the Latter Having Been Corrected to True Involute Form by Grinding. Chart Shows Some Eccentricity

same errors are reproduced in successive revolutions of the gears. Spacing errors are shown by quick radial jumps in the curve. Incorrect normal pitch is shown by a gradual change and then a quick radial jump. Faulty tooth curves are shown by an irregular curve for each tooth in the gear. An eccentric gear makes an eccentric chart.

The chart of Fig. 3 was made by a typical pair of 15-tooth gears, cut with a rotary cutter marked 15–16 teeth. It shows that the tooth curves are not true involutes and that they do not drive with uniform velocities at all portions of the tooth profiles. This speeding up and slowing down of the driven gear during every tooth engagement causes noise at high speeds.

The chart of Fig. 4 was made by a pair of gears for a high-grade automobile. These were procured from a service station.

Fig. 5 shows a chart made by a pair of ground gears. It is a spiral and the same errors appear in the successive parts of the spiral; the large jump was caused by a hair inserted between the gear teeth.

The charts of Figs. 6 to 11, inclusive, were made by printing-press gears cut in different ways, and show how gear action can be studied by the use of the Saurer machine. In color printing it is important to avoid streaks or gear marks on the printed page, as when these occur the wear on the plates is excessive. For this reason presses for color work require especially accurate gears. The captions under the illustrations describe the charts in detail. The two circles in the charts of Figs. 6 to 9 are made by turning one gear 180 deg. around.

These charts are a great aid in studying the action of a pair of

gears and are of material assistance in running down gear troubles. It is interesting to note that in all cases where a milled pinion is used, the charts have the characteristic sawtooth form denoting departure from the true involute tooth form. This is not so noticeable with the milled gear as the gear-tooth outline, especially when the gear has a large number of teeth, is flatter and any modification from the true involute is less apparent. The pinion is the most critical part of a gear drive and it can be seen that when the pinions are correct the charts are almost perfect.

The Saurer gear-testing machine is also provided with a vernier for setting the spindles to correct center distances and with an indicator for rapidly testing gears for eccentricity and uniformity of

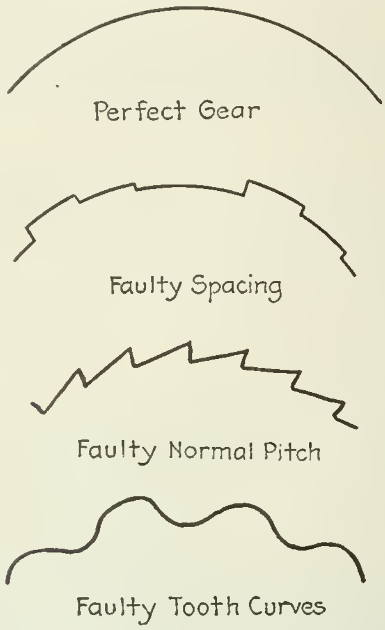

Fig. 12 Types of Charts Produced on Saurer Machine by Different Gear Inaccuracies

tooth thickness. One of the spindles is mounted on a slide that is held in position by a strong spring and is in contact with a dial indicator. When the gears are forced together this dial indicator should give a constant reading as the gears are revolved, if they are concentric.

The slide in contact with the indicator has ball bearings, making it sensitive to slight inaccuracies in the gears. It is comparatively easy to establish limits of eccentricity for any given gear when run with a master gear, and this application of the machine is useful in the commercial inspection of gears, as it is rapid, accurate, and sensitive.

The Odontometer

The odontometer was designed to meet the need for a quick, accurate gage to test gears for tooth curves and spacing. It is based on the principle that the involute curves of successive teeth are parallel—that is, the distance between the involutes measured on a normal is constant.

The instrument as shown in Fig. 13 consists of two rack teeth, one of which is fixed and the other is adjustable for different pitches. The adjustable tooth is mounted on flexible supports and is connected to a dial indicator. In use the instrument is allowed to roll in the gear to be tested. If the tooth curves are accurate involutes the needle of the dial indicator remains stationary while the two teeth of the instrument are in contact with the teeth of the gear; or, perhaps a better way of expressing it is to say that the needle pauses as the instrument is rolled in the gear. If the spacing is correct the needle pauses at the same point for each tooth. If there is no pause the tooth curves are not true involutes.

From Fig. 14 it will be seen that the odontometer does not test the whole tooth curve, but part of the dedendum of one tooth in relation to part of the addendum of the next. However, this is really the most important dimension because it is the overlap of the gears. That is, if this dimension is the same for all teeth, it means that when two teeth are driving each is taking its proportional part of the load.

To get good results from the odontometer the teeth of the gear should be smooth and should not be modified involutes. However, gears that are not true involutes can be tested for spacing errors with the odontometer.

The distance measured by the odontometer is the normal pitch, which is the same as the circular pitch on the base circle, and if the circular pitch on the pitch circle is desired, the distance measured should be divided by the cosine of the pressure angle.

In order that two gears may run together satisfactorily their normal pitches should be equal. In case there is any variation the normal pitch of the driver should never be less than the normal pitch of the driven gear.

One of the principal advantages of the odontometer is that it can be used during the process of manufacture and troubles located in the machines or tools. For instance, in grinding gears the odontometer can be used without removing the gear being tested from the machine or disturbing the setting. Further, it will measure gears designed to run at any pressure angle and can be quickly adjusted for different pitches. It can also be mounted on a stand

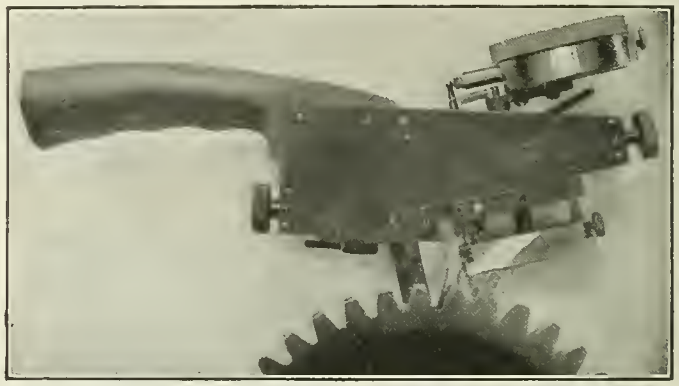

Fig. 13 Odontometer for Testing Gears of from 3 to 10 Diametral Pitch

(A smaller instrument is made for gears of 10 to 24 diametral pitch)

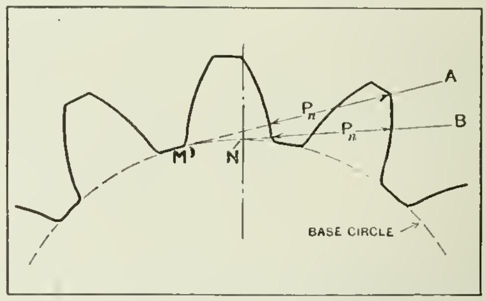

Fig. 14 Diagram Showing Part of Tooth Curve Measured by the Odontometer. Only the Part Between the Lines *AM* and *BN* is Measured

and used to measure the pinion-shaped cutters used in gear shapers.

In manufacturing, speed is of great importance and only those methods of testing gears should be selected that are relatively rapid. It should also be borne in mind that control of the equipment is fully as important as the inspection of the finished gears.

In the commercial production of precision-ground gears the Pratt and Whitney Company use the gear-tooth micrometer and the odontometer during the processes of grinding and subsequently test the finished gears by the hand-rolling or finger test and by the eccentricity test with dial indicator on the Saurer machine. The backlash and center distances are also checked on the Saurer machine and finally the gears are run under power for a noise test.

Nothing has been said regarding smoothness of tooth surface. This is an important point in the smooth running of gears, but as it is purely relative, definite limits cannot be fixed.

Attention should be called to the necessity of accurately mount-

(Continued on page 81)

Power Required for Cutting Metal

By Fred A. Parsons,[1] Milwaukee, Wis.

This paper gives results of an investigation extending over a period of more than ten years, the purpose of which has been to determine the fundamental laws governing milling, turning, planing and drilling operations on the various metals and alloys used in machine construction. In addition to a very large number of tests made on milling machines constructed by the concern with which the author is connected, those reported by Frederick W. Taylor and Professors Bird and Fairfield in the Society's Transactions have been subjected to analysis, the following variables being studied:

1 The efficiency of the machine
2 The rate of metal removal (cu. in. per min.)
3 The average thickness of chip before distortion
4 The front rake on the cutting blade
5 The material being cut
6 The spiral angle or shear on the cutting blade
7 The condition of the cutting tool, sharp or dull.

The author's results are presented in the shape of formulas and tables by means of which the power required to machine metal in any given case may be calculated, and an example of their use is worked out in detail.

In an article published in the technical press in 1920 were given the results of a preliminary study of a large number of milling tests run on Kempsmith milling machines. In the course of this study certain new laws were discovered, and a slide rule based upon them and constructed at that time gave very good results over the range of data then available. Later investigation over a wider range of tests showed, however, that further consideration was necessary, and it is the purpose here to give the results that have been obtained up to the present time.

The variables which may affect the relative power required at the drive pulley of a machine tool are, according to present data, limited to the following, there being no evidence that speed of cutting affects power economy to any marked degree:

a The efficiency of the machine
b The rate of metal removed (cu. in. per min.)
c The average thickness of chip before distortion (A.T.C.)
d The front rake on the cutting blade
e The material being cut
f The spiral angle or shear on the cutting blade (trifling)
g The condition of the cutting tool, sharp or dull.

It also seems likely that lubrication or flooding of the cutter may affect the power economy, but at present data on this point are not available.

In reality the seven variables mentioned above involve a variety of other factors, whose effect on the power required, however, is measured by their influence in fixing the value of the variables. These factors will be discussed in their proper place, as modifiers of the variables.

The data available were those of a very large number of tests made at the plant of the Kempsmith Manufacturing Company on various milling machines of their manufacture, and of other tests on power consumed, notably those of Taylor as given in his On the Art of Cutting Metals, and those of Professors Bird and Fairfield at the Worcester Polytechnic Institute (Trans. Am.Soc.M.E., vol. 26), these being chosen because the results were listed as "pressure on tool" or as "torque," from which the power to the tool itself could be computed and thus a distinction be made between the power required for cutting and that required for running the machine. The Kempsmith tests were mainly run under the following conditions:

a The machines were driven by a 25-hp. Crocker-Wheeler motor through a lineshaft having three roller bearings. This gave two belts and three roller bearings between the motor and the machine pulley
b The power input for each cut was measured by means of a voltmeter and ammeter connected through resistance across the line at the starting switch of the motor
c A reading was taken just before each test (1) of the motor, lineshaft, and machine pulley idle, and (2) of the same plus the machine with its speed and feed trains running but idle.
d The speed of the drive shaft of the machine was taken just before reading the instruments during the cut. This was done so that corrections could be made in the feed rate, from which the cubic inches of metal removed per minute was figured
e The readings for the power were taken after the cut was well under way, to make sure that the machine would really pull the cut. The No. 4 Maximiller originally incorporateda safety slip device in the feed train which caused considerable annoyance by reason of the fact that it worked too well, limiting the cut to the nominal rating of the machine, which was far under the actual limit of strength of the drive gearing or the capacity of the belt.

Some exceptions to the above conditions will be noted in their proper place.

Effect of Machine Efficiency

The efficiency of a machine is a variable quantity at different loadings. The power required to run the machine idle and the maximum efficiency of the mechanism at full load may be considered as determinants.

If a milling machine, for instance, is set up for a certain cut requiring, say, 1 hp. delivered to the pulley, and the width of the cut should then be increased fifteen times, the horsepower required at the drive pulley will not be increased in the same proportion. This is due to the increased efficiency of the machine at the new and larger load.

It was recognized that in order to arrive at consistent results the variations due to machine efficiency must be eliminated. Fig. 1 shows the efficiency at various loadings for two machines, one having 90 per cent maximum efficiency and the other 70 per cent. This chart was plotted as follows:

a The zero point in the efficiency curve was taken as 0.6 hp. from the average results of a number of tests of the power required to run the No. 4 Kempsmith Maximiller with all gearing running but idle
b The high points in the hp.-output lines were determined by a series of tests, which, while not very satisfactory, nevertheless showed that for a milling machine with anti-friction bearings a maximum efficiency of at least 90 per cent may be expected if the design is good, while for a machine having plain bearings throughout it may drop to as low as 70 per cent
c Taking these efficiencies as the extremes for milling machines of the two types gave the two lines for hp. output, and from the readings of these lines at intermediate points the values for plotting the efficiency curve were determined.

Referring to the first case mentioned, the 1 hp. delivered to the pulley would represent, according to Fig. 1, about $^1/_3$ hp. output from the machine, that is, to the cutter, on the 90 per cent machine. It is this value which must be increased fifteen times or to 5 hp. Again, reading from Fig. 1, this would require an input of 6 hp. or six instead of fifteen times the power for the first cut. The results on the 70 per cent machine would of course be somewhat different.

This all shows very conclusively that cutting tests must be corrected for horsepower and for machine efficiency before consistent results can be expected. The method used in doing this in these tests was to reduce all horsepower values to a value of "hp. delivered to the cutter" or tool hp. This can then be used to obtain a value of "cubic inches of metal removed per horsepower delivered to cutter," from which curves may be plotted for varying conditions.

[1] Chief Engineer, Kempsmith Milling Machine Co. Mem. Am.Soc.M.E.

Contributed by the Machine Shop Division and presented at the Annual Meeting New York, December 4 to 7, 1922, of The American Society of Mechanical Engineers. Abridged. All papers are subject to revision.

Effect of Rate of Metal Removal

The horsepower varies directly as the cubic inches of metal removed per minute, but only if all the other factors remain constant. This would seem fairly obvious, but it has been very much obscured by the variations caused by other factors, especially the variation in machine efficiency at various loadings and the variation in proportionate chip pressure for different thicknesses of chip.

Effect of Varying the Average Thickness of Chip (A.T.C.)

In the earlier investigation it was discovered that the power required for milling was closely related to the feed per tooth per revolution and to the depth of cut, the two items being considered separately. Later it was found that these items should be combined into an expression "Average Thickness of Chip" which influenced spiral and face mills alike (in fact, lathe tools, drills, etc. as well), gave uniform results over an extreme range of tests, and made

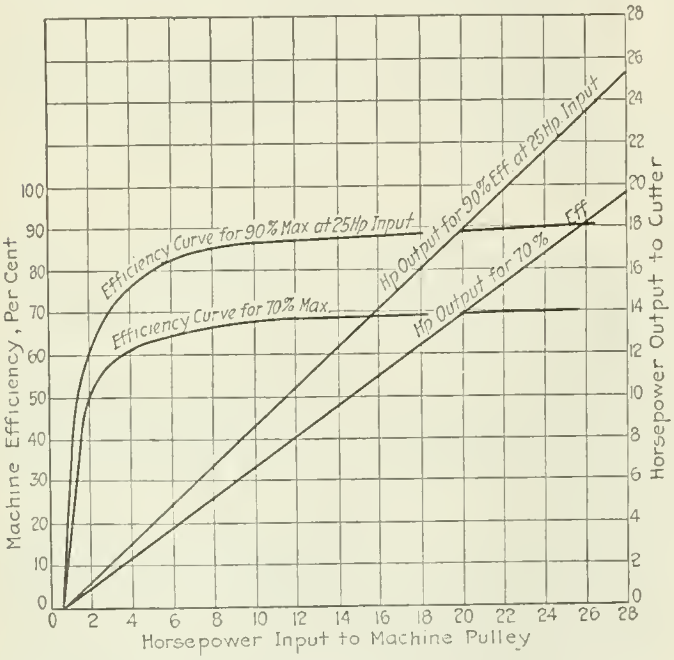

Fig. 1 Ideal Machine. Horsepower Output and Input and Efficiency at Various Loadings

proper allowance for the cutter diameter. Variations in the diameter of the cutter had been recognized during the first investigation as influencing the power required, but no definite law established which could be incorporated into the formulas.

The A.T.C. affects the power required for removal of metal directly according to a root of its value, the index of the root varying with different materials. Fig. 2 gives the results of a large number of tests and shows the relation for a variety of materials. This chart is a summary of five charts shown in the complete paper.

It will be noted that the tests charted include a considerable number for which the data were taken from the lathe tests run by Frederick W. Taylor and published by him in his book On the Art of Cutting Metals, as well as some drill tests run at the Worcester Polytechnic Institute. The fact that these tests fall into line with the milling-machine tests in such a completely satisfactory manner is considered as additional and very complete proof of the correctness of the general laws as formulated in Fig. 2. The logs of these tests are on file at the Society's headquarters and may be consulted by any one interested in their contents.

Several of the materials indicated in Fig. 2 have been tested for only a single point (see Table 1), and it is therefore not certain that the laws given for these should be considered as fully determined. From the fact that the lines for two materials, cast iron (machine castings) and soft steel, both come to a common point at about 0.0001 A.T.C., it is believed that this may safely be assumed for all other materials also. With this as a fixed point a single test is then sufficient to locate another, the two determining the direction of the line for the material tested, and thus determining the

TABLE 1 MILLING TESTS OF VARIOUS MATERIALS ON KEMPSMITH NO. 4 MAXIMILLER

formula. The lines for aluminum and brass were thus determined. Those for steel and for machine cast iron were determined for nearly the full extent of the chart, and those for the other metals over a limited range only, but one sufficient to show that they apparently follow out the theory of a common origin for the lines of all materials.

The A.T.C. for the various types of cutting tools must be determined in various ways according to the types, which, for this purpose at least, fall into five classes as follows:

a Spiral or slabbing mills
b Formed milling cutters, as gear cutters, etc.
c Face mills (1) with square corners on blades or (2) with corners rounded or chamfered
d Lathe and planer tools
e Drills, counterbores, etc.

For spiral or slabbing mills, and in general all milling cutters with the exception of formed cutters and face mills, it can be shown that the A.T.C. depends upon the feed per tooth per revolution, the cutter diameter, and the depth of cut, the relation being expressed with sufficient accuracy for all practical purposes by a formula derived as follows:

Let D = cutter diameter
R = cutter radius
d = depth of cut
f = feed per tooth per revolution of cutter
= feed per rev. ÷ number of teeth in cutter
A.T.C = average thickness of chip
t = maximum thickness of chip.

Then, referring to Fig. 3,

$$t = 2f\sqrt{\frac{d}{D}\left(1 - \frac{d}{D}\right)}$$

whence—

$$\text{A.T.C.} = \frac{t}{2} = f\sqrt{\frac{d}{D}\left(1 - \frac{d}{D}\right)}$$

The preceding formula is based on the following analysis: Referring to Fig. 3, in the triangle with the hypotenuse R the height is obviously $R - d$, and the base, from the law of squares, equals $\sqrt{2Rd - d^2}$. Since the triangle with hypotenuse f is similar to the triangle with hypotenuse R, their similar sides are proportional, or—

$$f : t = R : \sqrt{2Rd - d^2}$$

whence—

$$tR = f\sqrt{2Rd - d^2}$$

but—

$$R = \frac{D}{2}$$

$$\therefore t = \frac{2f}{D}\sqrt{Dd - d^2} = 2f\sqrt{\frac{d}{D}\left(1 - \frac{d}{D}\right)}$$

Since the chip is a regular geometrical figure whose maximum height is t and whose ends are zero, its average height (average thickness of chip) is $\frac{1}{2}t$, or—

$$\text{A.T.C.} = f\sqrt{\frac{d}{D}\left(1 - \frac{d}{D}\right)} \quad \ldots\ldots\ldots\ldots [1]$$

Formula [1] may be still further simplified by calculating and tabulating values of $\sqrt{\frac{d}{D}\left(1 - \frac{d}{D}\right)}$ for various values of the ratio $\frac{d}{D}$, as in Table 2, thus reducing to A.T.C. = $f \times$ constant. The

greatest value of the constant being 0.5 indicates that for slabbing mills the A.T.C. cannot be greater than half the feed per tooth per revolution, this maximum value being arrived at when the depth of the cut equals half the cutter diameter.

TABLE 3 CONSTANTS FOR A.T.C. FOR FORM CUTTERS
(Multiply A.T.C. obtained as for a spiral mill by the value corresponding to the ratio of d/W to obtain true A.T.C.)

Value of Ratio $\frac{d}{W}$ (See Fig. 4)	Value of W ÷ length of outline (approx.) (See Fig. 4)
0.5	0.67
1	0.45
2	0.24
3	0.16
4	0.12

against the edge of the circle generated by the revolving blades (see Fig. 5), it can be shown that the A.T.C. varies according to the ratio of the width of cut to the cutter diameter (W/D) and according to f, the feed per tooth per revolution. The A.T.C. for this type of mill is a definite ratio of W/D. (See Table 4.)

The method of arriving at the constants given in Table 4 is as follows: A face mill cutting a width W' (see Fig. 5) equal to the diameter D would have an A.T.C. equal to half the feed per tooth per

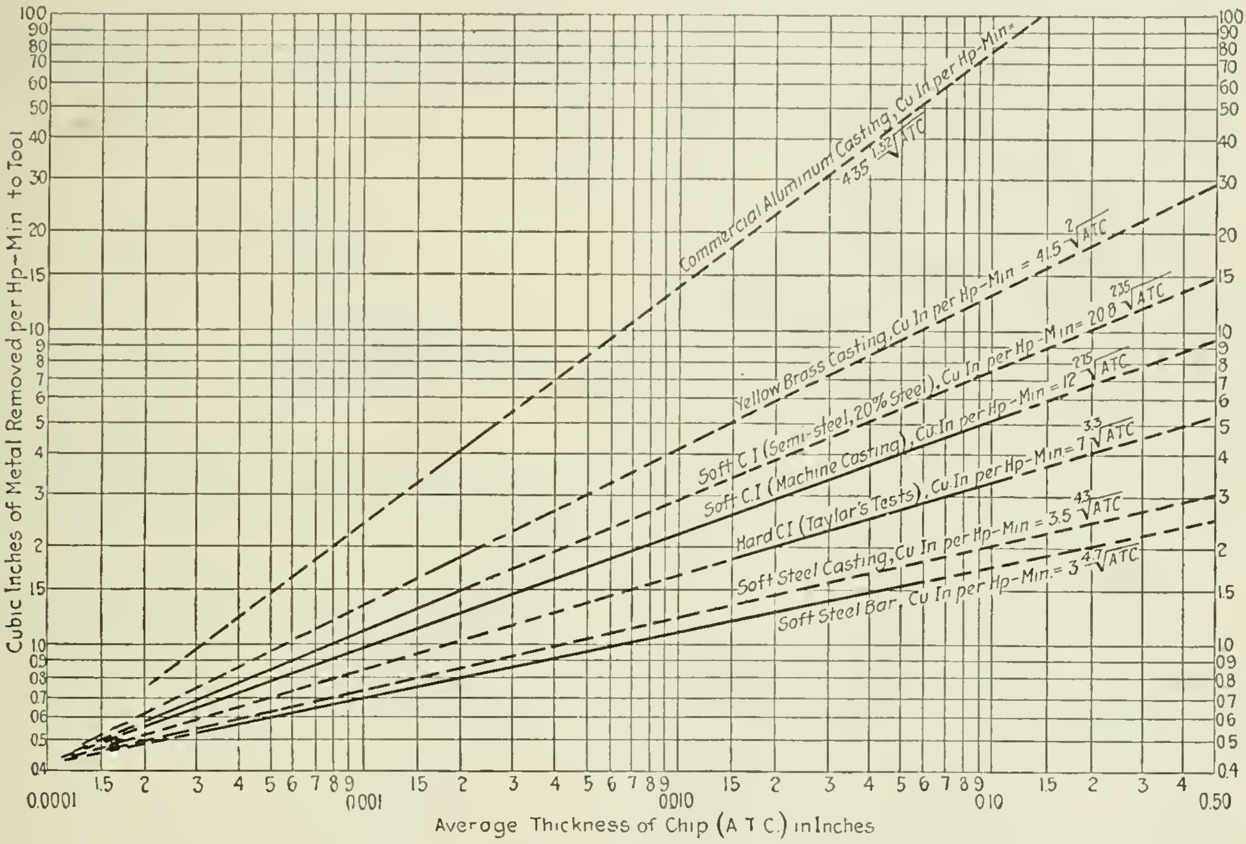

FIG. 2 RELATION OF AVERAGE THICKNESS OF CHIP (A.T.C.) TO CU. IN. PER HP-MIN. TO TOOL FOR VARIOUS MATERIALS

For formed milling cutters the A.T.C. found by the above method must be reduced in proportion to the ratio of the width of the form divided by the length around the outline (see Fig. 4); or—A.T.C.

$$\text{for form cutters} = f\sqrt{\frac{d}{D}\left(1-\frac{d}{D}\right)} \times \frac{\text{width of cut}}{\text{length around outline}}$$

This will be apparent if it is remembered that it is the *average* thickness of the chip which is required, and obviously if all the other factors remain the same an increase in the width of the chip as determined by the length of the outline will be accompanied by a corresponding decrease in the average thickness. This is explained more fully later in considering the effect of rounding on the corners of face mills.

A reasonable approximation may be had, however, if instead of employing the above method, which involves computing or measuring the outline, a constant be used representing the approximate value of W/(length of outline) for various values of d/W. Such constants are given in Table 3.

In practice the A.T.C. for form cutters should first be obtained as if for a spiral-mill cut, and then reduced as per the formula immediately preceding or by multiplying by the proper constant from Table 3.

For face mills, if the corners of the blades are square when cutting in the usual way, that is, with the work feeding centrally

TABLE 4 CONSTANTS FOR DETERMINING A.T.C.—FOR USE ONLY FOR FACE MILLS HAVING BLADES WITH SQUARE CORNERS.

Ratio $\frac{W}{D}$ (See Fig. 5)	A.T.C.	Ratio $\frac{W}{D}$ (See Fig. 5)	A.T.C.
0.1	0.999f	0.6	0.900f
0.2	0.990f	0.7	0.853f
0.3	0.976f	0.8	0.800f
0.4	0.959f	0.9	0.716f
0.5	0.932f	1.0	0.500f

revolution; for if the chip *mop* is considered as a regular geometrical outline whose greatest thickness *op* is the feed per tooth per revolution (f), and which tapers regularly to zero at the ends, it will be seen that the average thickness of such a chip will be $\frac{f+0}{2} = \frac{f}{2}$. As the width of the cut becomes smaller in proportion to the diameter D (see width W, for instance), then the A.T.C. will approach the value of f, until for a zero width of cut the ends of the chip would have the same thickness as the center and the A.T.C. would be $\frac{f+f}{2} = f$.

To determine the exact A.T.C. for intermediate widths of cuts we may use the formula as determined for spiral mills and find the value of t (see Figs. 3 and 5). Since t for a face mill is the thickness

of the end of the chip, the A.T.C. for any value of W/D will be $\frac{f+t}{2}$.

The value of t as determined for spiral mills is found by the formula $t = 2f\sqrt{\frac{d}{D}\left(1 - \frac{d}{D}\right)}$, and the same formula holds for t in Fig. 5 if d be considered as the distance from the edge of the cutter circle to the work instead of being the depth of cut as for spiral mills.

For a face mill having any width of cut W, the value of d in the

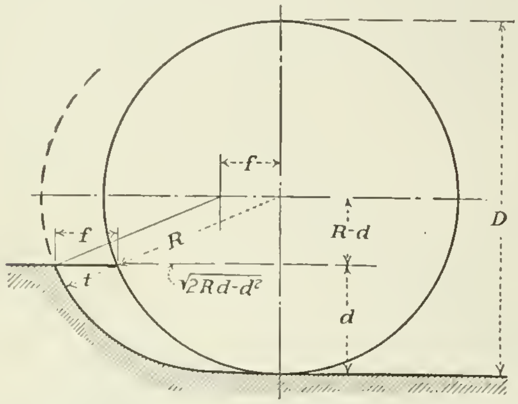

FIG. 3 THICKNESS OF CHIP FOR SPIRAL OR SLABBING TOOLS

above formula may be expressed in terms of the diameter of cutter and width of cut as follows:

$$d = \frac{D}{2} - \frac{W}{2} = \frac{D - W}{2} = 0.5(D - W)$$

Then for face mills:

$$t = 2f\sqrt{\frac{0.5(D-W)}{D}\left(1 - \frac{0.5(D-W)}{D}\right)}$$

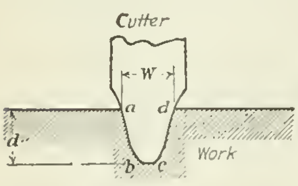

FIG. 4 REDUCTION IN A.T.C. FOR FORM CUTTERS

(W = width of form; d = depth of cut; $abcd$ = length of outline.)

It may be shown that the value of the term $0.5(D - W)$, and therefore the value of the preceding formula and also of the formula A.T.C. = $(f + t)/2$, will be constant for any given ratio of W/D if expressed in terms of f. (See list of such values in Table 4, which are much easier to use in computing A.T.C. than the formula.) The simplified formula for obtaining A.T.C. for face mills having square corners is therefore as follows, the constant being obtained from Table 4: A.T.C. = constant $\times f$.

For face mills having a corner radius on the blades, it can be shown that the A.T.C. as determined above for square-cornered mills must be decreased according to constants depending upon the ratio of the depth of cut d to the corner radius on blades r. (See list of these constants in Table 5.)

The method of arriving at these constants is as follows: If the corners of the blades are perfectly square (Fig. 6), then the width of the chip (= ek) is equal to the depth of the cut d, and the A.T.C. at all cross-sections of the cut will be the same.

If the corners are rounded (see Fig. 7), as is almost invariably the case in practice, the A.T.C. will vary at different sections of the cut, being a maximum only for sections of cut not coming on the radius of the cutter blade, as at A, and running down to zero at B. The real A.T.C. or average value of A.T.C. for all the sections would therefore depend upon the ratio of the depth of cut d to the corner radius r, or d/r. This real A.T.C. may for the moment be called A.T.C.^{R}, to distinguish from what may be called A.T.C.^{S} for a cutter with sharp corners.

TABLE 5 CONSTANTS FOR USE IN DETERMINING A.T.C. FOR FACE MILLS WITH ROUNDED CORNERS

(Multiply A.T.C. for equivalent cut with face mill having square corners by constant corresponding to value of depth of cut divided by corner radius on blades.)

Ratio $\frac{d}{R}$ (See Fig. 7)	Length of Chip = $A'B$ (See Fig. 7)	Average Area of Chip = A.T.C.$^S \times d$	Constant = $\frac{\text{area}}{\text{length}} = \frac{\text{A.T.C.}^S \times d}{A'B}$
0.1	0.445r	A.T.C.^{S} × 0.1r	0.225
0.2	0.645r	A.T.C.^{S} × 0.2r	0.31
0.4	0.925r	A.T.C.^{S} × 0.4r	0.43
0.6	1.16r	etc.	0.52
0.8	1.37r		0.58
1.0	1.57r		0.64
2	2.57r		0.78
3	3.57r		0.84
4	4.57r		0.87
5	5.57r		0.90

Now if the average area of chip is computed by multiplying the average thickness (A.T.C.^{S}) as obtained for face mills with square blade corners by the depth of cut d, this value will not be changed by the addition of the corner radius since it is obvious that if a certain area of work is removed by taking a definite number of chips, determined by speed, feed, number of teeth in cutter, etc., each chip will have a definite area regardless of its form. This can be stated thus:

$$\text{Average area} = \text{A.T.C.}^S/d$$

The addition of a corner radius, however, will change the length from gh in Fig. 5 to AB in Fig. 7, and the real average thickness or A.T.C.^{R} will therefore change accordingly, or:

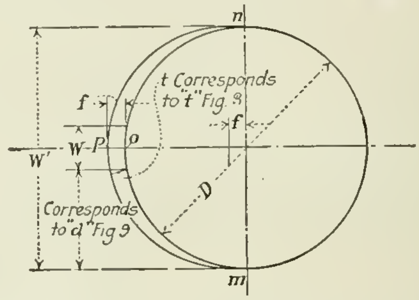

FIG. 5 DIAGRAM REPRESENTING A FACE-MILL CUT

(f = feed per tooth per rev; D = diam. of face mill; W, W' = various widths of cut; t = approx. end thickness of chip for cut of width W.)

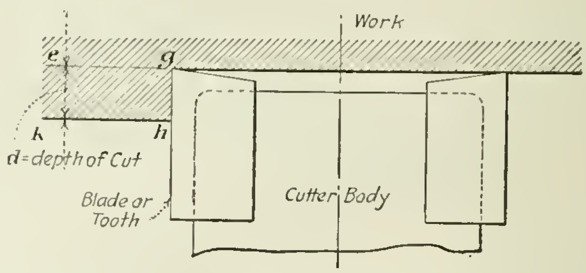

FIG. 6 FACE MILL WITH SQUARE CORNERS ON BLADES

$$\text{A.T.C.}^R = \frac{\text{average area}}{\text{length of chip}} = \frac{\text{A.T.C.}^S \times d}{\text{length}}$$

The length $A'B$ in Fig. 7 may be found by the formula—

$$\text{Length } A'B = 2\pi r \times \frac{\text{angle } S}{360°}$$

For any given value of d/r it can be shown that the length as expressed in terms of r will be constant and upon this basis it can also be shown that for any given value of d/r the value of A.T.C.^{R} will also be constant as expressed in terms of A.T.C.^{S}.

If these ratios are evaluated they result in the constants given in Table 5, by which the A.T.C. as determined for a given cut with a face mill having square corners must be multiplied to get the true A.T.C. for an equivalent cut with rounded or beveled corners.

A.T.C. FOR LATHE AND PLANER TOOLS

After having followed through the above it will be apparent that for lathe and planer tools the A.T.C. will also be dependent upon the form of the tool—

a If the tool has a sharp corner and acts square with the direction of feed, then the A.T.C. = feed per revolution or per stroke

b If the tool is rounded, or stands at an angle, the A.T.C. as determined above for the square-cornered tool must be

reduced to its true value by multiplying by the depth of cut and dividing by length of the chip, on the same principle as used in determining the true A.T.C. for face mills having rounded corners.

There are no accepted standards for tool forms in general use and therefore no table of constants can be given here, though these could easily be worked out for any standardized set of forms. For the lathe tests of Frederick W. Taylor which are incorporated in Fig. 2, the A.T.C. was modified as above according to the outlines of his standard tools as given in On the Art of Cutting Metals.

A.T.C. for Drills, Counterbores, Etc.

For counterbores, where the cutting edge is square with the feed, the A.T.C. = feed per revolution ÷ number of teeth in tool.

For drills the angle of the cutting edge must be considered. The A.T.C. as determined above should be multiplied by the cosine of the angle the cutting edge makes with the direction of the feed, which in the case of a drill ground to the standard angle of 59 deg. would be the cosine of 31 deg. or 0.857.

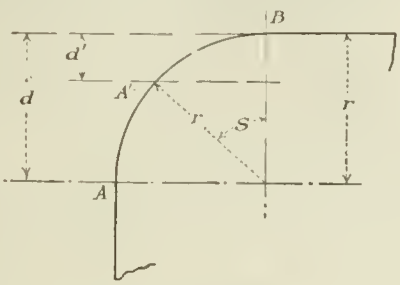

Fig. 7 Diagram of Rounded Corner of Face-Mill Blade or Tooth

(d, d' = various depths of cut; r = corner radius or equivalent bevel; $A\ B$, $A'\ B$ = length of chip.)

For the drilling tests the A.T.C. was determined as above, the cubic inches per horsepower-minute being reduced 20 per cent for the purpose of comparison with the standard line, as the line represents a tool half dulled.

Effect of the Front Rake of Cutting Blade on Power Consumed

Tests are available only for milling cutters, and only up to 12 deg. of rake (see Table 6). The results of such tests as are available seem to show that for milling cutters the power required varies directly as the ratio of the covered sine of the rake angle, or the cubic inches of metal removed per tool hp. varies inversely in the same way.

For milling cutters and lathe tools the front rake may vary considerably, and allowance according to the above should be made when computing metal removed or hp. required from the chart of Fig. 2, which is based upon milling cutters of about 10 deg. front rake and lathe tools of about 15 deg. front rake.

For drills the rake as determined by the helix angle is not subject to much variation in practice. Fig. 2 being based on drills having the rake angle of the standard twist drill (which is about equivalent to a 15-deg. average cutting rake), no allowance need be made when employing it unless the drill to be used is something other than a standard.

There is a possibility that front rake has different effects according to the material tooled, but this is not indicated to any marked extent in tests thus far available.

Power Required for Various Materials

Each material requires a different formula for determining the metal removed per hp-min. or the hp. required for any given cut—see Fig. 2.

It is apparently not possible to give any fixed ratio for the power required for different materials as this varies according to the A.T.C., the differences due to varying materials becoming small and negligible when the A.T.C. is reduced to a value of about 0.0001, as has been previously explained. The tests in Table 1 show the ratios of metal removed when the value of A.T.C. = 0.0021; ratios for other values of A.T.C. can be determined from Fig. 2.

Since allowance for various materials has already been made by the use of different lines on the chart, it is not necessary to consider this item when computing the hp. required or metal removed per hp. for any given cut, beyond choosing the proper formula or reading from the proper line.

Effect of Spiral or Helix Angle (Shear) on the Cutting Blade

It is important to distinguish between the action of a spiral angle or shear, as on a spiral milling cutter (which does not make the chip thinner), and the effect of setting a lathe tool on an angle, which thins down the chip by increasing its length while its area remains constant according to the feed in use in the same way that the chip thickness is decreased for a form cutter and for a face mill with round blade corners, as previously discussed, or by the angle on the point of a twist drill, which also thins down the chip. The effect of adding a spiral angle to a milling cutter, as far as power efficiency is concerned, seems to be largely confined to reducing the bumping action of the cut and thereby somewhat reducing the maximum power required. From the standpoint of power required this effect is not important.

30	....	......	..	..	..	...	....	.....	...	...	...	.....	....	...	2.00

A test run first with several narrow cutters set up with all the teeth on a line, and again run with the teeth staggered (to give the effect of a spiral cut), showed the power reduced in the ratio of 1.42 to 1.27 (Test sheet No. 4 Maxi. 4004–17–19).

The spiral angle is of considerable importance, however, from the fact that a large spiral angle will enable fewer teeth to be used in the spiral or slabbing cutter. The only reason for using many cutting teeth in such a cutter is in most cases to reduce the bumping action to a point where the work, jigs, and machine will stand it, and this can be done effectively with fewer cutting teeth if the spiral angle is large.

For the same reason a cutter with considerable spiral angle may take a heavier feed than one with small or no angle, though this is

often prevented by interference of chips. The increase in the feed rate is, of course, equally as effective as a decrease in the number of teeth in increasing the cutting efficiency.

No tests are available for extreme spiral angles such as those of the helical mills sometimes used, but it is believed that the greater efficiency of these mills is almost entirely due to the decreased number of teeth and consequent increase in A.T.C., which would fully account for a greatly increased efficiency.

Effect of Sharp and Dull Cutters

The condition of the cutter has a very pronounced effect on the amount of power required for removing metal. It is believed that a good part of the variations above and below the line on the various charts are due to differences in the degree of cutter sharpness.

Tests showing the variations for sharp and dull milling cutters cannot be expected to show uniform results as there is no standard for dullness. However, a number of tests (see Table 7) show that the power may be expected to increase as much as 40 per cent or more before the appearance of the cut warns the operator that it is time to resharpen in the case of milling cutters.

As the economical time between grinds varies with different jobs, being sometimes one or more days and sometimes the period required to finish a given lot of pieces, according to various considerations, it seems best to consider the entire interval from sharp to dull as ten equal units, irrespective of the time involved. The tests—1217-7, etc., Table 7—show that the cutter dulls in a fairly regular manner, and on this basis the power required could be considered as increasing regularly to a maximum of about 40 per cent above that required with a newly sharpened cutter, at which point the operator would notice that it needed resharpening from the fact that it was no longer cutting properly.

In computing power required or metal removed per tool hp. from the chart of Fig. 2, we would, according to the above method, take the results from the chart as being for a cutter which had been used for five of the allotted ten units mentioned: in other words, a cutter which was just half dulled. The computed power required for any given conditions would then be increased if the cutter had been run *more*, or decreased if the cutter had run *less*, than the time or distance required to half dull it; while if computing metal removed per tool hp. this procedure would of course be reversed, the amount of increase or decrease naturally depending upon the number of units less or more than half dulled up to approximately 20 per cent over and under for the maximum of 5 units.

The preceding paragraph refers only to milling cutters. For drills no data are available, but when allowance is made as above, they fall almost exactly on the line corresponding to the half-dulled cutter. Lathe tools, to be run economically, as shown by Taylor in his On the Art of Cutting Metals, should be run at speeds which dull them very rapidly as compared with the economical speeds for milling cutters. It is therefore probably safest to consider all lathe tools as *dull* tools, because the time interval between a sharp and a dull tool is, or should be, comparatively very short. Exceptions to this are formed tools and other tools in automatic machinery, etc., where the cost of resetting makes it necessary, as for a milling cutter, to increase greatly the time interval.

This completes the consideration of the variables mentioned at the beginning of the paper as affecting the power required for cutting metal, and from what has been set forth may be figured the power required by the cutter for almost any combination of tool and cut. Belt hp. can only be computed if the idle hp. and efficiency under some known load are known, though it can be approximated if the last item only is known, especially if the cut represents a fairly large percentage of the machine's capacity.

Example. To find the power required for a gang of 5 gear cutters of 6 pitch, No. 4, 3 7/16 diam., 13 teeth, when cutting in cast iron (semi-steel, 20 per cent steel) with a feed of 7 1/4 in. per min. and at a speed of 56.5 ft. = 63 r.p.m.

a Find A.T.C. for equivalent speed, feed and depth for spiral mill (see Par. 28) as follows:

1 $\text{A.T.C.} = f\sqrt{\dfrac{d}{D}\left(1 - \dfrac{d}{D}\right)}$

2 f = feed per tooth per revolution = feed per rev. divided by no. of teeth in cutter = $0.115 \div 13 = 0.0088$ in.

3 For a 6-pitch gear cutter, depth $d = 0.359$ in., whence $d/D = 0.359/3\,{}^7/_{16} = 0.104$ in.

4 From Table 2 the value of $\sqrt{\dfrac{d}{D}\left(1 - \dfrac{d}{D}\right)}$ when $d/D = 0.100$ is 0.300, whence—

5 A.T.C. for equivalent spiral mill $= 0.0088 \times 0.300 = 0.0026$ in.

b The value thus obtained must be reduced to obtain true A.T.C. for the form cutter:

1 True A.T.C. for form cutters = A.T.C. for equivalent spiral-mill cut × constant representing ratio of d to W

2 Width of cut W for a 6-pitch cutter is (measured) about 7/16 in. and the standard depth is 0.359 in., whence—

$$\frac{d}{W} = \frac{0.359}{0.437} = 0.82 \text{ approx.}$$

3 From Table 3 the value of the constant for $d/W = 0.82$ is about 0.50, whence—

4 True A.T.C. = A.T.C. × constant $= 0.0026 \times 0.50 = 0.0013$ in.

c Having found the true A.T.C. as above, we may now read from Fig. 2. at the point of intersection of the line of A.T.C. = 0.0013 with the line for cast iron (semi-steel), the cu. in. per tool hp., which is 1.25 cu. in. approximately.

We would therefore expect 1.25 cu. in. of semi-steel per tool hp. for this cut if the rake on the cutter were 10 deg. and the cutter were half dulled.

d As the rake is actually 0 deg., we must make allowance therefore as per Table 6:

$$1.25 \times (1/1.21) = 1.03 \text{ cu. in. per tool hp-min.}$$

e The amount of metal removed per minute by the above cut will be 3.4 cu. in. for the 5 cutters (= feed per min. × area of cut), assuming that the area for a single cutter is one-half the depth times the circular pitch.

f Since we expect 1.03 cu. in. per hp-min., 3.4 cu. in. per min. will require $3.4/1.03 = 3.3$ hp.

g The value thus obtained is for cutters half dulled. For sharp or dull cutters this would be decreased or increased 20 per cent, respectively:

$3.3\ (1 - 0.20) = 2.65$ hp. for newly sharpened cutters
$3.3\ (1 + 0.20) = 4.12$ hp. for dull cutters.

A test cut run with conditions as noted above required 3.26 hp. to the tool with cutters which, while in good condition, had been used before and were partly dulled (No. 4 Max. Test sheet 4004–21).

h To determine the belt hp. from the tool hp., the constants for idle hp. and for efficiency under cut must be known for the machine on which the cut is to be run; this being merely the reverse of the process of finding the tool hp. Having once been determined for any given machine, the relation of output to input (see Fig. 1) for the machine can be reduced to a formula for easy use.

i On the Kempsmith No. 4 Maximiller, for instance, the 4.12 hp. for dull cutters noted in *g* above would be increased as follows:

$$(4.12 \times 1.08) + 0.6 = 5.05 \text{ belt hp. required}$$

While the foregoing method of computing the hp. required for cutting metal may be employed provided a line similar to those in Fig. 2 has been established for the material to be cut, it is much more convenient to use a slide rule in which the data have been incorporated. Such an instrument is described and illustrated in an appendix to the complete paper.

Summary

For milling machines the power economy increases—

a For both slabbing and face-milling cuts:

(1) As the r.p.m. of cutter is decreased, but only if this increases the chip thickness, as in machines having feed rate independent of spindle speed
(2) As the feed per revolution of cutter is increased
(3) As the number of teeth in cutter is decreased (but only if the r.p.m. remains constant, thus increasing the chip thickness)
(4) As the front rake is increased.

b For spiral and slabbing cutters:

(1) As the cutter diameter is decreased
(2) As the depth of cut is increased.

c For face mills:

(1) As the cutter diameter is increased
(2) As the width of cut is decreased
(3) As the corner radius or chamfer is decreased
(4) As the depth of cut is increased, but this only affects power economy when the blades have a rounded or chamfered corner.

For lathes, planers, etc., the power economy increases—

(1) As the feed per turn or per stroke is increased
(2) As the round on tool point is decreased
(3) As the angle of the tool face with direction of feed is decreased
(4) As the cutting rake is increased
(5) As the depth is increased, but this only affects power economy if the end of the tool is rounded

For drills, counterbores, etc., the power economy increases—

(1) As the feed per revolution is increased
(2) As the number of flutes or cutting edges is decreased
(3) As the spiral angle or cutting rake is increased
(4) As the drill is ground with a smaller included angle of point.

While the foregoing points the way to greater power economy, possibilities must in many cases be subordinated to practical considerations. On a miller, for instance, too slow a cutter speed, too few teeth in the cutter and too high a feed, though desirable for cutting efficiency, will cause hammering, and usually the work and jigs will not stand this, even if the machine would do so. In certain cases this can be overcome by using helical mills with large angle of teeth, but not always.

In certain other important details, also, a given set-up may fail in operation even though the computed power is well within the cutting capacity of the machine. Almost any machine may be caused to chatter, or may chatter on certain speeds and feeds, even though the cut is fully within the machine's capacity—in fact, often because the cut is too light or the cutters too sharp to put an initial strain on the supporting structure and take out the slack. More often it is due to synchronized vibrations, which are difficult to avoid for all conditions.

Of two spindle speeds, both may be equally efficient in the transmission of power and have equal belt-hp. capacity, yet the gear leverages and bearing and shaft stresses by which one is obtained may be excellent, while for the other they may be very poor, causing unsatisfactory cuts, chatter vibration, and failure.

As another instance of practical limitations (though this applies only to spiral mills) it might be supposed that more teeth in the cutter would give equal power economy with greater production per unit of time, provided the feed was increased to give the same average thickness of chip, because more chips would be cut per minute by the greater number of teeth. However, not only is there danger of chip interference, but if it be considered that the r.p.m. for a given cutter is limited for any given material, and again that the feed per revolution is limited in most cases by the finish required—which is generally accepted as being determined for spiral mills by revolutions marks and not by tooth marks—it will be seen that a point of r.p.m. and of feed per minute is soon reached where the only way left to increase the average chip thickness and obtain greater economy is to reduce the number of teeth, the only limit in this direction being, as before mentioned, the hammering action of the cutter. As the cut approaches the limit of the machine's power capacity the advantage of few teeth in the spiral mill becomes very marked in its effect upon production.

It is certainly a fact, however, in spite of these limitations, that in many cases a considerable improvement can be made by applying the foregoing laws, and the saving in power, decreased wear on machine, increase in production, etc. which are sure to result will amply repay the effort.

Fiber in Metals

The association of a fibrous structure with strong and tough materials, such as wood and rope, and the corresponding association of crystalline character with weak and brittle materials, such as sugar or bismuth, has produced in the minds of many men, and even of competent engineers, the conception that all really strong and tough materials must be fibrous, and that all crystalline substances are likely to be weak and brittle.

A study of their microstructure, however, shows that all metals in a normal condition—i.e., when not severely cold-worked—are entirely crystalline, and that the minute crystals of which they are composed show no orientation of predominant length. There is, therefore, nothing in the nature of a "fiber" in the metal itself. The individual strips or bars into which a thick bar or plate becomes more or less completely divided by the presence of "slag" bands can never be any the stronger on that account. The metal itself, in fact, possesses no real fiber; its longitudinal strength appears greater than its transverse strength only because in the transverse direction the enclosure bands make their weakening presence felt far more actually than in the longitudinal. Were they entirely eliminated, the metal would be equally strong in all directions, and yet there would be no sign of "fiber."

It would thus seem that the desire for a "fibrous" structure is in essence a mistaken one, and that the cause of the fibrous appearance is in reality a weakness and not an advantage. It is true that under certain bending tests in which the power of the metal to undergo a large amount of plastic bending constitutes the main factor, the "fibrous" material shows higher results. Here the fibrous material gains a spurious advantage from the fact that it is enabled to behave very like a bundle of bars or thin plates rather than as a single piece of material. Owing to the weakness of the slag layers, the various rods and plates are approximately free to slide over one another and a larger amount of bending occurs before fracture takes place. But this is no real gain for practical use. *The Engineer* (London), Nov. 10, 1922, pp. 499–500.

Control of Lumber-Cutting Waste and Production

By CARLE M. BIGELOW,[1] BOSTON, MASS.

Increase in board feet per man-hour and reduction in waste percentage in the cutting department of woodworking plants by means of wage incentive are discussed in the following paper. A differential rate based upon the two factors of production and waste is paid a standard crew.

Eleven steps in the gathering of data required are described. An example of the working out of the payment method is given and its application outlined. The proper planning of cutting orders, standardization of lumber selection and drying, and operational standardization is essential to the method. An example showing results obtained is also given.

THE PURPOSE of this paper is to outline the principles and application of a wage-incentive plan which has been successfully operated to reduce waste and increase production in the cutting departments of furniture, box, toy, auto-body, and general millwork manufacturers.

Little attention has been paid to the reduction of lumber wastage in the past, and even now few concerns are giving the subject the consideration its importance warrants. When we take into account the fact that probably not over 35 per cent of the average tree is actually developed into lumber, and that of this lumber consumed in manufactured wood products from 11 to 60 per cent[2] is wasted, the necessity for conservation is evident.

The essential problem in the cutting of lumber—which differs from the cutting of metal and other materials—is the lack of constancy of the material. Two boards of the same size and supposed quality of lumber may, through the presence of knots, checks, and other defects, have to be utilized in two entirely different manners.

The usual method employed is to send orders for all current products required to the cutting room, where they are got out of the available lumber by a more or less rule-of-thumb, cut-and-try method.

After a number of years' experience in the industry, it is the author's opinion that it is absolutely impossible to utilize lumber economically in this manner; that in spite of the very variable nature of the lumber, the only solution for economical cutting is a carefully devised scientific method. The first step in the development of such a method is the collection of the following data:

1 *Production Budget.* The entire production (manufacturing budget) for a manufacturing period should be carefully estimated. This period should be never less than three months and if it is possible to estimate a year's production fairly well, it is better to make it up for this period.

2 *Parts List.* Analyze this production into a table of all parts required, grouping together all those that are interchangeable.

3 *Parts Dimensions.* Rough-dimension into length, width, and thickness the classification of parts given above.

4 *Cutting Bills.* After careful consultation with and advice from the practical management personnel, make up from this list average cutting bills for kiln loads of lumber so assorted that practically all the various usual lengths and widths may be utilized by each cutting and still satisfy the average flow of orders.

5 *Part-Stock Control.* Establish a careful physical control and perpetual-inventory method over any accumulation of part stock in order that in making up cuttings such stock may not be unduly increased over the requirements shown by the manufacturing budget.

6 *Operational Standardization.* Study and standardize each machine and manual operation in the cutting department, determining definitely the proper method, feeds, speeds, etc., and man-hour production for maximum first-quality production of the manufacturing budget.

7 *Standard Crew.* Considering the previously mentioned standards and the manufacturing budget, establish a normal working crew for the department with stated base rates of pay.

In one plant where this method was applied the original crew numbered 37 and were paid $884.80 weekly as follows:

2 supervisors	$ 59.80
22 operators	558.50
11 helpers	217.50
1 knifeman	30.00
1 sweeper	19.00
37	$884.80

The standard crew of 20 received $505 as follows:

1 foreman	$ 42.50
1 assistant foreman	32.50
1 dispatch clerk	25.00
9 operators at $26 each	234.00
6 helpers at $20 each	120.00
1 knifeman	32.00
1 sweeper	19.00
20	$505.00

8 *Board-Foot-Hours Standard.* Determine the average board footage per operative-hour required by the above-mentioned standard crew to produce the manufacturing budget.

9 *Lumber Assortment.* The general quality and sizes of lumber to be purchased should be studied to be sure that the best material for the product is available. In this connection it should be seen to that the proper thicknesses of lumber are on hand to avoid any wastage through the use of improper sizes, a common cause of waste.

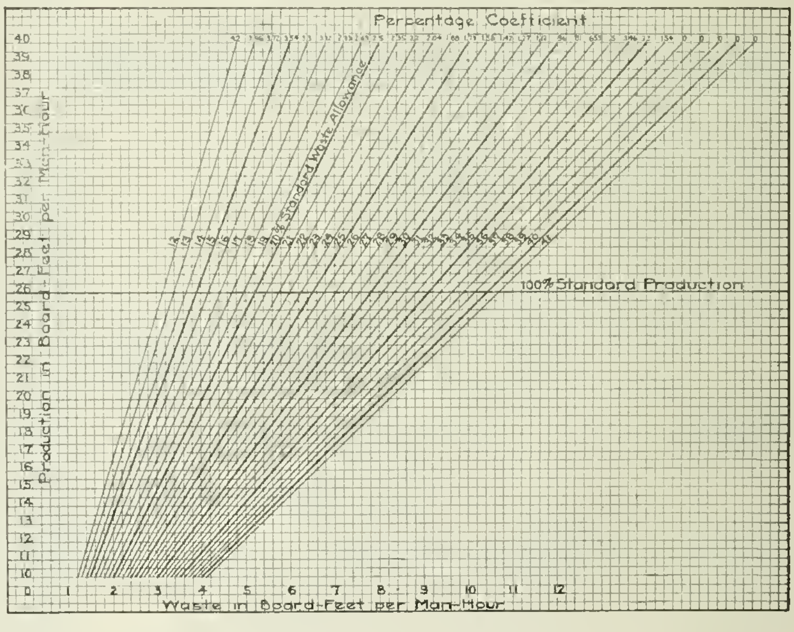

FIG. 1 PRODUCTION-WASTE RATIO CHART

(The percentage coefficient multiplied by the number of board feet produced per man-hour gives the bonus percentage for the hours worked.)

The assortment of No. 1 common, of 1s and 2s, etc., to be purchased must be based upon purely local requirements and should be proved by a series of lengthy test runs of the various grades. Such a classification developed in a certain high-grade cabinet plant was as follows:

Quartered White Oak. 1s and 2s specially selected for light color, all well-figured stock, free from mineral streaks, coarse grain, worm holes, pink flakes and sap. All stock to be well air-dried and the moisture content not to exceed 20 per cent.

Poplar. No. 1 common and selects, free from dark mineral streaks and black stain.

---

[1] Chief Engineer, Cooley & Marvin Co. Mem. Am.Soc.M.E.

[2] This wide variation in wastage depends upon lumber variety and quality, product, and cutting methods.

Contributed by the Forest Products Division for presentation at the Annual Meeting, New York, December 4 to 7, 1922, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS. Slightly Abridged. All papers are subject to revision.

Mahogany. 1s and 2s African, all ribbony-figured stock; end-grain stock not allowed.
Chestnut. No. 1 common and better, sound wormy.
Quartered Red Gum. No. 1 common and selects.
Sap Birch. No. 1 common and selects. On 5/8-in. birch 10 per cent of 1s and 2s and 10 per cent of No. 2 common acceptable where necessary.
Crating Lumber. 1 in. by 4 in. No. 2 common and better short-leaf yellow pine D2S to 11/16-in. square-edge soft-texture stock, random 10- to 16-ft. lengths, air-dried.

10 *Drying.* The kiln equipment and methods of drying should be carefully studied and standardized. Improper drying methods often render any attempts at waste reduction in the factory abortive.

11 *Waste Limits.* By test runs, knowledge based upon experience, and direct calculation, determine fair waste limits for the various cutting schedules, using lumber of the grades selected.

Devising and Installing the Plan

With the data available from the preceding eleven steps, we now have three major requirements:

1 Devise an incentive wage-payment plan
2 Inaugurate proper planning of cutting
3 Install the payment plan.

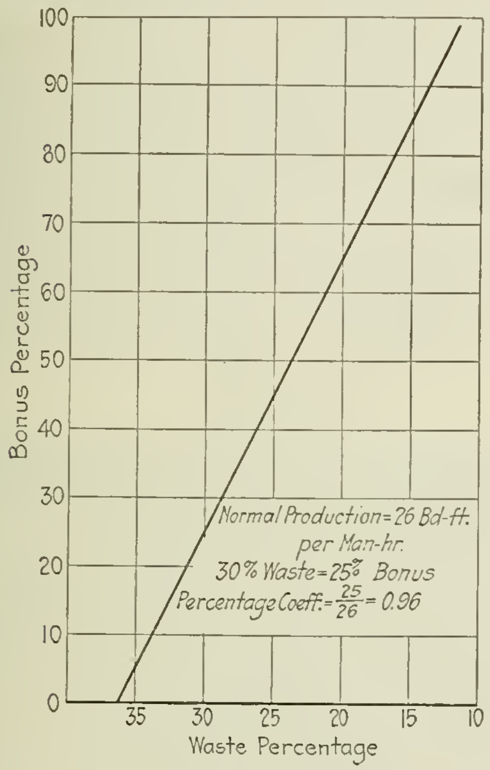

Fig. 2 Graph of Bonus Incentive for Waste Reduction at Point of Normal Production

Devising the Incentive Payment Plan. An incentive wage-payment plan for a cutting department must control both production and waste. The development of such a plan will be illustrated by an example, the plant in which it was applied being one manufacturing a very high grade of stock and special office and library furnishings and equipment.

The range of production per man-hour for the standard crew was determined to be from 11 to 30 ft. B. M., standard at 26 ft. The waste range was from 36 per cent down to 15 per cent, standard at 20 per cent.

The first step is to chart the relations between board-feet-per-hour production and waste, for a range of waste percentages somewhat wider than the standard. Such a chart is shown in Fig. 1. The percentage coefficients at the top of the chart are determined as follows:

A graph of bonus percentages for waste eliminations is plotted as shown in Fig. 2. The percentages of bonus used are determined by experience, and are set to produce the necessary incentive. The standard board footage per hour on Fig. 1 is 26. The waste bonus shown in Fig. 2 applies specifically to this production, therefore the percentage bonus allowed for any percentage of waste divided by 26 gives a coefficient which if multiplied by any board-foot production, gives an excellent differential bonus percentage for both production and waste.

For example: 30 per cent waste on Fig. 1 is allowed 25 per cent bonus; whence $25/26 = 0.96$ = coefficient for 30 per cent waste and the bonus for a production of 30 ft. B. M. hr. $= 30 \times 0.96 = 28.8$ (29) per cent; for a production of 25 ft. B. M. hr. $= 25 \times 0.96 = 24$ per cent, etc.

Fig. 4 is then calculated from the coefficients determined on Fig. 1, and gives the direct bonus percentage for each combination of waste and production within the standard range.

Inauguration of Planning of Cutting. A complete list of active dimension sizes, arranged according to woods, thicknesses, lengths, widths, and net board footage of each block, with adjacent columns showing clear sides and edges required, color requirements and, in the case of quartered oak, quartering-figure requirements, should be used by the planning department, and the superintendent and foreman of the lumber-cutting department in their coördinated efforts to put through economical dimension schedules of each kiln load of lumber ordered in.

The use of the standard cutting lists to make up a dimension-cutting schedule is as follows:

In the layout of the production orders in the planning department

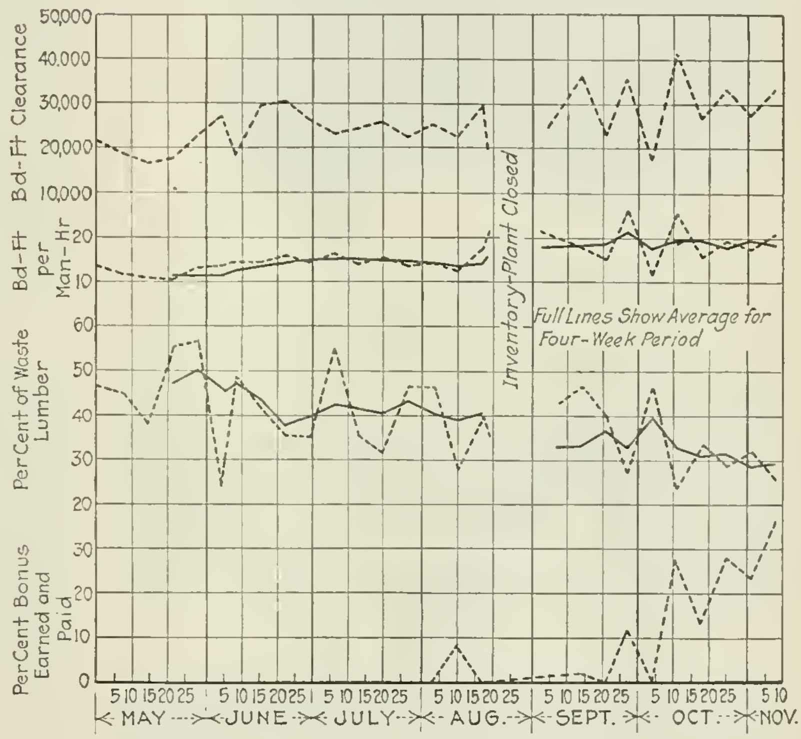

Fig. 3 Six Months' Results of Plan Outlined

they should be made into groups comprising the same or similar dimension stock of sufficient volume to enable the issuance of an advantageous manufacturing order. The head of the planning department should supervise the listing from these orders of quantities of dimension block sizes, to fill the orders and make up a dressed dimension-cutting schedule for at least a week ahead.

Continuous close touch should be maintained by the planning department with the part-stock inventory at all times in order that manufacturing orders and part-stock requisitions may be supplemented and filled out to an advantageous program in making out a dressed dimension-cutting schedule. Additional manufacturing orders should be issued for enough additional board footage of dimension stock in order that there will be balanced economy in the cutting, since some catalog units and their parts usually permit more advantageous dimensioning than others, and it is desirable to equalize the advantage week by week as much as possible for the lowest final average.

Installation of the Wage-Payment Plan. With the proper assortment of carefully dried lumber available and the cutting orders planned for widest possible range of sizes under the order require-

ments, the plan is explained to the personnel of the cutting department. During the investigation, records of intake, clearance and waste should have been installed. For several weeks a trained woodworking engineer should work continuously in the department, instructing and encouraging the workers.

For each pay period the net clearance of product from the department divided by the total number of hours worked by the standard crew gives the board-foot-per-hour production.

Waste Percentage	Production in Board-Feet per Man-Hour

Standard Waste

Standard Production

Fig. 4 Bonus Percentages for Standard Range of Waste and Production

Net intake less net clearance divided by net intake gives the waste percentage.

Fig. 3 shows the results obtained in six months in the plant at which the charts shown in Figs. 1, 2 and 4 were used. These figures were recorded in 1921, therefore over a year has elapsed since the results were obtained. During this past year the standard condition of 26 ft. B. M. per hr. and 20 per cent waste has been bettered several times.

Fig. 4 shows the bonus percentage of standard wages, which, added to the standard wages, gives the total pay.

The Dollars and Cents Results

Suppose—and these are average conditions—that a plant is operating with a clearance of 12 ft. B. M. per man-hour, cutting wages of 50 cents an hour, and 45 per cent waste. The application of the bonus rate shown in Fig. 4 should result in the following saving for each 1,000,000 ft. B. M. of lumber used if the standard waste and standard production are attained:

Labor:
- Original Cost:
  - Hourly wages = \$0.50
  - Hourly production = 12 ft. B. M.
  - \$0.50/12 = \$0.042 per ft. B. M.
- Resulting Cost:
  - Hourly wages = \$0.50 + 65 per cent bonus = \$0.83
  - Hourly production = 26 ft. B. M.
  - \$0.83/26 = \$0.032 per ft. B. M.
- Saving per ft. B. M.:
  - \$0.042 − \$0.032 = \$0.01
- Saving per Million ft. B. M.:
  - 1,000,000 × \$0.01 = \$10,000

Material:
- Original waste = 45 per cent
- Resulting waste = 20 per cent
- Lumber saving = 25 per cent
- Lumber cost 1,000,000 ft. (\$70 per M.) = \$70,000
- 25 per cent of \$70,000 = \$17,500

Total Saving Per Million Ft. B. M.:
- \$10,000 (labor) + \$17,500 (material) = \$27,500

In a plant using 500,000 ft. of lumber a year, the above saving will represent an appreciable reduction in manufacturing cost.

TESTS OF TYPE W STERLING BOILER AT THE CONNORS CREEK POWER HOUSE

(*Continued from page 31*)

$$\text{For floating bank, lb. coal} = 8600 + 105x$$
$$\text{For dead bank, lb. coal} = 8000 + 280x$$

where x = number of hours banked. These equations give a greater amount of coal for a floating bank than for a dead bank for periods of less than four hours; but under actual conditions there is practically no difference between the two kinds of banks for the first portion of a banking period, so the equations are meant to apply only to banking periods in excess of four hours.

General. At the present writing seventeen boilers have been rebaffled according to arrangement "B," modified slightly in the arrangement of the cross-baffle at the top of the front baffle. The vertical baffle has been shortened about six inches and the cross-baffle at the top inclined upward at about 35 deg. from the front baffle. The results being obtained indicate that the superheated-steam temperature has been increased fully 50 deg. fahr. over that obtained with the original baffle, and that there is a decided improvement in the overall efficiency.

A study of the heat absorbed in the different passes of the boiler indicated that a rearrangement of tubes would be beneficial. This possibility was studied by the engineers of the Babcock and Wilcox Company and The Detroit Edison Company, with the result that the new boilers recently installed at the Marysville power house have in cross-section but five tubes between the upper center drum and each mud drum and ten tubes between each mud drum and the upper drum directly above. The boiler is baffled similarly to arrangement "B," except that there are two vertical baffles in each rear bank which direct the gases in three vertical passes after they leave the superheater pass. Economy results are not yet available, but it is believed that a decided decrease in the stack-gas temperatures will be realized.

Discussion

Dr. D. S. Jacobus,[1] said that it gave him great pleasure to discuss the paper, as it brought back recollections of a test that he had made at the Del Ray plant about ten years ago, and of the many courtesies and kindnesses extended to him at that time.

His results, Dr. Jacobus said, were consistent with those obtained by Mr. Thompson. William Kent, in discussing his paper, had pointed out that Dr. Jacobus' tests gave the highest efficiencies at high as well as low rates of driving ever obtained from coal having over 25 per cent of volatile matter, and it was indeed gratifying to note that the results were substantiated and that Mr. Thompson had secured somewhat higher efficiencies than those found in his tests. The efficiencies secured by Mr. Thompson at the lower ratings with the baffles arranged in the same way as in the Del Ray tests were the same as those which Dr. Jacobus had obtained. At the higher ratings Mr. Thompson's results were about 2 per cent higher than his, this difference, as shown by the heat balances, being due mainly to there having been a lesser loss through the carbon in the ashes in Mr. Thompson's tests. When corrected for the differences in the ash pit losses, however, the results agreed within one per cent, which was remarkably close when one considered the error that might be involved in estimating the condition of the fires at the beginning and end of a test with about 15 tons of coal on the grates.

The tests clearly indicated the advantage of changing the baffles. In addition to obtaining higher efficiencies the superheat was increased in the arrangement adopted for use and as a higher superheat could be made good use of, this was also an advantage.

He had visited the plant when Mr. Thompson's tests were in progress and could certify to the fact that they had been conducted in a most exact and scientific way. He had held up these tests on several occasions as an example of the sort of industrial research that should be encouraged by Engineering Foundation and the National Research Council, as they were a direct benefit in the problem of the conservation of fuel and to the engineer at large.

The Torsional Strength of Bars

By CONSTANTIN WEBER

Mathematical treatment of the torsional strength of bars, giving a general solution of the problem together with precise solutions for certain cases and approximate solution for others. The article was briefly summarized in the November, 1922, issue of Mechanical Engineering, but so many inquiries as to details have been received that it has been decided to publish a more complete abstract.

In the middle of the 19th century Saint-Venant developed a general differential equation for the torsion of bars; he also found exact solutions for a limited number of cross-sections. In practice, however, bars are encountered of cross-sections vastly different from those treated by Saint-Venant. Foeppl gave exact solutions for a certain number of these, in particular for thin-walled rolled shapes composed of long rectangles, but there are still a number of sections of considerable interest from a practical point of view which remain unsolved. The present article is an abstract of a research monograph (Forschungsarbeit Heft 249) published by the German Society of Engineers. It comprises fundamental equations for the torsional strength of bars, the more important exact and approximate solutions for various shapes, the influence of normal stresses in the axial direction at considerable twists, and the curvature of certain cross-sections. Among other things, several errors in engineering handbooks are pointed out.

General Solution

If a couple acts on a prismatic bar made of a material which is isotropic and behaves in accordance with Hooke's law, and if this couple acts at right angles to the axis of the bar, the bar becomes subject to torsion, the moment of torsion being, say, M cm-kg. Let now axes of reference x, y and z be passed through the body as shown in Fig. 1, so that the z-axis coincides with the axis of torsion.

The longitudinal fibers lying in the z-axis remains straight, while all the other fibers assume helical shapes about this axis. There are therefore shear stresses τ in the cross-sections of the bar which may be resolved into shear stresses τ_{xz} in the y-direction and τ_{yz} in the x-direction. Simultaneously, however, these shear stresses appear in the z-direction in longitudinal sections parallel to the y-z or x-y planes. The condition that all the forces acting on a particle in the z-direction should be in equilibrium gives—

$$\frac{\partial \tau_{xz}}{\partial x} + \frac{\partial \tau_{yz}}{\partial y} = 0 \qquad [1]$$

This equation is satisfied through—

$$\tau_{xz} = \frac{\partial f}{\partial y}, \quad \tau_{yz} = -\frac{\partial f}{\partial x} \qquad [2]$$

in which $\frac{\partial f}{\partial x}$ and $\frac{\partial f}{\partial y}$ are partial derivatives of a function—

$$f\,(x,y) = K \qquad [3]$$

For each value of K a closed line is obtained on the cross-section and the resultant shear stress coincides at every point with a tangent to this line (Fig. 2). Equation [3] is therefore the equation of the family of lines of shear.

Two contiguous lines of stress corresponding to the values of K and $K + dK$ delimit the closed strip of variable width dn which corresponds in the body to a tubular lamination (Figs. 3 and 4).

Since there are no forces acting on the walls of this tubular lamination it may be separated from the rest of the body. Referring to Fig. 4, the area ABB_1A_1 of this tubular lamination (of length unity) is acted on by a constant longitudinal shear force—

$$dK = \tau dn \qquad [4]$$

If we integrate the force dK we shall obtain for the inner shear line the value K_i and for the outer limit line the value K_a. The entire longitudinal shear force acting in this cross-section is then $K_a - K_i$.

The cross-sections of the bar originally plane become curved. The points on any line parallel to the x-axis are displaced in the z-direction. At the point xy the curved line forms with the original position of the line the angle—

$$\gamma_x = -\delta y + \frac{\tau_{xz}}{G} \qquad [5]$$

where G is the modulus of rigidity and δ the angle of torsion in a given length. Correspondingly the equation holds good for points lying on the lines originally parallel to the y-axis:

$$\gamma_y = \delta x + \frac{\tau_{yz}}{G} \qquad [5a]$$

In order that the internal arrangement of all the molecules consti-

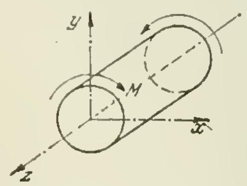

Fig. 1 Axes of Reference in a Bar under Torsion

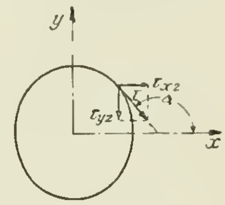

Fig. 2 Line of Shear

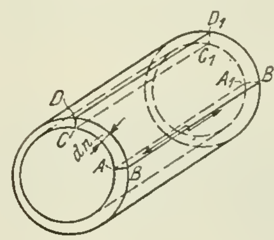

Fig. 3

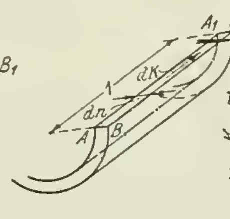

Fig. 4

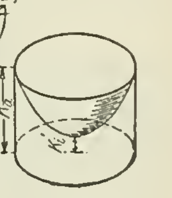

Fig. 5

Figs. 3 and 4 Longitudinal Shear in a Tubular Lamination
Fig. 5 Graphic Representation of the Moment of Torsion in a Bar

tuting the body remain unchanged, the following equation must hold good:

$$\frac{\partial \gamma_x}{\partial y} = \frac{\partial \gamma_y}{\partial x}$$

From this may be derived the equation of internal structure, namely,

$$\frac{\partial \tau_{xz}}{\partial y} - \frac{\partial \tau_{yz}}{\partial x} = 2G\delta \qquad [6]$$

Equations [2] and [6] give the differential equation for the family of lines of shear, or—

$$\frac{\partial^2 f}{\partial x^2} + \frac{\partial^2 f}{\partial y^2} = 2G\delta \qquad [7]$$

For the entire cross-section the equation for the family of lines of shear $f(x,y) = K$ must satisfy the differential equation [7], must always remain within the confines of the given cross-section, and must give the outer limit for the value $K = K_a$. In addition, for the case of a ring-shaped cross-section $f\,(x,y) = K_i$ must give the inside limit line, and the relation—

$$\int \tau dl = 2G\delta F \qquad [8]$$

must be satisfied as applying to the shear line surrounding the hole.

In this equation dt is the longitudinal differential of the corresponding lines of shear and F is the enclosed area. The integral extends over the closed line of shear.

The moment is obtained by integrating $y\tau_x df + x\tau_y df$ over the entire cross-section—

$$M = 2K_a F_a - 2\int\int f dx dy \qquad [9]$$

If over each point of the cross-section be plotted the heights $K = f(x, y)$, the body shown in Fig. 5 will be obtained. The moment is represented by double the volume of the funnel-shaped depression. In the case of ring-shaped cross-sections a truncated funnel is correspondingly obtained, but in both cases the moment may be expressed as follows:

$$M = 2\int_{K_i}^{K_a} F dK \qquad [10]$$

Where F is the area within the line of shear corresponding to the variable K.

The general solution of the differential equation [7] is given in

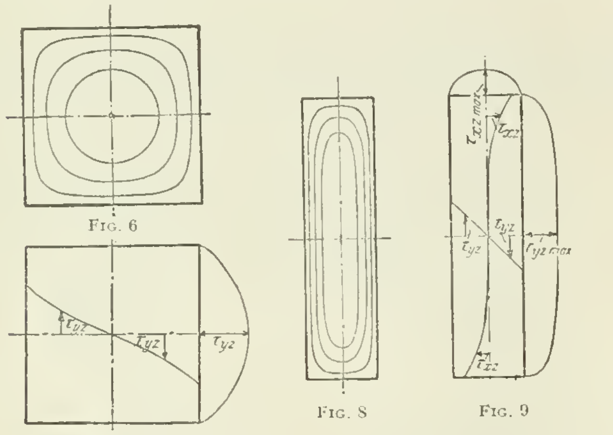

Fig. 6 Fig. 7 Fig. 8 Fig. 9

Figs. 6 and 7 Lines of Shear and Stresses in a Square Cross-Section
Figs. 8 and 9 Lines of Shear and Stresses in a Rectangular Cross-Section

$$f(x,y) = 2G\delta\left(\frac{x^2}{4} + \frac{y^2}{4}\right) + g_1(y + ix) + g_2(y - ix) = K \quad [11]$$

and the functions g_1 and g_2 must be so selected that the imaginary members will disappear. As examples of functions of $g_1(y + ix) + g_2(y - ix)$, the author cites the following:

Rational Algebraic Functions:

$$\tfrac{1}{2}\,[(y + ix) + (y - ix)] = y$$
$$\tfrac{1}{2}\,[(y + ix)^2 + (y - ix)^2] = y^2 - x^2$$
$$\tfrac{1}{2}\,[(y + ix)^3 + (y - ix)^3] = y^3 - 3yx^2$$

Trigonometric Hyperbolic Functions:

$$\begin{aligned}\tfrac{1}{2}[\cos a\,(y + ix) + \cos a\,(y - ix)] &= \cos ay \cosh ax\\ &= \cos ax \cosh ay\\ &= \sin ay \sinh ax\\ &= \sin ax \sinh ay\end{aligned}$$

In Polar Coördinates:

$$g_1(y + ix) + g_2(y - ix) = r^n \cos n\varphi$$

Here n may be any positive or negative number, fractional or integral.

Exact Solutions for Special Cases

Under this head the author discusses the solutions for a circular and elliptical cross-sections, an equilateral-triangle cross-section, and a rectangular cross-section. Only this latter will be presented here.

The author considers the case of a bar of rectangular cross-section of width a and height $h = na$ ($n \geqq 1$). The solution for the family of lines of shear is obtained by the use of a series of trigonometric hyperbolic terms:

$$2G\delta\left(\frac{x^2}{4} + \frac{y^2}{4}\right) + 2G\delta\left(\frac{x^2}{4} - \frac{y^2}{4}\right)$$

$$+ G\delta a^2 \sum_{k=1}^{k=\infty} (-1)^{\frac{k-1}{2}} \frac{\cosh\left(k\dfrac{\pi}{2}\dfrac{y}{{}^1\!/_2 a}\right)\cos\left(k\dfrac{\pi}{2}\dfrac{x}{{}^1\!/_2 a}\right)}{\left(\dfrac{\pi}{2}\right)^3 k^3 \cosh nk\dfrac{\pi}{2}}$$

$$+ c_1 = K$$

$$(k = 1, 3, 5 \ldots)$$

From this the moments and stresses may be calculated. Figs. 6 to 9 show the lines of shear and the distribution of stresses for a square and a rectangle with $n = 4$. The relation between the stresses, the moment and the dimensions of the cross-section may be expressed by means of auxiliary values ψ_1, ψ_2, etc. by the following equations:

$$\tau_{yz\,\max} = \tau_{\max} = \psi_1 G\delta a$$

Here $\tau_{\max}$ occurs at the middle of the long side. In long rectangles with $n>4$ the stress found close to the ends is zero)

$$\tau_{xz\,\max} = \psi_2 G\delta a$$

(This stress occurs at the middle of the short side)

$$M = n\psi_3 G\delta a^4$$

$$M = \frac{\tau_{\max} a^2 h}{\psi_4}$$

$$A = \psi_5 \frac{\tau^2_{\max} V}{G}$$

Here A is the work of deformation and V the volume of the bar. The longitudinal stress measured from the middle of the cross-section of the edge is—

$$K_a = \psi_6 G\delta a^2$$

The values ψ_1 to ψ_6 are presented in Table 1.

TABLE 1 VALUES OF ψ

n =	1	1.5	2	3	4	6	8	10	∞
ψ_1 =	0.6753	0.8476	0.9300	0.9854	0.9970	0.9999	$\sim$1	$\sim$1	1
ψ_2 =	0.6753	0.7279	0.7395	0.7423	0.7423	0.7425	0.7425	0.7425	0.7425
ψ_3 =	0.1404	0.1957	0.2286	0.2633	0.2808	0.2982	0.3070	0.3123	0.3333
ψ_4 =	4.81	4.33	4.07	3.74	3.55	3.35	3.26	3.20	3.00
ψ_5 =	0.1539	0.1362	0.1318	0.1357	0.1412	0.1491	0.1535	0.1562	0.1667
ψ_6 =	0.1472	0.2015	0.2277	0.2454	0.2491	0.2500	0.2500	0.2500	0.2500

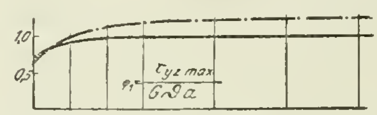

Fig. 10 Comparison of the Values of ψ_1 as Obtained by the Author and as Given in the Hutte Engineerimg Handbook

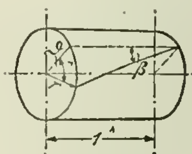

Fig. 11 Torsional Deformation of a Bar

For the most important of these values, namely, ψ_1, ψ_3 and ψ_4, the following approximate equations can be used:

$$\psi'_1 = 1 - \frac{0.65}{1 + n^3} \text{ (error} < 0.8 \text{ per cent)}$$

$$n\psi'_3 = \frac{1}{3}\left((n - 0.630 + \frac{0.052}{n^4}\right) \text{ (error} < 0.5 \text{ per cent)}$$

$$n\psi'_4 = 3 + \frac{1.8}{n} \text{ (maximum error, approximately 4 per cent)}$$

The author plots the values from the above table in a series of curves such as, for example, Fig. 10, and side by side in broken lines plots from the Hütte Handbook (22nd German edition, pp. 569–571) the values commonly accepted. It is of interest to note how far apart the two are. The values for A in the above formula in Hütte (same edition, pp. 597–598) appear to be likewise wrong.

Approximate Solutions

A series of approximate solutions are given covering various ring-shaped cross-sections, strip-like sections and composite sections. In arriving at these solutions the author uses the differential equation [7] for the family of lines of shear and by transforming it into one expressed in polar coördinates he obtains—

$$\frac{d\tau}{ds} + \frac{\tau}{\rho} = 2G\delta \qquad [12]$$

where ρ is the radius of curvature of the line of shear at a given point,

τ the stress, and $d\tau/ds$ the differential of the latter normal to the direction of stress.

Deformation Resulting from Torsion

Axis of Rotation. As a result of torsion longitudinal fibers of the bar assume a helical shape about the axis of rotation. In the case of small torsions such as occur ordinarily, the angle of inclination β of the helices (Fig. 11) to the axis is so small that for a finite length of bar each of these helices does not noticeably differ from a straight line and therefore each fiber may be considered as an axis of rotation.

In the case of greater rates of torsion the angle β of the outer fibers is greater and they can no longer be considered as lying in a straight line. In this case a given longitudinal fiber becomes the axis of twist, and a point in the cross-section of the bar the center of twist. Because of their stretch the outer fibers are subjected to tensile stresses, and if no force is acting on the bar in the longitudinal direction the fibers in the neighborhood of the axis of rotation are under compression. The center of torsion is at the point where no bending moment is produced by the longitudinal stresses. In polysymmetrical sections the center of torsion coincides with the center of the geometric figure, but this is not the case with non-symmetrical or simple symmetrical cross-sections. The normal stresses are expressed by—

$$\sigma_z = \frac{1}{2} E\delta^2 \left(r^2 - \frac{J_p}{F}\right)$$

where J_p is the polar moment of inertia with reference to the center of rotation, F the area of cross-section of the bar, and r the distance from the center of rotation. The stresses σ_z increase as the

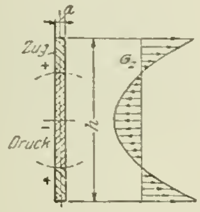

Fig. 12

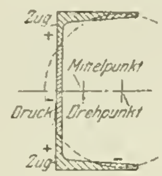

Fig. 13

Figs. 12 and 13 Normal Stresses at Twists of Considerable Magnitude

(*Zug* = tension; *druck* = pressure; *mittelpunkt* = center· *drehpunkt* = center of rotation.)

square of δ, while the stresses τ vary directly as δ. For small values of δ, τ is the most important stress and it is only when δ becomes large that σ_z takes on significance. Figs. 12 and 13 show the distribution of normal stresses in a long rectangular cross-section and in a channel cross-section. In the latter it is clear that the center of rotation does not coincide with the center of gravity. From this it follows that the statement in the Hütte Handbook (22nd German edition, p. 568), namely, "the center of the arc of torsion, i.e., the point on the cross-section which is not subject to displacement by the moment and in which, therefore, the shear stress is equal to zero, is the center of gravity," does not apply to all cases. Neither does the center of rotation always coincide with the center of gravity, nor is the stress τ at the center of rotation or center of gravity equal to zero.

In the center of rectangular sections with large values of the ratio n between the sides, $J_p \sim J_y$ and $p \sim y$. Because of this,

$$\sigma_z = \frac{1}{2} E\delta^2 \left((y^2 - \frac{1}{12} h^2\right);$$

$$\sigma_{z\,\max} = \frac{1}{12} E\delta^2 h^2; \; \sigma_{z\,\min} = -\frac{1}{24} E\delta^2 h^2$$

If $\tau \gtrless 1000$ kg. per sq. cm., $E = 2{,}150\,000$ kg. per sq. cm., and $G = 83{,}000$ kg. per sq. cm., the normal stress ψ_z has to be taken into consideration when $n > 40$ or thereabouts. Through the stress σ_z is transmitted the additional moment of torsion M_z. In the minute area of cross-section df distant r from the center of rotation, the force acting thereon is $\sigma_z df$. As the fiber forms at this point the angle $\beta = \delta r$ with the axis of rotation, we have a partial force $\beta\sigma_z df$ acting on the plane of the cross-section and creating a moment $r\,\beta\sigma_z df$. For the entire section the moment is—

$$M_z = \int r\beta\sigma_z df = \frac{1}{360} E\delta^3 n^5 a^6$$

where n is the ratio of the lengths of the sides of the rectangle and a the width of the rectangle. The moment transmitted by the shear stress and the normal stress is—

$$M_s = \frac{1}{360} E\delta^3 n^5 a^6 + \frac{1}{3} G\delta n a^4$$

The deformation A_z due to the normal stress is for the length of bar l,

$$A_z = \frac{1}{4} M_z \delta l$$

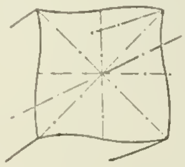

Fig. 14

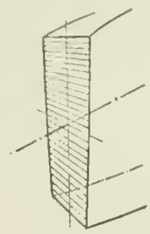

Fig. 15

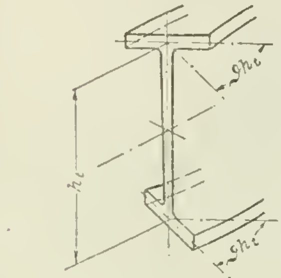

Fig. 16

Figs. 14–16 Curvature of Square, Rectangular, and I-Beam Cross-Sections

while the work of deformation due to the shear stress is determined by the usual formula—

$$A = \frac{1}{2} M_z \delta l$$

Curvature of the Cross-Section

Because of the presence of the moment of torsion the originally plane cross-sections of the bar become curved, only circular and circular ring cross-sections remaining plane. In symmetrical cross-sections the lines of symmetry remain straight. Thus, Figs. 14 and 15 show respectively the curvature of a square and of a long rectangular cross-section. The width lines of this cross-section remain at all points approximately at right angles to the longitudinal fibers of the bar which are here twisted to helices. Fig. 16 shows the curvature of an I-beam cross-section.

Some of the conclusions at which the author arrives are as follows: A homogeneous, elastic prismatic bar is stressed by a couple the plane of which is normal to the axis of the bar. This leads to a twist of two cross-sections of the bar located at a distance of 1 cm. apart through a relative angle δ.

The shear stress τ and the moment of torsion M are functions of and may be expressed by the dimensions of the cross-sections, the modulus of rigidity G and the angle δ in accordance with the formulas given in the November, 1922, issue of Mechanical Engineering on pp. 738–739. The functional relation between $\tau_{\max}$ and M depends on the distance for which δ is measured.

The original article gives a table containing expressions for the moment of torsion and stresses in bars of various cross-sections—twenty in all. This table was published in the November, 1922, issue of Mechanical Engineering, pp. 738–739, and is therefore not reprinted here.

Attention is here called to the fact that a correction should be made in this table: namely, the last formula in the column "Moments for Cross-Sections," No. 16, should read—

$$l_{t2} = l_2 - 1.67 s_f + 1.76 s_s.$$

(*Zeitschrift des Vereines deutscher Ingenieure*, vol. 66, nos. 31–32, Aug. 31, 1922, pp. 764–769, 35 figs. and an illustrated table, *tpA*)

Short Abstracts of the Month

AIR MACHINERY

Some Elements in Air Compression, W. Carter. A paper chiefly of a practical character discussing the essentials of construction of the air compressor and method of using it. Only a few features will be referred to here.

In discussing the various methods of drive, in particular, belt drive on close centers, the author calls attention to a recent development, namely, an arrangement involving the use of a floating idler pulley and a very slack belt. The weight of the idler takes up the slack of the belt and increases the arc of contact on the driving and driven pulleys so that the full power is transmitted without any undue strain on the bearings or on the belt itself.

A very modern development is the direct-connected electric-driven air compressor with the rotor of a synchronous motor mounted directed on the compressor shaft. This construction is not applicable to smaller units than about 700-cu-ft., 100-lb.-pressure compressors, because the cost for direct connected synchronous motors of smal' power becomes excessive. On moderate- and large-sized machines, however, this design affords the very highest possible economy. Recent improvements in air-valve movements and in air-cylinder design which permit much higher piston speeds than ever before were considered practical, have contributed to the success of the direct-connected compressor unit of this design. Unless the valve and port areas are very large, the compression efficiency is so greatly reduced at the customary speeds as to offset the advantages of compactness. The choice of a direct-connected motor-driven air compressor should therefore be determined by an investigation as to whether the compressor had been specially designed for this method of drive. (*Canadian Railway Club*, vol. 21, no. 7, Oct., 1922, pp. 19–39, *p*)

Multi-Stage Fan-Type Blower. Description of blowers of a new type made by the Syracuse Industrial Gas Co., Syracuse, N. Y. As shown in Fig. 1, the blower is essentially composed of three machines all located within the same casing. The air or

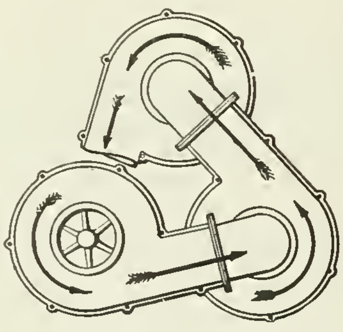

Fig. 1 Multi-Stage Fan-Type High-Pressure Blower

gas passes from fan to fan, each fan boosting the pressure in the same way as if it were a single-stage machine. The machines now built give pressures up to 2 lb. in small units. (*Forging and Heat Treating*, vol. 8, no. 10, Oct., 1922, pp. 484–485, 2 figs., *d*)

ENGINEERING MATERIALS (See also Special Processes)

The Influence of Phosphorus on Brass, A. Portevin. Tests were made on two series of brasses with an increasing proportion of phosphorus added in the form of phosphor copper containing 10 per cent of that element. The first series averaged 68 per cent copper and the second 58 per cent. Tests were made from both series cast in sand and in chills, the latter in the form of round brass $1^3/_4$ in. in diameter.

From these tests it was found that the mechanical properties are not sensibly affected as long as the phosphorus content remains below 0.05 per cent. When the proportion of phosphorus exceeds 0.5 per cent, a rapid fall in ductility and elongation takes place. (From the two tables given in the article it would appear that for some reason or other the phosphorus content was varied by big jumps. Thus, in one series of sand-cast tests the phosphorus content varied from nothing to 0.077 and in the next series from 0.51 to 1.47, there being nothing to indicate the behavior of the metal within the wide range of variation between 0.077 and 0.51.)

Among other things these tests have clearly demonstrated the danger of considering mechanical tests from the point of view of a few figures or a few properties only. As the phosphorus content is increased the metal becomes brittle, and the great decrease in ductility shows how unreliable are the ultimate tensile strength and the apparent elastic limit when considered alone. The tests have also shown the great differences resulting from the rate of cooling, and how useless it is to consider the results furnished by test prices that have been cast separately as indicating the quality of a casting. (Paper presented to the Nancy Congress of the Association Technique de Fonderie, abstracted through the *Foundry Trade Journal*, vol. 26, no. 323, Oct. 26, 1922, p. 344, *e*)

FORGING

Power-Plant Cost of Operating Hammers, R. E. Waldron. The variations in steam consumption for a given size of hammer depend entirely upon the condition of the hammer relative to its state of repair and valve adjustment. Another very important item is the condition of the cylinder and piston rings. The main valve may be set in such a way that the hammer will operate satisfactorily as a tool, but not economically from the point of view of steam consumption.

The author gives four curves to show steam consumption per hour for hammers from 1000 to 8000 lb., the data being taken from various tests. The results vary considerably depending upon the condition of the hammers, which makes it impossible to state what the actual consumption of any particular size of hammer is.

The author indicates a way for obtaining a basis for the comparison of steam costs for hammers.

One feature of importance has been brought out by analyzing the test results for the four hammers and, that is, that it is more expensive per 100 lb. of falling weight to operate small steam hammers than large ones.

Furthermore, steam consumption, or rather steam costs on a hammer, is greatly affected by conditions of operation, and is much less in shops working 24 hr. per day than in single-shift shops. (*Forging and Heat Treating*, vol. 8, no. 10, Oct., 1922, pp. 474–476, 7 figs., *t*)

FOUNDRY

Magnesium Castings, Carl Irresberger. A general discussion of magnesium and its alloys, together with practical data on casting articles from these metals and on the physical properties of magnesium castings.

Iron crucibles with gastight iron covers are recommended for melting magnesium and electron metal, these metals, unlike aluminum, having no tendency to attack iron. On the other hand, magnesium and its alloys even at comparatively low temperatures become plastic and from that point on manifest an increasing tendency to absorb gases of all kinds, which makes a reliable gastight cover on the crucible a basic condition of success in melting. Graphite crucibles should not be used, as magnesium absorbs from them considerable amounts of silicon.

Molds for magnesium castings may be made in sand, but satisfactory results have also beeen obtained with permanent iron molds. In order to avoid the danger of explosions, the molds should be thoroughly dried, say, at a temperature of 450 deg. cent. (842 deg. fahr.), at which temperature the chemically combined water in the clayey parts of the sand is driven out. Plenty of risers of generous proportions should be provided.

Extreme care should be taken not to leave any moisture in the mold. At high temperatures magnesium forms with water or water vapor white magnesium oxide and hydrogen, and the latter, together with air, forms a highly explosive mixture which is easily ignited by contact with the hot metal.

The article discusses magnesium foundry methods in considerable detail. It would appear that magnesium castings may show various colors on the outside, which depend apparently on the temperature of pouring and the degree of dryness of the mold. If the metal was poured at a correct, not excessively high, temperature in perfectly dry molds, the exterior skin of the casting should be of a silvery color. If poured at an excessively high temperature it will be of a bluish iridescent color, probably because of absorption of some silicon from the sand. If the temperature of pouring was right and the mold was not perfectly dry, a dirty grayish color will be shown, but in any event a brilliant silvery white may be imparted to the casting by pickling it in nitric acid of density 180 deg. Baumé, free from chlorine.

For castings magnesium is chiefly used in the form of electron metal which contains from 90 to 99 per cent of magnesium and from 10 to 1 per cent of a metal such as aluminum, zinc, magnesium or cadmium. They machine much better than aluminum and are used in particular where lightness of the part is a material consideration. Magnesium alloys have been used for perforated plates in textile machinery where the plate has to carry thousands of fine holes and where the slightest imperfection in the casting would make the product worthless. They proved to be perfectly satisfactory for this purpose. Magnesium alloys have been also used for spindles, one advantage being that owing to their lower weight as compared with iron they can be brought to speed in one third the time required for the latter. GAS PRODUCERS

The Treat Gas Producer. Description of a mechanical gas producer invented by F. H. Treat. The chief distinctive features of this producer consist in a number of devices and power-actuated mechanisms which perform automatically various functions in relation to the fuel bed. Thus, a mechanism is provided for agitating the fuel bed and for feeding and distributing the fuel in the producer chamber. The machine to do this is located in the central circular opening of the producer top and is arranged to revolve bodily at a slow rate in a horizontal direction. The action for feeding and distributing the fuel and the agitation of the fuel bed functions in unison with the rotary movement.

The machine has a number of agitator bars extending vertically within the producer chamber so that the pair of agitator fingers of the lower ends penetrate the fuel bed. By turning adjusting screws the agitator bars may be raised and lowered at the will of the attendant. Fuel-feeding devices are provided. The blast is supplied through eight independently controlled steam-jet blowers of special design which are disposed uniformly around the outside of the producer. To each blower is connected an independent tuyere pipe which is arranged to extend through the tapering lower portion of the producer body and into the ash zone. The ashes are discharged through a water seal over the edge of the ashpan and a scraper device is employed which is designed to act against the interior surface of the ashpan.

The original article describes the various mechanisms in detail and illustrates some of them. No data of tests or performances in practice are given. (*Iron Trade Review*, vol. 71, no. 20, Nov. 16, 1922, pp. 1351–1354, 3 figs., *d*)

MARINE ENGINEERING

Wind-Propeller Drive for Boats

Driving a Boat against the Wind by an Air Motor. Description of the experiments of Constantin Joessel and Daloz on driving a 6-ton fishing vessel by wind force in any direction, i.e., with or against the wind. It is obvious that this could not be done by means of sails in which the pressure is always normal to the sail and a motor of the windmill type had to be used. In this motor, which is of the variable-propeller type, it is necessary on one hand to consider the pressure exerted by the wind on the system in motion, and on the other the energy of rotation obtained on the axis by the movement of the blades, this energy being transmissible to a suitable propeller. The water propeller like the air propeller gives an axial thrust which is a function of the energy of rotation that it receives. In order, therefore, to drive a boat it becomes necessary to create conditions under which the axial thrust of the water propeller will be greater than the component along the axis of the ship of the axial thrust due to the movement of the air propeller. If the axial thrust of the water screw be greater than the total axial thrust of the air propeller, the boat will be able to move against the wind.

Calculations and tests made on a small apparatus with fans as the source of the wind have shown that the problem was capable of solution provided the screws have suitable dimensions and are connected in such a manner as to produce a suitable speed ratio.

As a first step it was necessary to determine the number of blades in the air propeller that would give the best efficiency. Numerous tests have shown that the two-blade propeller is the best.

In the installation on the *LeBois-Rosé*, a fishing vessel of 6 tons capacity, the air propeller is 9 meters in diameter and the blades are made of laminated wood. The water propeller, is of the 4-blade type, made of bronze, and 1.05 meters in diameter. Both the air and water propellers are of variable pitch. In order to save expense in installation there is no speed-gear change between the air and water propeller, such as was used in preliminary tests. This lowers the efficiency of the boat, but it is still perfectly able to run into the wind or across it.

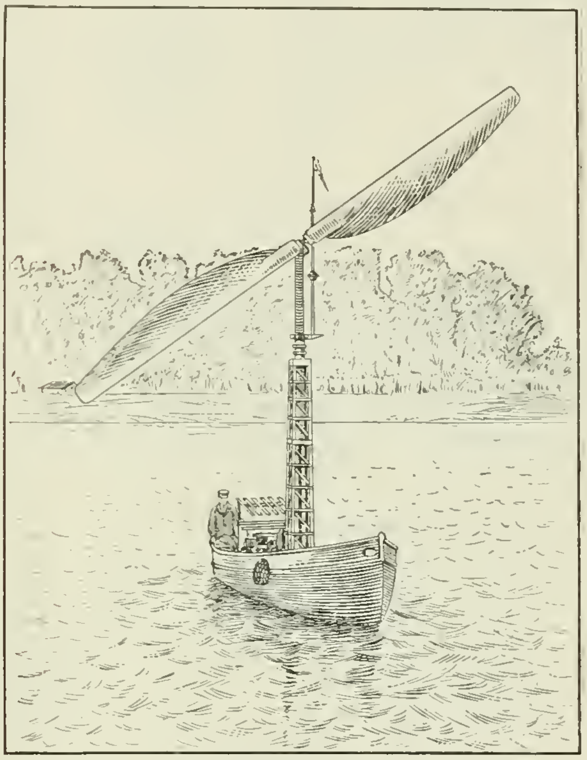

Fig. 2 Air-Screw-Propelled Vessel Capable of Breasting the Wind

The shifting of the air propeller, which must always be in a position normal to the wind, is effected by means of a worm gear which the pilot can operate simultaneously with the steering gear. It would be possible, however, to make the air propeller take its position automatically. In the experimental vessel serious difficulties arose due to the fact that the weight of the superstructure proved to be quite great and that the reaction of the wind on the propeller located at the top of the tower serving as a mast gave rise to a couple of considerable magnitude. It is claimed, however, that with suitable devices provided to take care of this situation, the boat has proved to be highly maneuverable, and with one man on board has been able to navigate successfully a crowded part of the River Seine between Sèvres and Saint-Cloud. The general appearance of the boat may be judged from Fig. 2. No data of the actual speeds attained with the various wind velocities are given. (Paper before the French Academy of Sciences, read Oct. 23. Abstracted through *Le Génie Civil*, vol. 81, no. 19, Nov. 16, 1922, pp. 421–422, 1 fig., *dA*)

MACHINE DESIGN AND PARTS

Gear Noises and Their Causes—Apparatus for Detecting Errors in Gears

Some Causes of Gear-Tooth Errors and Their Detection, K. L. Herrmann. The author analyzes the different gear noises and their causes and comes to the conclusion that production variables have a much greater influence on gear sounds than the changing pressure angles used or tooth-form detail.

The first of the gear noises discussed by the writer is a knock that

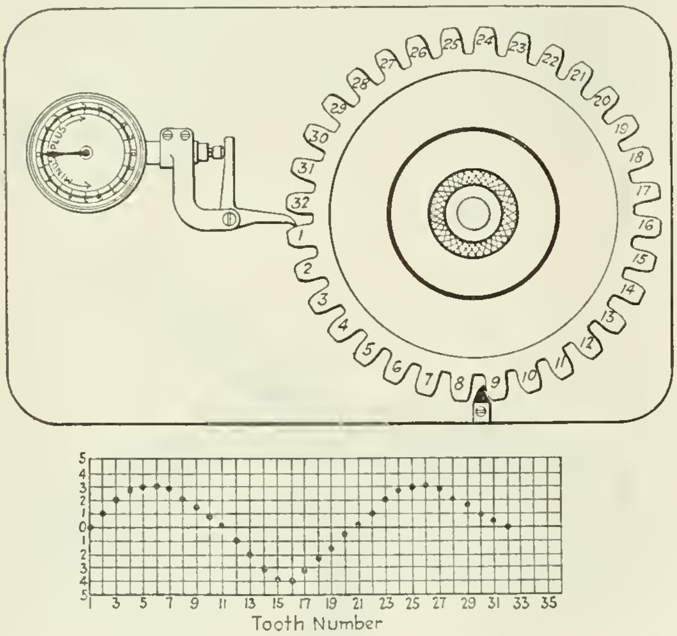

Fig. 3 Device Used for Checking Tooth Spacing and (Underneath) a Chart Showing the Results Obtained

in. from tooth to tooth. With eight successive teeth each gaining 0.001 in. on the side of the gear and a similar number of teeth that may be loosing 0.001 in., a total error of 0.016 in. might be imparted to the driven gear.

Fig. 3 illustrates a very simple device that has been used for checking tooth spacing. The gears are mounted on a bushing and one tooth comes against a stop. A dial indicator is arranged so as to be in contact with some tooth one-fourth, one-third, or one-half way around the gear. When the dial indicator is set at zero, with the tooth against the top at any one point, the distances between the two points can be measured and, if the gear be correct for indexing, placing any of the two teeth in the gear in similar positions should not cause the dial indicator to vary, especially if the gear runs true.

When the gear is first put on the indicating apparatus, the dial indicator is set at zero. A mark is then put at zero on the chart in Fig. 3. for tooth No. 1. The next step is to index the gear around to one tooth. Any reading obtained is marked above the tooth in vertical line. The gear is next indexed around to tooth No. 3 and the dial indicator reading is marked opposite the number of thousandths of an inch that it may show. The gear is then indexed to teeth Nos. 5, 6, etc., until all the teeth on the gear have been indexed.

For the purpose of record, we now have a chart showing the accumulated variables. It will be seen from Fig. 3 that at no point is the spacing variable as great as 0.001 in. between any two teeth, but it can be in error a total of 0.008 in. or more when the error between the several teeth has accumulated. A better visual demonstration of this condition occurring in gears is made by means of a gear-tooth-form projector. When a gear-tooth form is projected upon a screen by this device, it will be noted that the magnification of the shadow is 100 to 1, and that for every inch on the screen there is at least a 0.001-in. error somewhere in the gear. The shadow on the screen also shows the variation in uniform movement of the driven gear due to an error of this kind; that is, the driven gear, instead of having its tooth in the position of the outline on the screen, has been forced to advance a number of thousandths of an inch. It will be noticed, further, that this advance and retardation

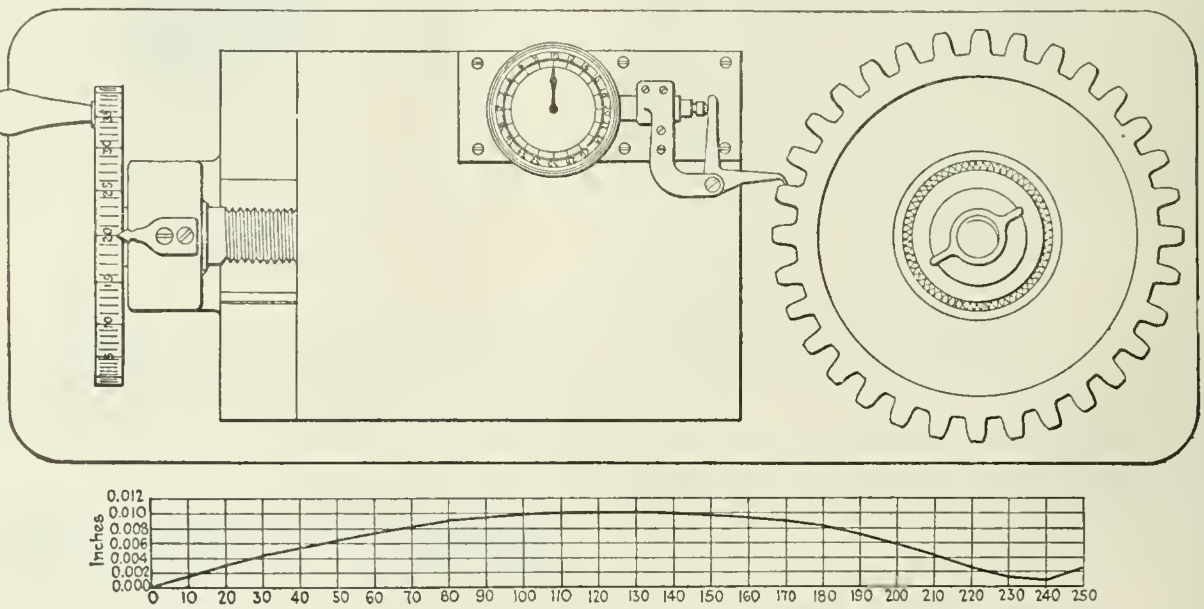

Fig. 4 Instrument for Obtaining an Analysis of Tooth-Forms Producing Noise and a Chart Showing the Outline of a Particular Tooth

might be caused by a nicked tooth or a single tooth of a pair of running gears that are in mesh. The same result may be produced by inaccurate conditions in the gears. For example, should the tooth spacing in a transmission drive pinion be such that the driven gear instead of rotating at a uniform speed is forced to increase or decrease its speed at every revolution of the pinion, there will be a noise. To avoid this it is not sufficient to check gears for spacing error from tooth to tooth. It is very desirable to check the accumulated error of a number of teeth because a gear may vary 0.001 does not occur uniformly; that is, the advance may be confined to a very small number of teeth, remain there for a certain length of time, and then be retarded slowly. A gear in this condition will give a rattle very similar to that which might be produced by unequal spacing. This condition can be studied best by charting it as described.

In addition to the two gears having a rather irregular action between themselves, their increasing and decreasing movement is carried on to the countershaft and the idler which often have similar

defects in themselves. Accumulating errors in gears often cause the fourth gear in a train to be as much as 0.025 in. away from its correct position. The countershaft then does not rotate smoothly and the gear at the other end of the countershaft in addition to the variable movement given it by the errors in the first two gears imparts its error to the gear meshing with it.

Fig. 4 shows an instrument developed by the author for the purpose of analyzing tooth forms producing the various sounds. It consists of a dial indicator mounted on a guided slide. The gear is placed in a definite position with respect to the indicator, when the operator starts at the point of the tooth and sets the indicator at zero. The slide is then moved toward the gear 0.010 in. and the indicator reading marked on the chart shown in the lower portion of Fig. 4. The slide is then moved 0.010 in. more, the reading is marked again, and this is continued until the bottom of the tooth is reached. By taking the gear that has just been charted off the bushing and placing another gear in its place, other tooth forms will be compared with the first.

The causes of the errors in gears referred to are various, some of them occurring in hardening, some of the cutting machines, and some in the cutters. To show this the author discusses the case of the hobbing machine and its possibilities for error, and also gives charts showing the conditions of the gear before and after hardening. From this it would appear that at times the hardening errors compensate for the cutting errors, while at other times the hardening errors cumulatively add themselves to the cutting errors. (*Journal of the Society of Automotive Engineers*, vol. 11, no. 5, Nov., 1922, pp. 391–397, 14 figs., *eA*. Abstract in *Automotive Industries*, vol. 47, no. 18, Nov. 2, 1922, pp. 869–873, 14 figs.)

MACHINE DESIGN

Epicyclic Gears and Gear-Ratio Diagram

Epicyclic Gears: the Gear-Ratio Diagram, P. Cormack. A diagram intended to be used for computing speed ratios of an epicyclic gear set. It is said that this diagram gives complete generality to the solution of problems on wheel trains and shows the properties of trains when used epicyclically. The diagram may also be applied to rotational accelerations.

Fig. 5 Cormack Gear-Ratio Diagram

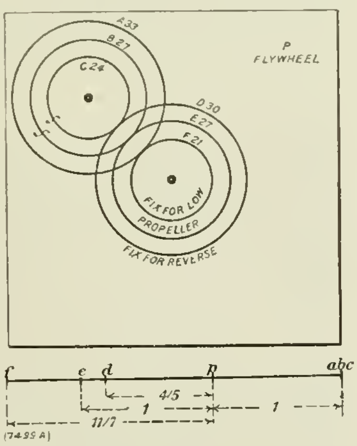

Fig. 6 Ford Epicyclic Gear and Gear-Ratio Diagram

Gear-Ratio Diagram. If the segments $p\,a$, $p\,b$, $p\,c$, $\ldots$, $p\,q$ of a line, Fig. 5, be proportional to the speeds of the wheels A, B, C, $\ldots$, Q, of a wheel train when P is fixed, then the segments $q\,a$, $q\,b$, $q\,c$, $\ldots$, $q\,p$, are proportional to the speeds of the wheels A, B, C, $\ldots$, P, when Q is fixed. A formal proof of this proposition may be obtained by considering the fixing of Q as being due to the imparting to the whole train of a motion equal and opposite to that possessed by Q. Thus, let a rotation $q\,p$ be added to the rotation $p\,a$, $p\,b$, $p\,c$, $\ldots$, $p\,q$, of $A, B, C, \ldots Q$, and P. The resultants are:

$$\begin{aligned}
\text{Rotation of } A &= q\,p + p\,a = q\,a \\
\text{Rotation of } B &= p\,q + p\,b = q\,b \\
\text{Rotation of } C &= q\,p + p\,c = q\,c \\
\text{Rotation of } Q &= q\,p + p\,q = 0 \\
\text{Rotation of } P &= q\,p + 0 = q\,p
\end{aligned}$$

Hence the proof.

Application to Epicyclic Gear Set. As an example the author shows how the gear ratios of the Ford motor-car transmission gear are exhibited by the diagram. This gear is shown in Fig. 6. The engine flywheel P carries the axle of the planet group $A\,B\,C$. B meshes with E, the propeller shaft; A meshes with F, which is fixed for the slow speed; and C meshes with D, which is fixed for the reverse. Taking P to be fixed, if A make one turn, so will B and C, since they are keyed to A. One turn of A gives $-33/21$ turns of F; one turn of B gives -1 turn of E; one turn of C gives $-24/30$ turns of D. To construct the gear-ratio diagram, therefore, draw $p\,a = p\,b = p\,c = 1$; $p\,f = -33/21$ or $-11/7$; $p\,e = -1$; $p\,d = -24/30$ or $-4/5$. We can now read off the low-gear ratio of the propeller E to the flywheel P, when F is fixed. It is $f\,e/f\,p$. Since $f\,e = 11/7 - 1 = 4/7$, and $f\,p = 11/7$, the low-gear ratio $f\,e/f\,p$ becomes 4/11.

With D fixed, as it is for the reverse gear, we have the speeds of the flywheel P and the propeller shaft E proportional to $d\,p$ and $d\,e$. The lines $d\,e$ and $d\,p$ being in opposite directions show that E and P revolve in opposite senses. Numerically $d\,e = 1 - 4/5$ or $1/5$, while $d\,p = 4/5$. The reverse gear ratio $d\,e/d\,p$ is therefore 1/4.

Angular Acceleration. Corresponding to the proposition of the second paragraph of this abstract for rotational velocities, we have the analogous proposition for rotational accelerations, a statement and proof of which is given in the second paragraph, if "angular acceleration" be written for the words "speed," "rotation," and "motion" occurring therein. (*Engineering*, vol. 114, no. 2965, Oct. 27, 1922, p. 511, *tp*)

MACHINE SHOP (See also Machine Design and Parts; Measuring and Testing)

Processing Spline Shafts by a New Method, James A. Ford. In this method a die is constructed according to the same principles that apply to the automatic threading dies now in general usage, the cutters being in the position that the die chasers ordinarily would occupy. The cam ring is practically of the same construction as that used on a threading die, except that the ring is made stronger. This opening feature is necessary on account of having to pass the shaft back through the die, because the body of the shaft beyond the splines is larger than the body portion between the splines, and the shaft will not pass completely through the die.

The shaft is entered into a bushing that is lined up with the die. Then the shaft is pressed through the die to a stop that has been set at a sufficient distance to permit the shaft to pass through to the shaft neck at the end of the splines. The cutters in the die are then released and the shaft is removed.

During the experiments with this die it was ascertained that a clearance angle on the cutter of 30 min. was about correct, and it was decided that one pass of the shaft through the die gave the most satisfactory result.

It is stated also that a method has been found to straighten the shafts to within 0.005 in. per ft. of being out of parallel with the true axis of the shaft. It is not stated how this was done. (*Journal of the Society of Automotive Engineers*, vol. 11, no. 5, Nov., 1922, pp. 433–434, 4 figs., *d*)

Manufacturing Distance Pieces. Description of machining processes and equipment. The piece is produced in four operations. First, the tube is cut to length in a press, next both ends are surface-ground in a surface grinder, then the hole is pierced in a press, and lastly the bore is ground in an internal grinder.

As to the first operation, namely, cutting the tube to length, the difficulty of preventing distortion under the shearing action must be overcome. This was accomplished by a device described in the original article in which the tubular stock is sheared.

The grinding of the ends of the tube, which is the second operation, is carried out in a surface grinder on a magnetic chuck. For the third operation a simple semi-automatic fixture described and illustrated in the original article is used.

Grinding the bore is the final operation, and in view of the fact that the internal dimensions are held to close limits, grinding is essential as it rectifies a slight distortion which may have taken place during the punching of the hole, and in addition removes burrs. This operation must be carried out carefully, as precaution must be taken to avoid the use of clamping devices that would cause distortion. For this purpose a special fixture has been designed, which is described and illustrated in the original article. (In this connection it may be noted that the fixture for internal

grinding is referred to as Fig. 4 in the text of the original article. It is really Fig. 3.) (*Engineering Production*, vol. 5, no. 109, Nov. 2, 1922, pp. 411–413, 3 figs., *d*)

MEASURING AND TESTING

Sound-Testing Devices—Testing Machinery by Sound

Detection, Location and Comparison of Sound, C. E. Noël-Storr. For a long time there has been an effort to build testing devices that would make it possible to determine and, in particular, locate irregularities in operation of machinery by the sound emitted.

The author developed his initial apparatus in order to locate mechanical defects in a series of very large engines which did not run quite right. To do this he devised an instrument with two ear pieces and flexible connections to the reproducer. While the device was crude and far from efficient, the difficulty in the engines was traced with very little trouble and with perfect comfort. Later on another problem arose in connection with small gear boxes which contained a double-reduction spur gear mounted on ball bearings. Some of these boxes failed to pass inspection on the ground of excessive noise. A difficulty also arose on account of the irregularity of the rejections, since batches considered noisy by the test room would perfectly pass, while nominally silent batches failed to do so, due, of course, to the entire lack of any definite standard of reference for either the inspector or the works staff. It therefore became desirable to find a way of measuring the sound of the boxes.

The construction of instruments for the detection and location of sound is complicated by the fact that in connection with mechanical work there are two distinct purposes for which such instruments may be applied, namely, the detection of internal or mechanical sound and external or atmospheric sound. For example, in examination of the running condition of the balls in a journal bearing the internal sound only is of interest and not any external noise the bearing may make. On the other hand, in many forms of construction it is desired to reduce the external noise to a minimum and it is quite possible that a test of the internal sound may lead in such cases to a totally incorrect conclusion.

To deal with the two different aspects of the matter there are two different types of reproducer. In the first place, there is the tectoscope, which is arranged with a test rod and reproduces only the internal sound of the bar with which the rod is in contact. The tectophone, on the other hand, is arranged with a conical mouth and reproduces the external sound when the mouthpiece is held close to any object.

It will be noted at once that one instrument serves to check the results obtained with the other. For example, the contact breaker of a magneto will show a considerable blow from the rocker arm when tested with the tectoscope, but except on a few very silent engines the blow will not be heard externally when tested with the tectophone. In other words, the first instrument will indicate that there is a distinct mechanical blow taking place, and the second test will show that in the matter of improving the general silence of operation this blow is of small moment.

The foregoing example serves to show that the clear reproduction of even minute internal noises should enable worn or faulty parts to be located quite easily, while it also brings forward the use of the second type of instrument for checking the amount of external noise arising from a given internal source. Thus parts which may give rise to external noises may be traced, although it is more than likely that in some cases the internal cause is of small magnitude.

There are other general applications of the tectophone; for example, there may be two universal joints on a common shaft, and either or both may be dry and noisy. In some cases of this nature the tectoscope applied to the nearest bearing on the shaft might fail to give a clear indication on account of the noise of the bearing, but if the tectophone is held quite close to each joint in turn the squeak can be instantly located. The above instance applies to many similar problems and includes the tracing of gas, compressed air, and similar leaks from pipes and plant in general, the flow of a liquid in the pipe being indicated quite distinctly by the tectoscope.

The author gives descriptions of ways to proceed in testing the operation of various parts of an automobile engine, selected here as an example, by means of his apparatus. Sounds picked up by this apparatus may be compared either with each other or with a standard which is to be taken as a fixed quantity. For general shop tests a pair of reproducers are used connected to the head frame. If, for example, the left-hand reproducer is placed in contact with No. 1 cylinder, the sound emanating therefrom will be the only sound audible to the operator. On placing the right-hand reproducer in contact with No. 3, however, the relative "slap" of the two cylinders can be instantly compared, this being preferable to an attempt to remember the relative intensity of No. 1 and making a mental comparison after testing No. 3.

It should also be noted that when required the method enables the internal sound to be compared with the external; and as in some forms of construction the section or shape of the casing may cause, say, four tappets and cams which are all of equal intensity internally to give very different external effects, the combined test should enable any confusion to be avoided as to the actual cause of the defect. In fact, it should be of considerable assistance in the industry for purposes as widely different as the choice of suitable material for the exhaust pipe and the design of a gear-box lid.

Other applications of the use of this apparatus are described, from which it would appear that by these means a considerable amount of information can be obtained at a small expense in time. For example, many sources of trouble in closed bodies can be easily obviated with the aid of the tectophone which will trace body squeaks, panel drumming, and the periodic drumming of wings and undershields under actual running conditions on the road. (Paper presented to the Coventry Branch of the Institution of Production Engineers, Nov. 7, 1922, abstracted through *Engineering Production*, vol. 5, no. 110, Nov. 9, 1922, pp. 439–443, 9 figs., *dA*)

MECHANICS (See Machine Design and Parts)

POWER-PLANT ENGINEERING (See also Forging)

Power-Station Design

Power-Station Design, C. W. E. Clarke, Mem. Am.Soc.M.E. Apart from market conditions for the sale of electrical energy, the author considers as the controlling factor in the selection of a power-station site the existence of an adequate supply of water for condensing purposes at all times, and from this point of view thinks that the so-called "mine-mouth" power plants would be of advantage in only very few locations.

The paper discusses the various features of design in considerable detail. Only a few points, however, can be reported here. The use of double stokers, that is, two stokers placed face to face, is seldom of advantage and the author considers it as justified only in cases where the boiler heating surface per square foot of floor area is very great, or when it is expected to operate boilers at very high ratings.

The use of pulverized fuel has only just passed the experimental stage, but there is little doubt that this system will be used in many of the plants built in the future, especially where only low-grade fuels are available. It has many advantages in efficiency and operating simplicity, but the additional cost of the system may militate against its wider adoption. Oil is the ideal fuel for use under boilers, but with the present relative costs of coal and oil it cannot be used economically for power-station work except in certain localities.

The installation of economizers, with fuel costs at their present level, is of doubtful advantage.

When increased building, economizer, induced-draft, fan, piping, maintenance, and operating costs are considered it will usually be found that an increase in the height of the boiler will result in a greater operating efficiency, considered financially, than if economizers are used. The curve in Fig. 7 shows a comparison between the efficiencies of a 15-high boiler with 64 per cent economizer and a 20-high boiler with no economizer. Every case should be considered in the light of its own peculiar conditions, but this curve is illustrative of the general trend.

Surface condensers are usually to be preferred to jet condensers because the pure condensate is available for boiler-feed purposes,

making elaborate systems for water treatment unnecessary. If there is a supply of good boiler feedwater available, which is rarely the case, a jet condenser is about as economical financially as a surface condenser. All surface condensers should be provided with some sort of screen to remove leaves and other matter from the condensing water. For this purpose a traveling screen is the only suitable apparatus. The water velocity through the free opening of screens should not exceed 2 ft. per sec., unless such a velocity requires extraordinarily large screens.

The only method left for improving the overall efficiency of a power station is through the system of heat conservation which goes under the general title of the "heat-balance system." Boiler design has reached a point beyond which little can be expected. Turbine generating equipment gives us efficiencies about as high as we can look for. We are then faced with the proposition of making the system of heat utilization in the station as efficient as possible. At best, there is only a little over 30 per cent of the energy put into the steam by the boiler which is available for conversion into power. The problem is how to approach as closely as possible to converting all this energy into power. This can be accomplished only by retaining in the station heat cycle as much as possible of the latent heat

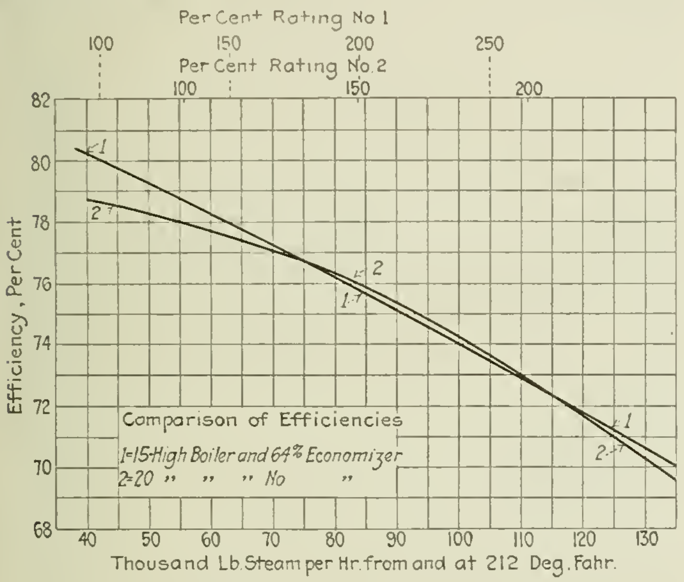

Fig. 7 Comparison of Boiler and Boiler-Economizer Unit

of the steam which ordinarily is transferred to the condensing water. A heat-balance system has this object in view.

There are four general methods of heat balance and the author discusses them in detail. For large stations he considers the following as the best system: House turbine, alternating current or direct current and electric drive for all but enough of the auxiliaries to keep the station running in case of accident to the house turbine and main generator.

Among other things, the article contains an interesting table giving piping and fitting schedules, as well as pipe materials best adapted for use in power-station work. (*Proceedings of the Engineers' Society of Western Pennsylvania*, vol. 38, no. 4, May, 1922, pp. 109–127, 1 fig. and 1 table, and discussion, pp. 128–167, 10 figs., *g*)

Slag on Boiler Tubes

Formation of Slag on Boiler Tubes, Harry H. Bates. The author claims that slag formation on boiler tubes and walls is essentially governed by the same rules as apply to clinker formation, and points out that in slag the iron must be kept in the ferric state, which is practically infusible. This can only be done by completely oxidizing the sulphur and iron before the tubes are reached.

All types of stokers have difficulty with slag formation and it is believed that slag particles are carried up with the draft in such minute form that they can be transported by the low-velocity gas as well as by the gas that rises rapidly.

An examination of the slag under the microscope revealed small spherical globules, substantiating the belief that the particularly troublesome particles were the small ones.

When these small particles come in contact with the free oxygen in the furnace gas for a sufficient time to oxidize them completely, they will be transformed into their completely oxidized state and become solid. If they solidify before touching the tubes or walls, they are carried through the boiler as solid ash. On the other hand, no free oxygen is obtained through the fuel bed. In this event the particles remain in a molten condition, on account of their low fusing temperature in their their -ous state, and are deposited on the tubes and walls where they may either be completely oxidized and solidified or be covered by successive coatings or layers of the same plastic material.

That the latter is true to a large extent is shown by layers of a very dark vitreous material covered by a reddish brown layer or protective coating. This reddish coating is largely ferric material and it prevents further oxidation of the dark ferrous material within by excluding the oxygen from it. A considerable portion of the material on the outer surface, especially on the tubes, is of a friable and nonfusible character, and it is of a completely oxidized nature.

The author calls attention to various efforts made for producing complete combustion in large furnaces, but points out that even if some efficient means is developed for mixing the gas and excess air together, it is very questionable whether the slag difficulty will be entirely overcome. It is to be remembered that in addition to the problem of supplying and mixing the oxygen and combustible gases, time is required for the various chemical reactions to take place.

There is but little chance for thoroughly mixing all gases in the combustion chamber, as the rapid rate with which the gases ascend prevents a thorough mixing, so that stratification of the gases results.

In proof of the above the author gives analyses of samples taken from the first-pass baffle opening of a boiler immediately under the first row of tubes.

These readings showed a carbon dioxide content of from 10.0 per cent along the walls to 17.5 per cent in the center. From these figures it can be appreciated that the chances for the ferrous material to change into the ferric state are very few. It was evident that there was an insufficient penetrative effect from the ventilated walls to take care of the wide furnace, and it is also noted that there was considerable excess air along the walls.

Numerous samples of coal ash and slag were analyzed and it was found that the slag on the furnace walls ran much higher in ferrous iron, by per cent, than did the slag on the tubes. In consequence of this the slag on the walls was much freer from the coarse, friable, infusible material than was the material on the tubes.

Numerous theories were advanced during this investigation as to the causes of slag formation on the tubes. Chief among these was the condensation of tarry vapors on the tubes, to which the flying particles could adhere and solidify.

Whether condensation of tar can actually occur is, however, subject to doubt in view of the facts pointed out by the author.

In the large number of tests made it was indicated that the slag deposit on the tubes was nearly proportional to the total amount of gas, and was not greatly affected by the rating. The amount of slag was affected by the temperatures in the furnace, however, for the hotter fires kept the slag in a more viscous state, which greatly increased the tendency for cinders and particles of ash to adhere.

In trying to prevent slag accumulation three methods were considered. Among these the injection of steam into the air supply was tried, but no decrease was noticed in the formation of slag on the tubes. Another method now being tried is that of intimately mixing air with the gases. The original boilers were set about 13 ft. from the grates. It was thought that by increasing the distance between the grates and boiler tubes the gases would have more opportunity to mix thoroughly. Also, since the total time of travel of the furnace gas is dependent upon the velocity and distance of gas travel, more time would be allowed for complete oxidation of the small particles. Consequently a boiler was set up 6 ft. higher than those originally installed.

Assuming that the rapidity with which the gas rises from the fuel bed is uniform, it is calculated that its velocity was about 18 ft. per sec. This is the lowest possible velocity that can be expected. The direction of gas travel is from the grate direct to the baffle opening, which was proportioned as 46 per cent of the grate surface.

Necessarily the velocity was twice as high under the baffle as it was leaving the fuel bed.

On this basis the time it took for particles to reach the tubes with the original installation would be 0.72 sec. This is very little time for oxidization to take place, unless it is of an explosive character. Further, by raising the boiler to 19 ft. this same time would be 1.05 sec., which is still a very short period.

This arrangement has not shown any great improvement in slag prevention and has the disadvantage of exposing more brickwork to high temperatures and to draft, with resulting greater infiltration of air through the setting.

Furnace construction undoubtedly has much to do with the external incrustation of the tubes with slag. The ratio of the exposed tube surface to the grate area was 1 to 1. This is very low and the lower the ratio, under set conditions of fuel and fuel bed, the higher will be the furnace temperature. It is apparent that the higher the furnace temperature, the greater will be the tendency for the ash to fuse and stick.

It has become common practice now to have the ratio of exposed tube surface to grate surface as high as 1.87 to 1, and it is seldom less than 1.2 to 1. By increasing this ratio the amount of heat radiated up and absorbed is very materially increased, with a consequent reduction in furnace temperature. This last item, namely, furnace construction, is a step in the right direction.

It is extremely fortunate that only a comparatively few coals give slag trouble to a serious degree. A great many coals have fusing temperatures so high that they give no trouble with ordinary furnace temperatures. Another class of coals have low fusing temperatures, but do not seem to have the tendency to be lifted from the fuel bed. But when a coal gives serious slag trouble, with the present knowledge of the art of burning coal, means must be provided for its mechanical removal. This, however, is not as serious a matter as it appears, for soot blowing in boiler plants is now recognized as a necessity, and apparatus for soot removal is now installed as regular boiler equipment. (*Power Plant Engineering*, vol. 26, no. 22, Nov. 15, 1922, pp. 1094–1098, 7 figs., *eA*)

Electric Steam Generators

Electric Steam Generator, E. M. Horstkotte. Description of an electric steam generator designed by the General Electric Co. It is stated that it requires power at the approximate rate of 1 kw-hr. for every 3 lb. of steam generated. The complete equipment consists of the shell with supporting feet, the electrodes, insulators, steam and water gages, safety valve, circulating pump and motor, and a panel on which is mounted the control equipment. The electrodes are of round iron and the electrical operation resembles somewhat that of a three-phase arc furnace.

Normally, the electrodes are submerged in the water, and the three-phase current passes through the water to the sides of the tank and to the neutral of the system, also from electrode to electrode. The steam is generated by current flowing through the water, which is of high resistance. The mechanical circulation of the water has been described, but some of the operating features arising from it are of sufficient interest to merit further consideration. One result is that the temperature of all the water in the system is practically uniform. If the steam pressure lowers owing to an increased demand, rapid steam generation, due to the high temperature of the water and the degree to which the electrodes are submerged, quickly brings the pressure up again.

Another operating feature is that since the water level is maintained by the adjustment of the throttle of the circulating pump, the energy consumption of the generator is not dependent on the operation of the feedwater pump. The supply of water in the hotwell is regulated by an automatic feedwater regulator. Furthermore, when it is desired to reduce the load, the generator does not have to be blown. The only energy losses in the circulating pump operation are the motor losses and the bearing-friction losses. Practically all the energy delivered to the pump impeller goes into heat in the water, therefore the loss from this source is small.

These electric steam generators have been designed for pressures ranging from 200 lb., maximum to 15 lb. minimum. Tentative layouts have also been made on generators of 3000 kw. capacity operating at 1 lb. pressure. These generators can be designed for any boiler pressure now being used, up to 50,000 kw. capacity and down to 250 to 300 kw. Below this lower limit generators of this type would probably not be as economical to build as some sort of immersion type using a metallic resistor.

One of the interesting features of operation of the electric steam generator is the interlocking of the various controls for purposes of safety. Suppose, for example, the circulating pump ceases to function, from voltage failure or other cause. The water in the electrode chamber simply drains into the hotwell, and since the electrodes are no longer submerged, no more steam is generated. On resumption of the pumping, since there is no hot metal surface in the electrode chamber, there is no danger of an explosion similar to that due to a hot crown sheet in a boiler. Also, when the water drains out there is no danger of burning any part of the electrode chamber, because when there is no water there is no heat generated. Too high a level of the water is prevented by an emergency overflow pipe of large diameter, whose top is some distance from the top of the electrode chamber.

There are instances where the electric steam generator might prove a valuable adjunct to the plant equipment either in utilizing excess electric power formerly wasted or in providing process steam directly where it is needed. An electric generator operates with only very little attention and therefore may be economically used under certain circumstances in preference to a steam generator.

This applies, in particular, to mills that purchase power on a maximum-demand basis. Suppose, for example, a factory contracts for 10,000 kw. maximum demand. It is possible that, owing to one cause or another, the load factor for the year may be as low as 75 per cent. In such a case 2500 kw-years, or 21,900,000 kw-hr., are being paid for but not used. By installing an electric steam generator to utilize this energy the fuel bills would be cut materially. Assuming a coal-fired boiler with an efficiency of 65 per cent and coal with 13,000 B.t.u. per lb., for every 4953 kw-hr. used in the generator one ton of coal would be saved, or 4421 tons per year. If oil-fired boilers are used, operating at 75 per cent efficiency and using oil weighing 8 lb. per gal. with 18,700 B.t.u. per lb., for every 32.9 kw-hr. there would be saved one gallon of oil, or 665,650 gal. per year. These figures are calculated on the basis that all the excess energy would be utilized. If only 75 per cent was so utilized, the savings is said to be still enough to more than justify the installation of a steam generator. (*Power*, vol. 56, no. 21, Nov. 21, 1922, pp. 795–797, 3 figs., *dA*)

In commenting on the progress of the electric boiler, an editorial in *Power* calls attention to the fact that there is installed or under construction in this country and in Canada about 200,000 kw. normal capacity of this kind of equipment. This is equivalent to the evaporation of 700,000 lb. of water per hr. from and at 212 deg. fahr.

While the size of this equipment varies, the average unit is large, and for 19 installations the average size of boiler is over 9000 kw. while the largest unit with a normal rating of 25,000 kw. has absorbed as high as 33,000 kw. (*Power*, vol. 56, no. 21, Nov. 21, 1922, pp. 811–812, editorial)

The Flash Evaporator. Description of an apparatus for producing distilled make-up water made by the Schutte-Koerting Co.

The particular feature of this type of evaporator is that evaporation takes place in a chamber containing no tubes. This is accomplished by circulating the raw water continuously through the closed heater operated by exhaust steam to a vacuum flash chamber or evaporator and then back to the heater. In this apparatus the vapor discharge line of the flash chamber may be connected to the main unit condenser or to a special "distiller condenser." In this way a vacuum is maintained such that the temperature of the raw water leaving the closed heater is considerably above that corresponding to the absolute pressure in the flash chamber. The result is that as the water enters the chamber a certain fraction of it flashes into vapor. This passes over to the condenser and enters the system as distilled make-up water.

The following advantages are claimed for the flash evaporator; Elimination of evaporator scale trouble; removal of air and other gases; automatic control of evaporator feed and evaporator blow-down; and high rate of heat transmission in the heater due to the absence of a steam film between the tubes and the surrounding water. (*Power*, vol. 56, no. 22, Nov. 28, 1922, pp. 834–835, 3 figs., *d*)

POWER TRANSMISSION

Wave Transmission of Power

Wave Transmission of Power. Description of the machinery and exposition of principles underlying the operation of the Constantinesco system of power transmission by waves generated in a liquid.

During the war this system was applied with great success in the so-called CC synchronizing gear for firing machine guns through aircraft propellers in such a manner as to avoid hitting the blades of the propeller. The apparatus proved to be so reliable that it was ultimately used for testing ammunition, it having been found that premature explosion and especially delayed ignition of ammunition powder was more liable to occur than irregularities in the operation of the gear. The patents in Great Britain and the Dominions are controlled by W. H. Dorman & Co., Ltd., who, among other things, have applied this method to the operation of hammer rock drills.

Notwithstanding the fact that until recently information available as to this process has been scarce and difficult to obtain, fairly complete particulars concerning it were given in Mechanical Engineering, vol. 42, June and November, 1920, pp. 359–360 and 633–634.

The present article, among other things, gives data on the operation of the Dorman wave-power-driven rock drill as compared with a compressed-air drill.

Different figures have been published setting forth the performance of the Dorman wave-power rock drill. They show some considerable variation, as might be expected, in view of the fact that the rate of drilling must naturally depend upon the precise degree of hardness of the rock and upon the exact condition of the drill steel as regards sharpness. The first-named factor is not constant from hole to hole even on the one piece of rock, while the latter is subject to progressive deterioriation during the drilling of a hole to an extent which reflects the hardness of the rock. We give below a set of comparative figures which we ourselves observed in the course of a test made in our presence. The exact rate of drilling depends, of course, upon the operator to a considerable extent. He has it, at least, within his power, if skilful, completely to upset the value of the figures obtained in a comparative test. On the other hand, a close observer can readily tell when the operator is not working the drill to its full capacity, for if he holds it back at any time he must make it good afterward by turning the feed handle for a time at above the average rate. During the tests to which the following figures relate one operator—an employee of Messrs. Dorman—was employed throughout. We saw no evidence of any undue reduction in the feed during the compressed air drill trial. On the contrary, we noticed that with both drills occasional jamming occurred as a result of the steel being fed into the rock at slightly too great a rate.

TEST RESULTS ON HARD GRAY CORNISH GRANITE

Drill	Diameter of steel, in.		Feed per min., in.	Volts	Amperes
Wave transmission...	$1^7/_8$		$7^1/_2$	410	37.5
Wave transmission...		light load		410	22.5
Compressed air......	$1^7/_8$		$4^1/_2$	410	48.5
Compressed air......		light load		410	18.0

On the basis of these figures it will be seen that the Dorman drill performed about 75 per cent more work in the same time than the compressed-air drill, and consumed in so doing about 25 per cent less power. When running with the drill out of action, the Dorman drill consumed 25 per cent more power. The figures for the Dorman drill include the energy required to supply the flushing water. In the case of the compressed-air plant the flushing water was supplied by a separate pump, the energy consumption of which was not measured. The compressed-air drill was of a modern type—we cannot obviously specify its design—and was supplied by an air compressor of equally modern form. The compressor was not unduly large. In fact, it was only just large enough to drive the drill, as was shown by the fact that the receiver pressure fell slightly—from 82 lb. to 75 lb. per sq. in.—when the drill was brought into full action. It will be understood that the electrical consumption figures represent the energy supplied to the motors driving the wave-power generator and the air compressor, respectively. The same instruments were used in both cases. (*The Engineer*, vol. 131, nos. 3187 and 3188, Oct. 27 and Nov. 3, 1922, pp. 444–445 and 466–468, 8 figs., *deA*)

In view of the novelty of the subject and comparative difficulty of securing the necessary information, the following list of U. S. patents and patent applications on wave transmission held by the British W. H. Dorman & Co., Ltd., may be of interest:

Patents

This list is taken from a pamphlet printed for Mr. Walter Hadden, connected with W. H. Dorman & Co., in London, which gives, in addition to U. S. patents, patents issued in other countries including Great Britain.

PUMPS

Rotary Pump with Reduced Friction Losses

A New Type of Rotary Pump with Blades, A. Poitrineau. The general belief is that rotary pumps with blades are inefficient because of the excessive friction between the blade and the casing, rapid wear of parts, and excessive leakage.

The author considers (without, for the time being, going into the question as to how it can be done) the case of a rotary pump with blades where the blades do not come in actual contact with the

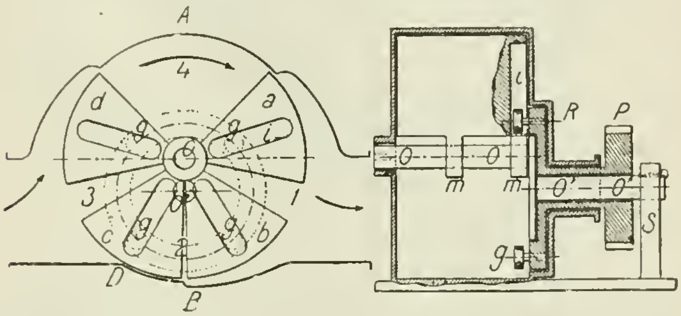

Fig. 8 Poitrineau Rotary Pump

casing. If this be so, friction between blades and casing will be eliminated but leakage increased; but this may not be very objectionable, as the author shows that in such a case the amount of leakage becomes of less and less importance as the velocity of the pump increases.

In the pump designed by the author the following four conditions have been satisfied: (1) There is no friction between the blades and the casing; (2) rubbing contact between parts is replaced by rolling contact, (3) high velocities of rotation have been secured; and (4) all liquids are admitted near the axis.

Fig. 8 shows a pump with four blades, a, b, c, d, rotating about an axis O in a cylindrical casing with one orifice for water admission and another for its exit. A wheel R, driven by pulley P, revolves around the shaft $O'O'$. This wheel carries four equidistant rollers g which travel within rectilinear guides in the blades (i in the section). The operation of this pump is similar to other blade pumps with an eccentric drum—with this essential difference, however, that the drum is here replaced by the roller-bearing wheel R. The wheel R in rotating at a constant velocity carries with it the rollers which roll in their respective races and push the blades at velocities varying with their distance from the axis. In other words, it is simply a quick-return mechanism of the first order but of multiplex type. The thickness of the blades is so proportioned that at an instant when the bisecting planes form with the faces of two consecutive blades a minimum angle, the two adjacent walls are in touch. An examination of Fig. 8 shows that the two blades b and c, now in contact, will separate during one-half of the revolution and then tend to come together again. This will easily explain the method of taking in and driving out the liquid. In the case of Fig. 8, at each revolution a volume of liquid is delivered equal to four

times the volume 4, or practically equal to the volume within the casing.

The author explains the balancing of the parts at high speeds and the method of making the blade. From the article it is not clear whether any such pumps have been actually built, and if so, in what sizes and what were the actual efficiencies of the apparatus. (*Arts et Métiers*, vol. 75, no. 24, Sept., 1922, pp. 260–264, 9 figs., *d*)

RAILROAD ENGINEERING

Rowan Locomotive Piston Packing

ROWAN LOCOMOTIVE PISTON PACKING. Description of a type of locomotive piston packing applied on several of the Irish railways. The piston ring as applied to locomotive pistons is shown in Fig. 9.

There are two casting rings *A,A* turned to the exact diameter

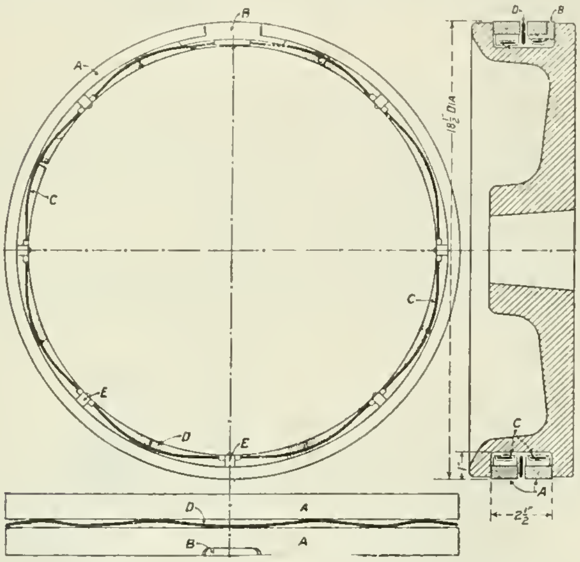

FIG. 9 ROWAN LOCOMOTIVE PISTON PACKING RINGS

of the cylinder, the split being covered by a steel spring *C* which consists of a hoop of steel of a diameter somewhat larger than the internal diameter of the ring. At intervals on the spring *C* there are a number of knuckles *E*. By forcing the hoop into the ring it is deflected from its circular form into a series of arcs—one between each pair of knuckles.

As shown by this the distinctive feature of this packing lies in the use of a separate spring to produce the proper expansion of each ring, with the addition of a third spring to keep the rings in steamtight contact with the outer side of the groove in the piston.

It is claimed that with this design each spring can be accurately adjusted for its particular function and that the pressure exerted by the rings against the cylinder walls does not exceed 2 lb. per sq. in. and is ordinarily about $1^1/_2$ lb. per sq. in., this being sufficient to insure steamtightness without causing excessive friction.

With superheated steam the piston springs are exposed to temperatures which draw the temper of ordinary spring steel. To meet this condition the manufacturers of the Rowan piston ring have developed an alloy having special heat-resisting and temper-retaining qualities which is being used in the manufacture of this locomotive piston packing. (*Railway Review*, vol. 71, no. 19, Nov. 4, 1922, pp. 615–616, 1 fig., *d*)

THE STREET LOCOMOTIVE STARTER. Description of a device the purpose of which is to give increased power to a locomotive at starting. Its function is different from that of the booster, as it is intended to assist the locomotive only when starting and is designed for use only at very low speeds. The starter consists essentially of a heavy cast-steel ratchet wheel driven by a steam cylinder. The piston of this cylinder is driven through its working or forward movement by steam pressure and through its return or backward movement by a spring. With the ratchet wheel goes a ratchet which can engage it and is carried by a pair of lever arms operated by the piston rod. When the machine is idle and during the return stroke of the piston this ratchet is held out of contact with the ratchet wheel. When steam pressure is admitted to the cylinder the ratchet is forced down into contact with the ratchet wheel and holds it there as long as the pressure exerted by the steam is greater than that of the springs which hold the ratchet up. The steam pressure and the strength of the springs are so proportioned that the ratchet is forced down before there is any forward movement of the main piston and lifted before its return movement. This arrangement eliminates any dragging of the ratchet over the ratchet wheel and the unnecessary wear and noise which would result if this were permitted.

The control mechanism consists of a 1-in. steam line leading from the dome of the locomotive to the cylinder of the starter with a throttle at the dome and a flexible joint at the cylinder. The throttle is opened and closed through the medium of a $^1/_4$-in. copper pipe leading from the throttle to a push button in the cap. When the push button is held down the machine will run, and when it is released it will stop.

It is important that all piping and the cylinders be free of water in order that the machine may respond instantly when action is demanded. To insure this the starter has an automatic drain valve at the lowest point of the cylinder which remains open at all times when there is a pressure of less than 10 lb. in the cylinder, and closes automatically under any greater pressure.

In the original article is shown a machine designed for application to a locomotive trailing truck having wheels 43 in. in diameter and carrying a weight of 52,500 lb.; the tractive force exerted at the rim of the wheel with a $10^1/_2$-in. cylinder and 200 lb. boiler pressure would be 12,900 lb. A smaller type is also built.

It is claimed that in passenger service the starter will eliminate starting shocks resulting from taking up slack. In freight service it will eliminate the need for taking up slack in order to get a train under way, and in so doing will reduce break-in-two's and draft-gear and coupler failures. (*Railway Age*, vol. 73, no. 19, Nov. 4, 1922, pp. 858–859, 1 fig., and *Railway Review*, vol. 71, no. 19, Nov. 4, 1922, pp. 613–615, 3 figs., *d*)

REFRIGERATION

Experiments on Ice Making—Supercooled Water

METHODS OF FREEZING RAW WATER, Halbert Paul Hill. Description of what appears to be a novel method of ice manufacture in which an attempt is made to make a practically continuous cake of ice from which pieces may be cut off as desired. The method is based on the use of supercooled water. It is known that strongly agitated water may be cooled below its theoretical freezing temperature without solidifying. In tests made by the author, water strongly agitated and surrounded by a 14-deg. fahr. brine was reduced to 26.8 deg. fahr. before it flashed and ice crystals were formed. In other experiments water was not agitated but covered with a film of oil and a temperature of 25 deg. fahr. was reached without crystals forming. A piece of ice was dropped into the water and crystals slowly formed. The peculiar thing in the formation of these crystals is that they formed in laminated sheets. After proving that water could be supercooled, a plant was built with the idea in view that if ice crystals could be made in sufficient quantities and the ice cans filled with a concentrate of ice crystals and water at 32 deg. fahr., a marked step in the development of a more commercial method of manufacturing ice would be obtained. Notwithstanding all efforts made it was found impossible to use this plant on a commercial scale as the equipment would work only a few minutes, when the cooler would freeze up. This happened even when high back pressures from 42 up to 100 lb. per sq. in. were used. The apparatus, it seems, was provided with screens of 200 mesh in the bottom of the tank to prevent the crystals from being carried to the cooler. As a matter of fact, however, the crystal formations break up into such minute particles that they readily pass through eight to ten thicknesses of 200-mesh screen reinforced with cheesecloth, and these minute crystals once in the cooler cause the flashing.

A device was then developed for separating crystals by gravity. After this separator was connected between the tank and the cooler, supercooled water could be made and maintained for an indefinite period at temperatures below 32 deg. fahr, and it was

believed that by introducing the supercooled water into a refrigerated can or receptacle the water coming in contact with the refrigerated surface would deposit laminations of ice thereon, thus removing the heat through water instead of through ice. Numerous experiments were made but without satisfactory results on a commercial scale at first. Thirty-seven forms of cans of various types and shapes were made. In all of these absolutely clear ice was made but in no case was it possible to deposit crystals that would adhere to the refrigerated surface or to the ice formed. This led to further experiments to determine the relation between supercooled water and ice crystals.

In the course of these experiments another means was employed in the hope of solving the problem. A large cast-steel ammonia-jacketed can, weighing 7000 lb., was made in two sections, machined inside and bolted together. This can was 6 ft. 9 in. long and the ammonia-jacketed section 6 ft. long. It was open at the ends and the front end was provided with a cover and an inlet and outlet; in the center an agitator was provided. The idea was to admit supercooled water into the can through the top inlet, agitate it in the can, and discharge it from the lower outlet. The object of the agitator was to mix the supercooled water and crystals so that the entire mass would be of one temperature and the crystals would be deposited on the refrigerated surface of the can and thus make ice. Means were provided to lubricate the inner surface of the can, the intention being to make ice continuously, allow it to slide out of the can as made, and then saw it off into standard lengths. The system was not a success.

Experiments are now being conducted in an attempt to make ice in an open tank, separate the crystals in the water by a centrifugal separator and then press them into a cake by means of hydraulic pressure. The crystals made from supercooled water are so minute that they can hardly be distinguished from water when in a glass, being so clear. By subjecting them to pressure, however, they can be compacted so that solid ice can be made.

In the course of these tests an endeavor was made to stabilize the crystallization point by catalytic action. Various acids and alkalies were added to the water with a view of decreasing the freezing point and with the hope of discovering some means whereby the crystal formation would be retarded. Certain dyes were used, as well as starch, glycerine, and other chemicals. A thorough study of the crystal formation of sugar, salt, glycerine, and various chemicals was made and a number of very interesting experiments were conducted with electrical apparatus. Glass containers were made surrounded by coils of wire through which both alternating and direct current were applied with a view to stimulating or directing crystallization by magnetic lines of force.

It would appear, therefore, that while no commercial result has yet been obtained from the work of the writer, some facts of considerable scientific interest have been established. (*Refrigerating Engineering*, vol. 9, no. 4, Oct., 1922, pp. 127–131 and discussion, pp. 131–132, 11 figs., *eA*)

Thermodynamics of Ammonia Compression, W. H. Motz. Brief discussion of general thermodynamic principles followed by a derivation of the various formulas used in the design of ammonia compressors.

For the constant k in the formula for mean effective pressure where ammonia is compressed adiabatically (ratio of specific heats) the author recommends a value of 1.31. Some of the formulas are accompanied by examples and a number of curves and tables are given, among them being a table for the mean effective pressures of ammonia and curves for mean effective pressures for various suction and discharge pressures. Formulas for the mean effective pressure with and without clearance are given, and the author points out that the mean effective pressure with clearance is equivalent to the mean effective pressure without, multiplied by the clearance factor, or the volumetric efficiency due to clearance. The effective displacement of the compressor cylinder with clearance is reduced in direct proportion to the volumetric efficiency due to clearance, and the mean effective pressure of the cylinder with clearance is reduced in the same proportion. This indicates, theoretically, that the clearance does not effect the work requirements for a given amount of refrigeration. In passing, the author calls attention to the formulas and tables given by Carl J. Jefferson in an article entitled Mean Effective Pressure of Ammonia Compressors, in the Sept. 18, 1917, issue of *Power*. He claims that the formula given therein is incorrect (because it apparently assumes a 100 per cent condition the whole distance), as is also Mr. Jefferson's table of mean effective pressures with varying clearances, suction pressures, and condenser pressures. (*Refrigerating Engineering*, vol. 9, no. 4, Oct., 1922, pp. 119–124, 6 figs. and discussion pp. 124–125 and 132–133, 2 figs., *gt*)

SPECIAL PROCESSES

Dust Separation by Gravity

Gravity Method of Dust Separation, Dr. Karl Wiest. The gravity method of dust separation is still used in many instances because it is the cheapest to employ under certain conditions, and when properly applied gives excellent results. The method of operation of gravity-type dust-separation plants rests on the fact that when the velocity of the gas in which the dust is held in suspension is decreased the dust particles have time to settle out because of their higher specific gravity. The author shows that both in stationary and in moving air each particle of dust has a certain velocity of fall peculiar to itself, and establishes a law to the effect that *the efficiency of a dust-separation chamber is a function of its floor area*, while the height must be only great enough to prevent the flowing gases from picking up and carrying off dust from the floor. If this is so, the general opinion as to the importance in a dust chamber of sufficient *volume* would appear to be incorrect. This is of considerable importance in connection with the use of standpipes forming part of the usual air-cleaning equipment in blast-furnace plants.

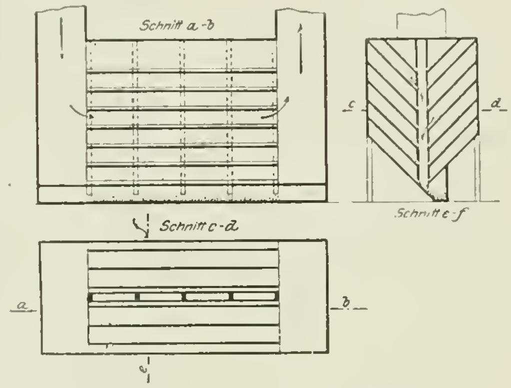

Fig. 10 Dust-Separating Chamber with Multiple Partitions between Floor and Ceiling

In order to test out the correctness of the above rule, in a certain dust-separating chamber of rectangular cross-section a false floor was built in at half the height of the chamber over one-half of its width. If the law as to the importance of the floor area of the chamber in governing the amount of dust separated out from the air be correct, there should be deposited on each of the two halves of the subdivided chamber approximately as much dust as on the floor of the undivided half. The test proved that this is so.

Furthermore, the dust chamber with the multiple subdivision in the vertical direction as shown in Fig. 10 (patented by the author) gave a dust separation many times greater than that obtained in a simple chamber. Among other things, the author shows a smokestack where steplike baffles have been built in to modify the free flow of the gases and to force them to deposit the heavier particles of dust on these baffles.

The effect of velocity of fall on the separating out of dust particles may be utilized in the case of smokestacks delivering their gases into the open air, where, for some reason or other, excessive dust may be objectionable. A smokestack in itself is not an apparatus for the dust separation, but it may help to protect from dust the surroundings of the plant. If a particle of dust having a velocity of fall k leaves a smokestack of the height H and is immediately picked up by a wind velocity w, it is carried away for a period of time necessary to have it fall through a height H. Its distance of flight will therefore be $f = Hw/k$. The higher the smokestack

the greater the wind velocity, and the smaller k the greater will be the distance to which the particle of dust is carried. If the wind is very slight the gases, and with them the dust particles, do not spread horizontally immediately upon leaving the mouth of the smokestack, but rise more or less. If, however, the smokestack has built into it a dust-separating chamber which gives a certain velocity k', no dust particles can leave the smokestack which have a velocity of fall greater than k', and therefore the minimum distance of flight will be $f_{\text{min.}} = 3H/k'$, the wind velocity being here assumed as 3 meters per second. As a result no dust can fall within the radius of $f_{\text{min.}}$. (*Stahl und Eisen,* vol. 42, no. 44, Nov. 2, 1922, pp. 1650–1653, 4 figs., *de*)

Reinforced-Concrete Pipe Made by Centrifugal Process. Description of centrifugally cast concrete pipe made by the Lock Joint Pipe Co. at Ampere, N. J., and Denver, Colo. The machine used does not essentially differ from similar machinery in the Hume process (described in Mechanical Engineering, July, 1922, pp. 474–475) and in some German processes. The whirling form is of wrought iron in take-down construction and is set up around the reinforcement cage so arranged that the cast-iron joints at the end of the cage are flush with the circumference of the form. The grooves or sheaves of the form are then engaged by an endless steel cable hanging from the frame and give the form its motion.

In one respect the machine is different from the Hume, viz., in that it uses a charging bucket consisting of a longitudinally placed cylinder with a slot a few inches wide along its elements. It is completely filled with concrete through the slot and then moved longitudinally on tracks into the center of the whirling form. Once the charging bucket is inside, the form is started to whirl and the charging bucket is slowly turned over so that it discharges its concrete content uniformly along the inside of the form where it is immediately thrown outward by centrifugal force. The size of this charging bucket is so proportioned as to give the proper concrete content to form a shell of a required thickness.

After the form has been whirling for about five minutes there is inserted into the center a pan resting clear of the form at either end and projecting from the center of the form. It is used as a guide for brushes, manipulated by the attendant, which clean the interior of the pipe and collect the excess water which clings to the whirling surface. It is said that in a pipe 20 in. in diameter, $2^1/_2$ in. shell thickness, and 12 ft. long with a concrete that would be considered of normal working mortar plasticity, a full wheelbarrow load of cement, colored water and laitance is drawn off.

The concrete from which the pipe is made is a mortar rather than concrete, as it is a one-half mixture of portland cement and ordinary good, clean building sand. The finished pipe presents a remarkably uniform surface. So far no tests have been made as to their strength, but they are being used for pressures up to 50 lb. per sq. in. for the 20-in. pipe and have resisted pressures up to 200 lb. per sq. in. (*Engineering News-Record,* vol. 89, no. 80, Nov. 16, 1922, pp. 829–830, 4 figs., *d*)

STEAM ENGINEERING (See Power Plants)

THERMODYNAMICS (See Refrigeration)

VARIA

Sculpture by Camera. In the December, 1922, issue of Mechanical Engineering (p. 843) a method of portrait sculpture by the aid of photography was described by W. F. Engelmann of Chicago. It is now stated that Howard M. Edmonds, a graduate of the Massachusetts Institute of Technology, has developed another method for accomplishing the same result. In this method a lantern projector popularly known as a magic lantern throws on the face of the sitter a series of closely spaced lines. These lines projected on a screen are fine, straight parallel lines, but when thrown on the face of the subject and viewed from a certain angle they appear curved and follow the contours of the face. A photograph is then taken of the subject with these lines projected on the face with a strong light, and the negative shows the many curved lines on the face. A positive is then made from a negative and given to the operator of the carving or sculpturing machine.

Connected with the machine is a drill which can be made to rotate and also to move in a straight line and scratch thin lines on the marble or such material as may be chosen. The operator by the use of levers and handles can control the drill and make it begin and end at any point, and can also regulate the depth of cut. To secure a likeness of the model the operator manipulates a pointer which is connected to the drill so as to follow the curved lines on the photograph. As the pointer traces out the lines on the photograph the drill moves up and down, making cuts of various depth as it moves along in its straight-line path. As the lines curve in on the photograph the drill cuts deeper and as they curve out it cuts shallower, and in this way the varying contours of the subject's face are reproduced in marble. In practice it is found that polishing and a certain amount of hand carving of the hair

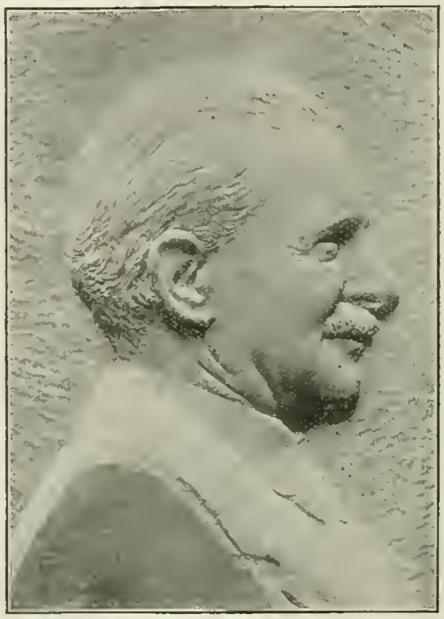

Fig. 11 A Bas-Relief Made by the Edmonds Photographic Process

is necessary, but otherwise the machine does the entire work of carving, and by eliminating the necessity of a skilled sculptor brings the sculptured portrait within the province of persons of moderate means. (*The Tech Engineering News,* vol. 3, no. 5, Nov., 1922, pp. 148–149, 1 fig., *d*)

German Export Policy. The more important of the German oil-engine manufacturers maintain a complete sales organization covering the entire world. For example, one prominent builder has over 400 salesmen in South America, Egypt, India, China, etc. These salesmen are not mere brokers but direct representatives, selling the builder's product and devoting their whole time to this business. If the engine sales are insufficient to give the salesmen a profitable business, the engine builder takes on some other line of machinery that can be readily sold in the territory under question. This increases the profits of the representatives and ties him still closer to the engine builder. The engines for export are finished according to the demand of the country into which they go. Local desires as to painting, extra parts, crating, etc., are complied with. In making export prices on account of exchange conditions the factory cost has but slight influence and the quoted price depends on the price prevailing in the country to which the engine is going. The extent of the German foreign trade in oil engines may be judged by the fact that in one South American country a German builder maintains a repair shop having a payroll of 40 men. (*Power,* vol. 56, no. 23, Dec. 5, 1922, pp. 878–879, *g*)

CLASSIFICATION OF ARTICLES

Articles appearing in the Survey are classified as *c* comparative; *d* descriptive; *e* experimental; *g* general; *h* historical; *m* mathematical; *p* practical; *s* statistical; *t* theoretical. Articles of especial merit are rated *A* by the reviewer. Opinions expressed are those of the reviewer, not of the Society.

Forty-Third Annual Meeting of the A.S.M.E.

Noteworthy Week Comprising Twenty-four Sessions Dealing with Professional Subjects, Economics, and Industrial Education and Training—Local Sections' Conference a Prominent Feature

THE FORTY-THIRD Annual Meeting of The American Society of Mechanical Engineers was notable for its well-balanced, diversified program with splendid papers and enthusiastic discussion. The four days of the meeting, December 4 through 7, 1922, formed a very intense period, however, for during that time there were twenty-four sessions, fifty-three committee meetings, and four social events. This was followed by the National Exposition of Power and Mechanical Engineering which opened on Thursday, December 7, at one o'clock at the Grand Central Palace. It was a remarkable week and the 1836 who registered left the meeting with a feeling of having attended a very successful affair.

The presidential address of Dean Dexter S. Kimball attracted wide attention and gave mighty inspiration in its challenge to the engineer to assume his proper responsibility in maintaining and developing civilization. He was given an ovation at its presentation on Monday evening of the meeting. The address appears in full as the leading article of this issue.

Perhaps the most interesting session of the meeting was that on Engineering and Economics held on Wednesday evening, December 6. President Dexter S. Kimball presided over a program arranged jointly by the A.S.M.E. Management Division and the American Economic Association. Papers were presented by Dr. W. C. Mitchell on Making Goods and Making Money, and by E. M. Herr on The Human Problem in Industry; and H. R. Seager, E. F. DuBrul, F. J. Miller, and J. L. Harrington contributed to the discussion. These addresses with the discussion appear on other pages of this issue.

The Council met on Monday to transact routine business, and on Friday to install the new officers and consider questions arising from the proceedings of the business meeting. The outgoing President, Dean Dexter S. Kimball, was presented with a gavel, and the custom was inaugurated of also giving the incoming President this symbol of his authority. John Lyle Harrington was formally introduced as President; as were the new Vice-Presidents, W. S. Finlay, Jr., W. H. Kenerson, E. F. Scott, and H. H. Vaughn; and Managers, A. G. Christie, J. H. Herron, and R. V. Wright.

JOHN LYLE HARRINGTON — PRESIDENT, 1923
THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS

This Annual Meeting was also the scene of a very remarkable conference of Local Sections Delegates which lasted throughout the week. On Monday the delegates met all day to talk over Local Sections problems, breaking the gathering, however, for luncheon with the Council, at which a number of inspiring four-minute addresses were delivered by the officers and chairmen of standing committees. During the rest of the week the Local Sections Delegates met with the various Standing Committees of the Society for the discussion of national Society problems, and on Friday they attended the Council meeting. In the afternoon the Council attended the final meeting of the Local Sections Delegates. As a result of this week-long conference the members of the Society from afar learned of the inspiring importance of the Society's activities. A more complete account of the transactions of the Council and the deliberations of the conference of Local Sections Delegates appeared in the December 22 issue of *A.S.M.E. News*.

Business Meeting

On Monday afternoon, December 6, the annual business session was held. Its feature was the presentation of the report of Calvin W. Rice Secretary of the A.S.M.E., on his recent trip to South America. This appears in its complete form on page 72 of this issue of MECHANICAL ENGINEERING. Mr. Rice preceded this report by his customary summary of the work of the Standing Committees of the Society. The formal report of the Tellers on the ballot for the new Constitution and Code of Ethics was read. The following selection of the Nominating Committee by the Conference of Local Sections Delegates was approved: Charles L. Newcomb, Holyoke, Mass.; A. E. Allen, New York City; William H. Kavanaugh, Philadelphia; W. T. Magruder, Columbus; W. L. Abbott, Chicago; Louis Bendit, Kansas City; Sam H. Graf, Corvallis, Ore.; and alternates, L. D. Burlingame, Providence; S. H. Libby, New York City; H. S. King, Atlanta; C. W. Bennett, Columbus; William M. White, Milwaukee; L. D. Crain, Ft. Collins, Colo.; R. D. Hoyt, Portland, Ore. Announcement was made of the final approval of three parts of the work of the Power Test Codes Committee: The General Instructions, Code on Definitions and Values, and Code for Reciprocating Steam Engines. The following reports of the Research Committee were also presented for final approval: Standards on Malleable Iron Screw Fittings, Gears and Pinions for Electric Service, Gray Iron Industrial Spur Gears, Specifications for Steel Castings for Gears, Specifications for Brass and Bronze for Gears, and Specifications for Forged and Rolled Steels for Gears.

In presenting life membership to Major Fred J. Miller, resolutions of thanks from the Council were read which expressed an appreciation of Major Miller's service as president and as advisor and servant under all circumstances, not the least of which was his assumption of the burden of the secretaryship while Mr. Rice was in South America.

Life membership in the Society was also presented to Prof. R. C. H. Heck for a paper on Steam Formulas which was adjudged by the Committee on Awards and Prizes as the best one appearing in the 1920 volume of Transactions. The Junior prizes were awarded to R. H. Heilman of Pittsburgh for his paper on Heat Losses from Bare and Covered Wrought-Iron Pipe at Temperatures up to 800 Deg. Fahr., and to F. L. Kallam of Los Angeles, Cal., for his paper on The Investigation of the Thermal Conductivity of Liquids.

E. S. Carman, Junior Past-President and Chairman of the A.S.M.E. delegation to the American Engineering Council, emphasized the fact that the organization of national, state, and local societies composing The Federated American Engineering Societies is concerned more particularly with those engineering activities that are of great civic import.

L. W. Wallace, Executive Secretary of the Federation, gave a convincing report of the activities of the Federation.

Mr. Wallace called attention to the fact that in the two industrial reports which have been issued by the F.A.E.S., Herbert Hoover has written the introduction to the one on Waste in Industry and President Harding the one to the report on the Twelve-Hour

Shift in Industry. He spoke of the coöperation of the Federation with the Department of Commerce in standardization work and in adjusting the relations of the Federal Government with contractors; also of their coöperation with the Post Office Department in organizing a division for the handling of materials. Certainly the Federation has been influential in presenting certain legislative measures; and in the matter of a topographical map of the United States they have had introduced into Congress a law which will make possible the completion of this necessary map in twenty-five years instead of the one hundred years it will take at the present rate.

Following Mr. Wallace, Rudolph P. Miller gave a report on the National Board of Jurisdictional Awards in the Building Industry. This Board has been meeting on an average of four times a year and to date has rendered about 38 decisions, many or all of which have been instrumental in the settlement of industrial disputes before they have actually occurred. He urged that engineers everywhere give their support to this Board, showing that untold money may be saved for the people of this country by the elimination of the labor disputes over which the Board arbitrates. A review of the activities of this Board will be found on page 75.

Student Session

On Wednesday afternoon, December 6, Dr. William H. Kenerson presided over a gathering of representatives of Student Branches at which a number of problems relating to the activities of the Branches and their relation to the Society were given careful consideration. Addresses were made by Edwin S. Carman, Past-President, John Lyle Harrington, President-Elect; John Younger, and Calvin W. Rice. Representatives were present from the following colleges:

Armour Institute of Technology	Massachusetts Institute of Technology
Brown University	Michigan Agricultural College
Bucknell University	University of Michigan
California Institute of Technology	New York University
Carnegie Institute of Technology	North Carolina State College
Case School of Applied Science	Ohio State University
College of the City of New York	Oregon Agricultural College
University of Cincinnati	Pennsylvania State College
Cornell University	Polytechnic Institute of Brooklyn
Drexel Institute	Purdue University
Georgia School of Technology	Rensselaer Polytechnic Institute
Johns Hopkins University	Rutgers College
University of Kansas	Stevens Institute of Technology
University of Kentucky	Agri. and Mech. College of Texas
Lafayette College	Tufts College
Lehigh University	Virginia Polytechnic Institute
Lowell Textile School	Worcester Polytechnic Institute
University of Maine	Yale University

Social Events and Excursions

The meeting furnished its usual quota of valuable opportunities for good-fellowship. Although the President's Reception, usually held on Tuesday evening, was held this year on Monday, it was exceedingly well attended and an enjoyable evening resulted. The informal dinner and smoker on Tuesday evening gave the desired opportunity for the men to get together, and on Wednesday afternoon the ladies served tea. The dinner dance Thursday night was a success from every point of view.

Throughout the week an enthusiastic and capable ladies, committee was in attendance at the building and large groups of visitors were taken to the Museum of Natural History, to a private gallery of modern American paintings, to inspect the *Pictorial Review* building, the Hecksher Foundation and the Museum of the American Indian, and to a Fashion Show at Wanamaker's, where tea was served.

The more technical excursions included visits to the Hell Gate Station of the United Electric Light and Power Company, the Broadcasting Station WEAF of the American Telephone & Telegraph Company, one of the automatic exchanges of the New York Telephone Company, and the plant of the Wheeler Condenser Company at Carteret, N. J. Large groups visited the McGraw-Hill building for luncheon on Thursday, and the Battleship *Maryland* at the Brooklyn Navy Yard on Friday. A very interesting demonstration of the Christie amphibious gun mount was held on Tuesday afternoon, when this new device traveled over smooth roads on wheels, over broken country on its caterpillar tread, and then propelled itself across the Hudson.

Refrigeration Session

THE FIRST technical session of the meeting was held jointly with the American Society of Refrigerating Engineers, on Monday afternoon, December 4. Harry Sloan, President of the A.S.R.E., presided over a program of two papers. In the first paper, on the Design of Cooling Towers, C. S. Robinson[1] the author established a general principle applicable to cooling-tower design and derived equations for the use of the design. Extended discussion as to the practicability of the paper was submitted by Barton H. Coffey,[2] L. A. Phillips[3] and W. S. Grosvenor.[4] This paper will appear in abstract with the discussion in a later issue of Mechanical Engineering.

The second paper, by Percy Nicholls,[5] on the Economic Thickness of Insulation in Refrigerating Field, appeared in the December issue of *Refrigerating Engineering.* In this paper the author defines economic thickness for refrigeration as that which will reduce to a minimum the sum of the expenses due to heat passed through the insulation plus the expenses of prevention. The author discusses the factors entering into this definition, proposes a formula for determining the economic thickness of insulation, and points out some of its applications. In his conclusion Mr. Nicholls states that it has not been his purpose to recommend definite thickness but rather to establish a standard of reference and set out a basis of argument on which the figuring of thickness may be done. Neither will it be worth while to attempt in most cases to introduce refinements in calculation since corresponding close values for the various constants cannot often be predicted. Fuel prices in the future may be different and the efficiency of operation will depend on how the plant is run. It is, however, advisable to have an agreed standard method of computation to refer to in case of dispute, and on which to base practical rules, and if such agreement can be expressed as a definite formula, then the problem is reduced to fixing the values of the various symbols.

In the discussion Prof. A. J. Wood[6] stated the advantage of plotting "cost-thickness" curves. For ease in simplifying calculations, Professor Wood suggested combining the factors of interest, depreciation, maintenance, and taxes. He also suggested a chart to take care of surface effect and conduction of the structure independent of the insulation and to provide for that part of the year in which there are heat losses. He agreed with the author of the paper that the practical economic thickness is not an exact thickness.

C. H. Herter[7] pointed out the difficulty of evaluating some of the factors in Mr. Nicholls' formula and suggested some simple rules. If the average plant where the cost per ton of refrigeration amounts to about $2.50, he suggested the provision of 1 in. of pure cork board, or its equivalent, for every 15 deg. fahr. maximum air to air temperature difference. Where refrigeration is very cheap, allow 1 in. per 20 deg. maximum difference, and where refrigeration is expensive allow 1 in. for each 10 deg. maximum difference. He also suggested that for 1 sq. ft. of insulation it is proper to pay up to one-fifth or one-fourth of the total cost per ton of refrigeration. J. B. Starr[8] emphasized the need for consideration of upkeep as a factor in cost of installation.

Management Session

THE MANAGEMENT Session, held Tuesday morning, December 5, furnished a further opportunity for a discussion of the paper by L. P. Alford[9] on Ten Years' Progress in Management which had been discussed previously before a number of Local Sections during Management week, October 16–21. R. A. Wentworth, Chairman of the Management Division, presided over this discussion as well as over the discussion of the paper by Wallace

Clark on Relieving Industry of Burden, and the presentation of Progress Reports by the Committees on Standards for Graphics and Standardization of Terminology.

In introducing the discussion on Mr. Alford's paper, Fred J. Miller[1] expressed the thought that the most important progress in the ten-year period cannot be measured nor weighed as it is manifested mainly in the changed attitude of mind shown in the installation of management methods by the promotion of coöperation instead of the arousing of opposition and antagonism.

Dr. H. S. Person[2] stated as his opinion that the real measure of progress in management would be an analysis of the existence of the combination of the various management mechanisms listed in the report, which he thought to be impossible at present. He also thought that the greatest measure of advance in management, a more or less intangible but very real thing, is a new point of view, a new method of approach by management.

J. P. Jordan[3] combated the idea that cost control is a mechanism and emphasized that it is an absolutely indispensable organ of enlightened management. He decried the fact that management had failed to recognize the importance of cost control.

Dean Dexter S. Kimball[4] told of his experience in establishing a course of instruction for the fundamentals of management which he believed will be much more clearly understood during the coming years.

Dean R. L. Sackett[5] pointed out that the advance in management has been accompanied by the development of administrative engineering courses which are drawing the attention of students to the humanistic side of industrial engineering.

David B. Rushmore[6] emphasized the need for a true definition of management. He also spoke of the need for developing executives along fundamental lines as a real constructive work for industry.

L. W. Wallace[7] expressed the hope that during the next ten years management would become more informed as to the fundamental economics involved so that they can be more intelligently placed before labor and the public.

The paper by Wallace Clark[8] on Relieving Industry of Burden appeared in the December issue of Mechanical Engineering. In his discussion Dr. Person expressed the feeling that it is important that the problem of relieving industry of burden be treated from the social point of view, which must consider the internal forces that impinge upon the individual plant and against which the management is sometimes almost helpless unless they may be modified by concerted effort. Dr. Person pointed to the joint session with the economists at this Annual Meeting as a hopeful sign that the engineer is attempting to broaden his viewpoint.

Joseph E. Pogue[9] defined the major problem for the management engineer as the formulation of an industrial policy which will require technical proficiency and economic insight involving not only a coördination and control of the internal components of the industrial units but also a synchronization of this unit with the industry at large. The big job for the future is to learn how to explore and control the industrial interstices—the inter-department, inter-company, and inter-industry spaces—which now, unmeasured and neglected, cause the major inefficiencies in our industrial system.

Fred J. Miller emphasized the importance of perfecting administrative methods first and spoke especially about the reduction of inventories by reducing manufacturing time, one of the points stressed in Mr. Clark's paper. The reduction of manufacturing time can be brought about by proper planning and routing, and by entire coöperation on the part of all individuals in the plant.

John Younger,[10] speaking from the point of view of the manufacturer, emphasized the importance of external industrial conditions effecting idleness in a specific plant.

[10] Standard Welding Co., Cleveland, O. Mem. Am.Soc.M.E.

L. W. Wallace stressed the responsibility of manufacturers to secure facts as to the need for a given commodity before money is invested in factories to manufacture this commodity.

John J. Swan,[1] representing the A.S.M.E. on the Joint Committee on Standards for Graphics, presented a progress report. The Committee has had a fairly complete bibliography prepared and a start has been made in the preparation of definitions and terminology and the presentation of chart forms. A questionnaire has been sent out to those using graphics and a great deal of valuable material has been received.

F. E. Town,[2] Chairman of the Joint Committee on Management Terminology, presented a progress report for this Committee in which was included a classification of management literature in accordance with the Dewey Decimal System. The general subject of classification was given consideration and it was the consensus of opinion that classification procedure should be inaugurated and changed as occasion warrants.

Session on Ash Handling

THE MATERIALS Handling Division arranged the program for the Session on Ash Handling on Tuesday, December 5, over which H. V. Coes, Chairman of the Division, presided. The program consisted of a paper by John Hunter and Alfred Cotton which described systems of ash handling for marine and stationary work. The discussion presented some added material about ash-handling methods which was of particular importance as an expression of the point of view of operating engineers. An abstract of the paper with an account of the discussion will appear in the February issue of Mechanical Engineering.

Machine Shop Session

FIVE papers were presented at the Machine Shop Session on Tuesday, December 5, at which F. O. Hoagland, Chairman of the Machine Shop Division, presided. The paper by F. E. Cardullo[3] describing a new system of Helical Involute Gearing for Use in Metal Planers appeared in abstract in the December issue of Mechanical Engineering. In the discussion of this paper F. K. Hendrickson[4] agreed with Mr. Cardullo as to the unquestionable need of helical gears for planer drives with a consequent reduction in chatter marks and machine vibration. Mr. Hendrickson also spoke of the advantage of the helical driving gear in reducing the tendency to lift when heavy cuts are being taken. Charles Meier[5] expressed the opinion that Mr. Cardullo's form of gearing increased the friction losses and end thrust. He was also of the opinion that greater accuracy may be required in mounting this system of gearing. G. M. Eaton[6] spoke of his experience with helical gears on railway work, telling especially of one gear that after 60,000 miles of operation was superior to a spur gear, although the drive possessed less efficiency.

Mr. Estabrook's paper on Testing Involute Spur Gears appears in abstract in this issue of Mechanical Engineering and the discussion on it follows thereafter.

The paper on Spherical Gears by Charles H. Logue appeared in full in the November issue of Mechanical Engineering. There was no discussion on this paper.

The remaining papers were by Walter Ferris,[7] on Application of Hydraulic Transmission Variable Speed Drive to Machine Tools and Manufacturing Processes, and by Fred A. Parsons[8] on the Power Required for Removing Metal. Mr. Ferris' paper will be abstracted in a future issue of Mechanical Engineering and will be accompanied by the discussion. Mr. Parsons' paper appears in abridged form in this issue.

Session on Education and Training

AT THE Session on Education and Training for the Industries held Tuesday, December 5, the program was presided over by W. W. Nichols, Chairman of the Committee on Education and Training for the Industries. The presentation of the subject was in the form of a report of the Committee which was introduced by Mr. Nichols. The report itself consisted of three parts, one on Extension and Correspondence Schools, by James A. Moyer;[1] a section on Industrial Education as Represented in Schools, by C. R. Richards;[2] and the final section on Schools for Apprentices and Shop Training, by R. L. Sackett.[3] Each of the sections of this report were presented separately and discussed. The report of the Committee with a complete account of the discussion will appear in the March issue of Mechanical Engineering.

Research Session

A GROUP of five notable papers resulting from the activities of the Research Committee were presented at the Session on Tuesday afternoon, December 5, with Walter Rautenstrauch, Chairman of the Research Committee, as presiding officer.

In his paper entitled A New Method of Determining the Effect of Speed upon the Strength of Gear Teeth, Wilfred Lewis[4] discussed the analytical work on this subject performed by Oscar Lasche, Professor Marx and C. H. Logue, and described a modification of his gear tester as a device for measuring exactly the relation of speed to pressure. This paper appeared in the December issue of Mechanical Engineering. The discussion, which was contributed by Messrs. E. D. Church, Carl G. Barth and G. H. Marks substantiated the need for further investigation of this subject.

The report of the Research Sub-Committee on Sudden Initial Pop Lift of Safety Valves removed the fear that a relatively large sudden steam discharge from the boiler or the sudden stopping of such a discharge may cause dangerous shock to the boiler.

The Committee which was made up of P. G. Darling, Chairman, E. F. Miller, W. E. Jerauld, G. H. Clark, I. E. Moultrop, A. M. Houser, A. L. Fitch, and G. S. Coffin, conducted two series of tests, one at Boston with the work carried on by three thesis men at the Massachusetts Institute of Technology, and one at Bridgeport.

In the tests an extremely sensitive pressure indicator of special design was used which employed a thin diaphragm with a maximum allowable movement of 0.007 in. This diaphragm was balanced between the pressure of the steam or water in the boiler and an outside air pressure. Any change in pressure would cause a movement of the diaphragm which could be detected by a microphone or an electric light. In the Bridgeport, tests which were conducted on a 94-hp. B. & W. water-tube boiler at 300 lb. pressure, the Committee selected four points at which shock on sudden relief of steam would be most likely to occur as follows:

a At the upper or front ends of the tubes where the water in circulating takes nearly a right-angled turn into the front header

b At the top of the front header where it enters the drum

c Against the headers of the drum

d At the middle of the drum.

The quick-opening test valve was arranged so that the discharge of steam could be varied from six to seventeen times the capacity of the valve assigned in the A.S.M.E. Boiler Code. The test showed, however, that even with steam discharging from the valve at the maximum rate of 95,000 lb. per hr. there was no indication of change in pressure from any of the four pressure indicators. The closing paragraph of the report is as follows:

> This investigation might be continued with prolonged trials on different types of boilers, under different conditions of steaming, and with additional points of attachment for the diaphragm indicators. However, considering the fact that no degree of pressure increase or shock whatever has been detected under the severe steam-discharge conditions tried, we believe that it is extremely unlikely that any boiler conditions would be found so radically different as to produce a shock. In other words, if a pressure-increase shock could be produced by any reasonable boiler operation, we believe that the conditions of our tests were representative enough to have detected at least some trace of such shock.

The only discussion on this report consisted of expressions of relief that no conditions of shock were set up upon the opening of safety valves.

The paper on Torsion of Crankshafts, by S. Timoshenko,[1] resulted from the work of the Committee on Stresses Due to the Vibration of Shafting. This paper will appear in abstract in a later issue of Mechanical Engineering. There was no discussion.

The two papers on flow of gases, one entitled The Effect of Pulsations on the Flow of Gases, by Horace Judd[2] and D. B. Pheley,[3] and the other on Orifice Coefficients, by J. M. Spitzglass,[4] were related to the work of the Sub-Committee of Research on Fluid Meters. Abstracts of these papers with the discussion will appear in later issues of Mechanical Engineering.

Steam Table Research

PROFESSOR A. G. Christie presided over an exceedingly interesting session on Tuesday afternoon, December 5, at which the problems and progress in research work were discussed. George A. Orrok, Chairman of the Executive Committee of the Steam Table Fund, told of his correspondence with physicists and engineers in France and England to secure interest in further research on this subject in those countries, and to develop all possible sources of information so that the tables when finally completed will be ready for adoption internationally. Dr. Harvey N. Davis told of the work being carried on at Harvard on the Joule-Thomson effect and introduced Dr. R. V. Kleinschmidt who is conducting this work. Dr. Davis also read a report from Dr. Frederick G. Keyes, of the Massachusetts Institute of Technology, who is preparing to handle one phase of the research. Dr. N. S. Osborne, of the Bureau of Standards, told of the preliminary study that is being made of the calorimetry of fluids as the basis of part of the program the Bureau of Standards will carry on.

The proceedings of this session are being more carefully prepared for publication at a later date.

First General Session

AT THE First General Session Tuesday, December 5, at which Arthur L. Rice, Vice-President of the Society, presided, three papers were presented. The first paper, by W. L. Wotherspoon,[5] on Refinery and Rolling Mill for Monel Metal at Huntington, W. Va., describes the steps taken in selecting the site for the location of the mill. The paper also deals with the layout of the plant, emphasizing some features of design of particular interest. There was no discussion on the paper. It will appear in abstract in a future issue of Mechanical Engineering.

The second paper, by E. W. Noyes[6] and H. V. Sturtevant,[6] entitled The Size of Dry-Vacuum Pump to Employ in a Given Case, proposed a rapid method for this determination. This paper will appear in abstract in a later issue of Mechanical Engineering with the discussion thereon.

A description of the Diesel Engine Used in German Submarine "U-117," prepared by William H. Nicholson,[7] was presented by L. H. Morrison. This will also appear in abstract in a later issue of Mechanical Engineering.

Session on Stokers

THE STOKER Manufacturers' Association coöperated with the Fuels Division of the A.S.M.E. in preparing the program of the Symposium on Stokers which was held Wednesday morning, December 6. Professor Breckenridge presided over the

presentation of the following papers: Development and Use of the Modern Chain Grate, T. A. Marsh; Overfeed Stokers of the Inclined Type, G. I. Bouton; Design and Operation of Underfeed Stokers, H. F. Lawrence; and Chronological History of Stoker Development to the Present Day, A. H. Blackburn. The first three of these papers are abstracted on pages 14 to 21 in this issue of Mechanical Engineering and are followed by the discussion.

Railroad Session

VOLUMINOUS discussion was brought out at the Session of the Railroad Division on Wednesday, December 6. James Partington, Chairman of the Railroad Division, presided over the presentation of three papers, one by G. H. Hartman[1] on Steam Distribution in the Locomotive, one by F. H. C. Coppus[2] on Mechanical Draft for Locomotives, and one by R. Eksergian[3] on Stresses in Locomotive Frames.

Mr. Hartman's paper appeared in abstract in the December issue of Mechanical Engineering. O. W. Young[4] submitted a lengthy written discussion in defense of the steam distribution accomplished by locomotive valve gears of all recognized designs. He came to the conclusion that there is a practical necessity in locomotive engines for moderately large cylinder clearance, variable points of release, variable points of closure and variable points of pre-admission. He presented an indicator diagram showing steam distribution by comparing the results of the Pilliod valve and the conventional valve, and questioned whether the factors determining cutoff, release, etc., will not necessitate the readjustment of valve events to approximately the same points in the cycle that existing locomotive valve gears now place them. In closing he stated that practical refinements in locomotive steam engines must be limited to greater accuracy in registering valve events for prolonged service periods and increased port and passage areas proportioned to increases in cylinder sizes.

J. J. Jones[5] stated that in his opinion the defects of the locomotive valve gear are much exaggerated. He questioned whether any improvements in the device described by Mr. Hartman would be sufficient to warrant the additional cost of the device.

After a brief review of the steps in the progress of steam-locomotive development, L. D. Freeman[6] stated that by no line of reasoning can the quality of the steam entering the cylinder have any bearing upon the events produced by purely mechanical movement of the valve arrangement. Mr. Freeman suggested as proper steps in improving locomotive cylinder performance the separation of the action of the steam side of the valve from the exhaust side and the adjustment of the steam clearance space to properly absorb the inertia of the reciprocating parts.

H. B. Oatley[7] criticised the author's derogatory treatment of arches, feedwater heating and superheating and presented a table giving the per cent of water and fuel saving for superheated steam at several temperatures for various cutoffs and pressures as compared with dry saturated steam. Mr. Oatley called attention to the fact that in spite of the large amount of heat required to produce a pound of superheated steam over that required to produce a pound of saturated steam, the net savings are more than could be expected from any change of steam distribution.

H. H. Vaughan[8] questioned the treatment by Mr. Hartman of the subject of cylinder condensation and the effect of clearance. Mr. Vaughan called attention to the large amount of experimental and theoretical work which has been done on the locomotive in the past twenty years which does not seem to be reflected in the statements in Mr. Hartman's paper.

R. C. H. Heck[9] compared the Pilliod valve to the old Meyer gear.

The paper by R. Eksergian on Stresses in Locomotive Frames is a preliminary analysis of the major reactions brought on the locomotive frame as well as of the nature of frame action as regards variation of bending moment, shear, etc., for definitely supported types of frames. The first section of the paper is a careful analysis of the various methods of equalization, spring design, and the nature of cab supports in electric locomotives. This is followed by a section dealing with the dynamics of the steam locomotive where the variation of torque and a quantitative investigation of the various oscillations are discussed in detail. Further, a careful analysis of the variation of side-rod loads and journal-bearing loads is included. The succeeding section deals with electric-locomotive drives and the major reactions brought on the frame. This section includes the dynamics of the electric side-rod drive, which discussion augments the previous one on side-rod loads in steam locomotives. The next section discusses the dynamics of braking, its change in load on the equalization and the reactions brought on the frame. In this section is included a brief discussion of bumping loads and dynamical loads on the drawbar. Finally the nature of the lateral reactions and the dynamics of lateral oscillations on entering a curve, etc., are discussed, a short recapitulation of the static reactions while on a curve being also given.

Due to delay in the preparation of advance copies of this paper it was not possible to secure proper discussion on such a highly complicated subject. It is planned to have the paper submitted for discussion at a later meeting.

W. E. Woodard,[1] Chairman of the Research Committee of the Railroad Division, emphasized the importance of the paper as the basis for experimental research on frame stresses. Other comments were made by A. H. Houston, George M. Eaton, Selby Haar, Clement F. Street, and W. E. Simons.

The paper by F. H. C. Coppus on Mechanical Drafting of Locomotives was also well discussed. This paper will appear in a later issue of Mechanical Engineering with an abstract of the discussion.

Second General Session

THE SECOND General Session of the meeting was held on Wednesday morning, December 6, under the chairmanship of Walter S. Finlay, Jr. Three papers were presented. Stresses in Cylindrically Shaped Rotors of Uniform Diameter, by C. M. Laffoon,[2] developed a general theory and analyzed mathematically the stresses in cylindrical rotors of uniform diameter such as are commonly associated with different classes of machinery. This paper with its discussion will appear in complete form in Transactions.

The second paper, on the Design of Flywheels for Motor-Driven Impulse Machines, prepared by C. O. Rhys,[3] was presented by S. C. Stovall, of Atlanta. In his paper Mr. Rhys analyzed the torque and speed curves for such machines and derived expression by which the characteristics of these curves may be determined. This paper with its discussion will also appear in Transactions.

The paper, on Stress Distribution in Electric-Railway Motor Pinions, by Dr. Paul Heymans[4] and A. L. Kimball, Jr.,[5] described the photo-elastic method by which this stress is determined. The paper also reported and discussed the causes of rupture of gear pinions in electric railway motors. An abstract of this paper with discussion will appear in the February issue of Mechanical Engineering.

Power Session

FIVE papers were presented at the Power Session on Thursday morning, over which John H. Lawrence, Chairman of the Power Division, presided. The paper on The Commercial Economy of High Pressure and High Superheat in the Central Station, by Geo. A. Orrok, appeared in Mechanical Engineering for December. A running account of the discussion of this paper is given below. The paper by Linn Helander on Feed Heating for High Thermal Efficiency will appear in the February issue of Mechanical Engi-

neering, but a brief abstract of the paper and discussion is included in the present account of the meeting. An extended abstract of Paul W. Thompson's paper giving the results of tests on different types of baffling in a Type W Stirling boiler appears in this issue and is followed by an abstract of the discussion it elicited. The papers by Sabin Crocker and S. S. Sanford on The Elasticity of Pipe Bends and by B. N. Broido on High-Temperature and High-Pressure Steam Lines, together with the discussions thereon, will appear in abstract in future issues. Mr. Broido's paper was presented by title and will be discussed at the January 4 meeting of the Metropolitan Section, A.S.M.E.

Discussion of Paper by Geo. A. Orrok on The Commercial Economy of High Pressure and High Superheat in the Central Station

The discussion of Mr. Orrok's paper and its appendices on the properties of metals at high temperature and the cost of piping materials by W. S. Morrison, was opened by John A. Stevens[1] who presented by means of lantern slides data on the influence of coal cost and load factor on the efficiency and first cost of a power plant. Comparing a refined design, 15,000 B.t.u. per kw-hr., with an original design, 20,000 B.t.u. per kw-hr. and costing $100 per kw., his figures showed that with a 40 per cent load factor the increase in permissible cost in the refined design varied from 6.9 per cent with coal at $2 per ton to 69 per cent with coal at $20 per ton, while these percentages would be 10.3 and 103.3 if the load factor were 60 per cent.

Henry B. Oatley[2] questioned the correctness of assuming a turbine efficiency of 78 per cent with pressures as high as 1200 lb., saying that the increase in density at this pressure would result in greater friction losses in the turbine. He also pointed out that the specific heat transfer from the inner wall of a superheater to the steam decreased with the density and velocity of the steam. It was therefore not possible, he wrote, to produce a total steam temperature of 1100 deg. without considerably increasing the temperature of the metal tube wall. The only known means of holding down the excess of metal temperature was the employment of much higher steam velocities and pressure drops, the use of small tubes, and the restratifying of the steam during the superheating processes so as to mix the denser core with the more rarefied stratum in contact with the tube wall.

C. H. Smoot,[3] in a written communication, compared the relative advantages of increased pressure versus increased temperature and showed that at present the greater advantages lay with the former. He also pointed out that the regenerative cycle should be given more careful study. In his opinion the present type of turbine was not suited to this cycle, and his reasons formed a part of his discussion. He thought that an extension of our knowledge of the properties of steam at high pressures might indicate an even greater improvement in thermal economy by the use of high-pressure saturated steam than was now deduced from our inaccurate data.

Walter J. Wohlenberg[4] presented a written discussion which included a revised table of results (author's Table 1), the comparisons in which were based on the single-stage regenerative or heat-balance cycle of the modern power plant instead of the Rankine cycle used by the author.

I. E. Moultrop[5] said that while he was not as optimistic as the author that the manufacturer would be able to build apparatus for such high pressures as those considered in the paper, he did feel that the boiler and turbine could be built without great difficulty. The piping and valves between these two units, he said, would give considerable trouble. He concurred heartily with the author's fourth conclusion that there was more economy to be gained by close study of operation and construction losses than in an attempt to increase widely the temperature range of heat cycles.

Peter Junkersfeld[1] said that the final question with any central station was always, Does it pay? In discussing the curves of the author's Fig. 2, especially that called "Extra fixed charges per kw-hr.," he showed that the determining factor of this item was the generator capacity factor. This factor, which was the ratio of the actual output to the possible output of a steam turbine as rated and all its accessories when averaged over a period of years, was much less than usually supposed, especially among central stations which had a substantial annual average increase in output.

An examination of the experience of 7 companies with 14 power stations and 92 steam turbines, aggregating 1,730,000 kw. rating, showed that in substantially the same 12 months' period one had had an average generator capacity factor on all its turbine units of 44 per cent and another of 25 per cent. The extra fixed charges per kw-hr. for the latter would be almost double that for the former.

An average experience curve for these 7 companies, all in large and growing cities, indicated a capacity factor of about 58 per cent on turbines one year old and 30 per cent or less on turbines ten years old.

The falling off with age of the capacity factor of turbines reflected good operating procedure with improved equipment in the successive installations. The fact that only one company operated its one-year-old turbines at 77 per cent, another at 52 per cent, and the third at only 23 per cent, and that the average of 10 turbines 2 years old operated by 6 companies was only 50 per cent, indicated that there was still very great room for improvement in construction and operation of equipment with what might today be called moderate pressures and superheat.

In all of the foregoing, wherever reference was made to turbine experience it meant not only the turbine proper, but also on one end the condensing equipment, piping and other mechanical accessories, and on the other end the generator, the excitation, the switching equipment and other electric accessories.

The development toward higher steam pressures and superheat had been under way many years and would inevitably continue. It should be given every reasonable encouragement consistent with established scientific facts and sound economic possibilities. It should be remembered however that this development in the past in a broad and overall aspect had tended toward lower construction as well as lower operating costs of the station. The development now immediately before us seemed to tend toward higher costs of construction and of operation with the exception of fuel. It thus would become even more necessary than heretofore to determine proper balances between fuel saving and what Mr. Orrok had called "extra fixed charges per kilowatt-hour." The latter was, therefore, particularly important and especially because experience had shown that it varied so widely from turbine to turbine from station to station, from company to compnay or city to city and from year to year.

A. M. Houser[2] presented a written discussion in which he pointed out that the values given by the investigations by Crane Co. on cast steel should be considered conservative.

Henry D. Hibbard[3] sketched briefly the behavior of boiler steel when subjected to increase of temperature. The paper, he said, gave a partial résumé of the properties, at elevated temperatures and for a limited time, of metals which would be employed in superheated-steam containers contemplated by the paper, but no one, so far as he knew, had investigated how the properties of such metals would be affected by long use in boilers for making highly superheated steam and in apparatus for handling it.

V. T. Malcolm[4] contributed an illustrated discussion, too extensive for abstract here, on metals for valves.

D. S. Jacobus[5] said that, speaking from the boiler maker's standpoint, pressures up to 1200 and even 1500 lb. might be attained, whereas there were special features of design that had to be carefully considered when it came to the construction of a unit

of large size for power-plant work and no large-sized units for these pressures had so far been constructed. He agreed with Mr. Orrok that temperatures up to 750 deg. should not be exceeded. He spoke of the difficulties of designing fittings, particularly flanges for such pressures and expressed the opinion that it would seem best in the design of flanges to make the bolts the weaker element as in case of overstrain they could be readily replaced, whereas should the bolts be made strong enough to dish and distort the flanges, the flanges would have to be replaced. He also stated the need of data to show whether the elastic limit of steel at high temperatures would be permanently elevated in the case of an overstrain in the same way as at ordinary temperatures. Experiments on this feature would be most useful. He reviewed the experiments on high-pressure boilers made by Perkins and published in a book by Galloway in London in 1830.

H. L. Whitney[1] said that there had been built and kept in operation for over two years a pipe line on 1500 lb. and 850 deg. fahr. The largest point was 36 in. in diameter. There was no trouble with steam piping from increased pressure he, said, if the temperature was kept below 700 deg. fahr.

Robert Cramer[2] pointed out the relative theoretical advantage of raising pressure rather than temperature.

Max Toltz[3] said that there was a middle course between high and low pressures and temperatures of steam which was to be found in the use of resuperheated steam between stages. He had seen an experimental plant in Europe in which the economies were very high.

Francis Hodgkinson[4] said that manufacturers were embarrassed by lack of standards for pipes for the higher pressures and urged the Society to undertake the formation of such standards. He thought that the tendency to use alloy steel for bolts was unfortunate because of the danger of mixing such bolts with those of commercial steel when dismantling machinery.

Nevin E. Funk[5] spoke of some of the difficulties of operating a high-pressure power station.

Oscar F. Junggren[6] said that the discussion of high pressure was not new. As had been said, if high pressure did not pay it was useless. There had been in the past a gradual increase in pressures, each accompanied by a development of apparatus, and every increase had paid so far. Why, therefore, doubt that there could be further gain? Until some one gave higher pressures a trial, he said, no one could know what the efficiencies might be.

T. E. Keating[7] wrote that granting that the gains in individual apparatus, desirable as they might be, must be relatively small, then improved thermal efficiency of steam stations must depend upon:

1 The use of regenerative cycles which would divert from the turbine the latent heat of part of the steam, thus reducing the losses to the condenser

2 The use of heat-reclaiming apparatus for eliminating losses in the flue gases

3 The utilization of a greater range of the heat cycle.

Referring to the paper by Messrs. Orrok and Morrison, and particularly to the appendix including test data on metals under high temperatures, it was evident, he wrote, that an increase of the temperature range was today more of a problem for the chemical and physical laboratories than for central stations, as modern stations had nearly reached the limits for materials now commercially applicable.

The use of the high pressure range of 1200 to 1500 lb. suggested by the paper, he wrote, would require some new principles of turbine design, as with present designs it was probable that a greater efficiency would be obtained with 500 lb. pressure and 280 deg. superheat than with 1500 lb. and 150 deg. superheat, both conditions being equivalent to a total steam temperature of approximately 750 deg. The selection of a proper pressure and temperature depended upon combined commercial and engineering judgment applied to the problems surrounding the particular station involved, but a discussion of this factor would be of value.

Discussion of Paper by Linn Helander on Feed Heating for High Thermal Efficiency

In order to make the discussion intelligible to those who did not attend the meeting and who have not obtained a copy of the pamphlet, we present the following brief summary of Mr. Helander's paper.

The author investigates the problem of determining the correct feedwater temperatures for conditions of high thermal efficiency. For illustrative purposes he bases his calculation upon several assumed stations of 25,000 kw. capacity using various methods of feedwater heating. The steam conditions assumed for all plants are steam pressure, 330 lb. gage; superheat, 200 deg. fahr.; vacuum on main unit, 29 in. To illustrate the influence of factors such as the water rate on the main unit and the slope of the Willans line of this unit, the Rankine-cycle efficiency of the bled steam and the Rankine-cycle efficiencies of the house turbine, two cases—designated Case 1 and Case 2 respectively—are worked out for each arrangement of feedwater heating. In the various solutions arrived at by the author the feedwater derives its heat from three possible sources: (*a*) the feedwater of the main unit is used as the condensing water of the house turbine, thereby absorbing all the heat in the steam exhausting from the house turbine; (*b*) steam is bled from the main unit in such quantities and at such temperatures as to increase the amount of heat delivered to the feedwater by the house turbine, and (*c*) before entering the boiler the feedwater may pass through the economizer.

Under Case 1 the Rankine-cycle efficiency for the bled steam based on the steam pressure on the turbine side of the throttle was approximately 67 per cent, the slope of the Willans line was 12 lb. per kw-hr. and the water rate of the main unit when carrying the gross station load was 10.6 lb. per kw-hr. The combinations of feedwater heating investigated under Case 1 included single- and double-stage heating and were as follows. For single-stage heating (*a*) no economizers, no bleeding, 1600-kw. house turbine, (*b*) no economizers, bleeding, 650-kw. house turbine; (*c*) 50 per cent economizer surface, bleeding, 650-kw. house turbine; (*d*) 100 per cent economizer surface, bleeding, 650-kw. house turbine. The greatest thermal efficiency is obtained with the last of these combinations and at a feed temperature of approximately 180 deg. fahr.

For double-stage heating and for approximately the same combinations of apparatus supplying the heat, with the exception of the substitution of a 1400-kw. house turbine for the 1600-kw. turbine and of economizers of slightly different area, the same general conclusions are drawn: that is, that the best combination is obtained with the maximum economizer surface, the maximum amount of bled steam, and the smaller house-turbine unit. For the cases investigated the feedwater temperature for best economy lies between 180 and 220 deg. fahr.

Single-stage, double-stage, and four-stage heating are worked out for Case 2 in which the Rankine-cycle efficiency of the bled steam is 80 per cent, the slope of the Willans line 9 lb. per kw-hr. and the water rate in the main unit 10.26 lb. per kw-hr. In general the same combinations of feed-heating apparatus were used with Case 2 and the results for single-stage, double-stage, and four-stage heating show that maximum economy is obtained with a maximum economizer surface, a maximum amount of bleeding, and the use of the smallest house-turbine unit. The feedwater temperatures for Case 2 are for single-stage heating, 160 deg., for double-stage heating, between 160 and 200, and for four-stage heating, between 190 and 220 deg.

The author devotes two paragraphs to discussing the effect of air preheaters, but does not bring these effects into his numerical calculations.

In conclusion he says that so many factors enter into the determination of the proper feedwater temperature that figures determined for one station should not be applied to another. The temperature should be lower for plants using single-stage heating than for those using multiple-stage heating and also should be lower for plants using economizers than for plants not using economizers.

Efficiencies of auxiliary apparatus as well as of the main generating units have their influence. If the feedwater temperature be raised much above 212 deg. fahr., factors incident to the use of pressures well above atmosphere in the auxiliary exhaust piping come into play. The proper feedwater temperature is dependent somewhat upon the initial steam pressure and temperature and on the temperature of the condensate, increasing as these increase. It is quite impossible, therefore, to determine, except within wide limits, feedwater temperatures applicable to all plants, and the purpose of the paper has been rather to indicate in a broad way the effect of feedwater temperatures on power-plant efficiency, leaving out the matter of costs, and to give some basis for estimating the sacrifice in fuel made to assure practicable operation of the feedwater-heating system as laid out for a particular station.

The discussion of the paper was opened by George G. Bell[1] who said that about a year ago he had made a study of the heat balance of the Windsor Station of the West Penn Power Co. and at that time had determined 210 deg. to be the most economical feed temperature. The turbine was a 30,000-kw. G. E. unit, the boilers 1450 hp. and the economizers had 8341 sq. ft. of surface. Two-stage and three-stage heating were studied after Mr. Helander had begun the preparation of his paper and the results, with economizers, of one-, two- and three-stage heating produced curves practically parallel with the author's: about 1.75 per cent above. These results showed a saving of about one per cent, comparing two- with one-stage heating, and about one-half of one per cent, comparing three- with two-stage heating. The temperatures he obtained did not check as closely as those obtained by the author. They were, with economizers, 200 deg. fahr. for one-stage, 235 for two-stage, and 270 for three-stage heating. Without economizers they were 265 deg. fahr. for one-stage, 290 for two-stage, and 310 for three-stage heating. The savings without economizers were about $1^1/_2$ per cent between one- and two-stage, 0.8 per cent between two- and three-stage, and 0.5 per cent between three- and four-stage heating. These two studies, he said, would indicate that even with economizers the feed temperature should be at least 210 deg. fahr.

T. E. Keating[2] read a discussion in which he said that it was somewhat surprising to find that in the application of economizers with 350 lb. boiler pressure and stage heating the most efficient temperature was close to 200 deg. fahr., as it had been rather generally believed that the efficient use of economizers demanded a somewhat lower temperature. The use of multi-stage heating was receiving considerable attention, he said, in central-station engineering, and its application involved many practical problems. He also discussed the question of the exhaust pressure at which the house turbine should be operated, and the preheating of air.

W. M. Keenan[3] spoke of some studies of bleeding at one point which had been made in connection with a new Brooklyn station. The results were surprising in that they showed that the best point to bleed the turbine was not in the vacuum range, as had been supposed, but at about 25 lb. absolute pressure. Continuing the studies to include bleeding at two points showed that best conditions prevailed with bleeding at 12 lb. and 100 lb. absolute pressure.

Prof. A. G. Christie[4] said that he was becoming convinced heating should be done by the steam from the main unit and the power should be generated by it, thus doing away with the house turbine.

Oscar F. Junggren[5] reiterated Professor Christie's statement and pointed out a further advantage in bleeding the main unit in that the more congested low-pressure end of the turbine was relieved thereby.

Francis Hodgkinson[6] said that he was surprised that the author had laid so much stress on the relations of the house turbine, because the house turbine was not going to be used very much in the future on account of the greater efficiency of the main unit and the greater efficiency of bleeding from it for feedwater heating.

Nevin E. Funk[1] said that while stage heating might prove to be more efficient theoretically, it would involve greater complications in the power plant. Simplicity made for more efficient operation, and a scheme which had great theoretical advantages on paper might not prove so in actual operation because the human element would have to be considered.

F. H. Rosencrants[2] presented a written discussion in which he showed, using the author's assumed condition, that the theoretical Rankine efficiency would be 35.35 per cent, while that of the Carnot cycle would be 40 per cent. Assuming it possible to approximate the Carnot cycle as readily as the Rankine, he showed that the saving by attempting the former ideal would be 13.15 per cent compared to the latter. He spoke further of the tendency of many engineers to ignore the superiority of the Carnot cycle over the Rankine. Accepting the figures given in the papers, he said, led one to question whether an economizer had a place in a central station of modern design with multi-stage bleeding, in view of the fact that a multi-stage bleeder heater system and additional boiler surface was likely to be less expensive than the economizer installation.

C. M. Hardin[3] wrote that every one concerned with steam-power generation realized that reliability was of first importance and must be obtained even at the sacrifice of plant efficiency and other requisite factors. Without discounting reliability, it was, however, vitally important that high efficiency be obtained. To obtain maximum plant efficiency every integral part of the station equipment must be of such correlative design and construction as would individually produce and maintain high efficiency. Stage bleeding from the main prime mover was, without question, the method that did give highest feedwater heating efficiency as compared to using the house turbine or other steam-driven auxiliaries. If stage bleeding should even in the slightest degree tend toward unreliability as regards continuity of service, the problem was to perfect the equipment used and allied with the scheme.

Session on Standardization

THE Session on Standardization, consisting of a program prepared by the Standing Committee of the A.S.M.E. on Standardization with the coöperation of the American Engineering Standards Committee, was held Thursday, December 7, with E. C. Peck, Chairman of the Standardization Committee, acting as presiding officer.

The first paper, by William J. Eynon,[4] was a progress report on the Program for the Standardization of Paper and Printing Machinery in which the new A.S.M.E. Committee on Printing Machinery is keenly interested. Mr. Eynon's paper, which was presented by Winfield S. Huson,[5] indicated the possibilities of standardization of printing presses, of which there were over two hundred sizes and styles in use today, and of folding machines with six hundred sizes and types. The first step in this simplification was a reduction in the number of sizes and grades of paper and Mr. Eynon told of the coöperative work being carried on by printers, printing-machinery manufacturers, lithographers, purchasing agents, and advertisers to secure the adoption of standard sizes of paper.

R. E. Rindfusz[6] expanded one phase of Mr. Eynon's paper by stressing the importance of reducing the number of items of paper as an important step in reducing idleness in paper-making machinery. He also pointed out that the important field for standardization was that of grade and trade names. This lack of fixed grade meant a multiplicity of brands with little or no difference. The addition of each brand of paper with its ramifications of color, sizes, weights and finishes meant an increase of 108 items with consequent increased complications in paper manufacture. Mr. Rindfusz commended the work of the Committee which was

[5] Consulting Engineer, New York City. Mem. Am.Soc.M.E.

[6] Secy., American Writing Paper Co., Holyoke, Mass.

carrying out the standardization program in a fair-minded, broad-gaged constructive manner.

W. C. Glass[1] also emphasized the importance of standardization of grades of paper as a step toward simplicity in selection of paper, fairness in competition, and simplification in the manufacturing processes.

F. A. Curtis[2] told of the coöperative work being carried on by the Bureau of Standards to secure simplification and standardization.

F. B. Gilbreth[3] bespoke support for standardization in any field as a step in developing industry. Mr. Kalkoff told of the progress which had already been made in the standardization of type and stated that the over-equipment in the printing industry in New York State was about 75 per cent and throughout the country about 150 per cent, because printers purchased special machinery to do special jobs, and when the jobs were finished the machinery was idle and might never be employed. W. Green emphasized the importance of standardization from the printers' point of view.

In his closing remarks Mr. Huson pointed out the importance of the printing industry and directed the attention of the engineering profession to its problems. He stated that the further development of this industry would challenge the skill and precision of the trained mind and indicated that the function of the Committee on Printing Machinery was to bring the engineering point of view to the assistance of the industry.

The paper on Size Standardization by Preferred Numbers, by Messrs. C. F. Hirshfeld[4] and C. H. Berry,[5] which appeared in the December issue of Mechanical Engineering, brought out a very heavy discussion. The points developed therein require very careful editorial consideration and a more complete résumé of it will appear in a later issue of Mechanical Engineering. Written discussions were submitted by C. G. Barth, Buckner Speed, F. O. Hoagland, L. D. Burlingame, L. B. Tuckerman, E. R. Hedrick, A. E. Kennelly, B. M. Eaton, E. H. Rigg, W. A. Durgin, W. A. DelMar, Major G. F. Jenks, C. J. Oxford, R. Trautschold, and E. Buckingham. Those orally discussing the paper were F. B. Gilbreth, A. L. DeLeeuw, W. H. Timly, and Alfred B. Carhart.

Safety Engineering

THE American Society of Safety Engineers joined with the Safety Codes Committee of the A.S.M.E. in the preparation of the program for the Session on Thursday morning, December 7, devoted to Safety Engineering. John W. Upp, Chairman of the Safety Codes Committee, presided, and the following papers were presented: Safety Codes, M. G. Lloyd; Safety Engineering in Connection with the Compression of Gases, A. D. Risteen; Safety Codes for Grinding Wheels, G. E. Sanford; and Some Hazards of the Logging Industry, John A. Dickinson. These papers will appear in abstract in a later issue of Mechanical Engineering.

Ordnance Session

AT THE Session on Ordnance held Thursday afternoon, December 7, with Waldo H. Marshall, Chairman of the Ordnance Division, in the Chair, two papers recording wartime ordnance manufacturing experience were given. R. A. Vail[6] presented a paper on Methods Used in Manufacture of Gun Recoil Mechanism, and J. B. Rose[7] one on Machining and Lapping Very Deep Holes. An abstract of Major Rose's paper appeared in December Mechanical Engineering. An abstract of Mr. Vail's paper with the discussion on both papers will appear in a later issue.

On Tuesday, December 5, members of the A.S.M.E. witnessed a demonstration of the Christie amphibious gun mount and as a special feature of this session, motion pictures of the demonstration were shown. In addition, the War Department displayed pictures of motorized artillery and modern types of guns.

[7] Major, Ord. Div. U. S. A. War Dept. Fort Leavenworth, Kan. Mem. Am.Soc.M.E.

Aeronautic Session

PROF. E. P. Warner, Secretary of the Aeronautic Division, presided at the session on Aeronautics on Friday, December 7, at which the following papers were presented: Influence of Design on Cost of Operating Airplanes, Archibald Black;[1] The Airship for Long Haul Heavy Traffic Service, R. H. Upson;[2] and Air Navigation by R. W. Willson[3] and M. D. Hersey.[4] Mr. Black's paper appeared in the December issue of Mechanical Engineering. Abstracts of the other papers and discussion upon them will appear in a later issue.

Forest Products Session

ON Thursday afternoon, December 7, Robert B. Wolf, Vice-President of the Society, presided at the Session on Forest Products. The following papers, which will appear in abstract in a subsequent issue of Mechanical Engineering, were presented: New Factors Which Are Influencing Woodworking Machinery Design, S. Madsen;[5] Control of Lumber-Cutting Waste and Production, C. M. Bigelow;[6] Some Engineering Aspects of the Design of Musical Instruments, W. B. White;[7] Lumber Dry Kilns, Thomas D. Perry;[8] and Lumber Standardization, F. F. Murray.[9] Mr. Bigelow's paper is published in this issue and the other papers will appear in later issues.

Boiler Code Hearings

THE BOILER Code Committee held two hearings during the Annual Meeting. One on Monday morning, December 4, was devoted to the revision of the Code for Power Boilers. A number of groups entered into animated discussion of some of the features of the proposed Code. The safety-valve manufacturers discussed the limitation of the blowdown and multiplex casing; manufacturers of boilers for the oil country asked that the diameter of the dome be restricted to not less than 60 per cent; stamping was brought up by representatives of state and municipal inspectors; and there was also a discussion on the thickness of pipe walls. Although the Code for Unfired Pressure Vessels was not thrown open for discussion, there were a number present interested and they were given an opportunity to advance their views.

The hearing on Tuesday, December 5, on the Code for Low-Pressure Heating Boilers was taken up largely by protests against the requirement for preheating seams to be welded.

Hearing on Power Test Codes

AT THE Public Hearing on Monday, Dec. 4, the Test Code for Reciprocating Displacement Pumps and the one for Feedwater Heaters were discussed and a few changes suggested, after which it was recommended that the Council approve them for adoption as the recommended practice of the profession.

The First Power Exposition

THE first National Exposition of Power and Mechanical Engineering in New York City opened auspiciously on Thursday, December 7, and continued through December 13. Forty seven thousand five hundred and eighty visitors viewed the exhibits that filled one floor of the Grand Central Palace. The fact that this was the first show of its kind on a national scale makes it difficult to judge its value, but the comments of the visitors prove conclusively that a show of this character is needed and appreciated by those who are engaged in the design and operation of power plants. The Exposition was made up of over 100 exhibits and all classes of power plant apparatus and equipment, except large boilers and prime movers, were well represented.

ENGINEERING RESEARCH

A Department Conducted by the Research Committee of the A.S.M.E.

More Information Service

THIS time it is an informational clearing house for the whole of science and engineering. The National Research Council in Washington is maintaining such a service as one of its major departments in order to promote research and to extend its usefulness to industry by increasing the availability of reliable information.

Mechanical engineers naturally will use the Engineering Library and the resources of their society to meet special and technical informational needs. But they are likely to find it distinctly worth while to use the Research Council Information Service as a source of help in the case of border-line subjects and such as lie entirely beyond the confines of mechanical engineering.

Research Information Service has a technical staff representing the chief divisions of science and technology. Members of this staff are constantly answering inquiries about research problems, methods, processes, apparatus, reports, and their relations to industrial progress. The Service specializes in sources. If it does not happen to have at hand the facts you need, it most likely can tell you where to find them.

Except as special search of the literature, compilation of a report, or copying of data make a charge necessary, the aid of Research Information Service is free. Mechanical engineers are cordially invited to use this new informational clearing house, not in place of the specialized service provided in the Engineering Research pages of MECHANICAL ENGINEERING, but in addition to it. The best possible way to find out about the usefulness of Research Information Service is to try it. The proper form of address is Information Service, National Research Council, Washington, D. C.

Research Résumé of the Month

A—Research Results

The purpose of this section of Engineering Research is to give the origin of research information which has been completed, to give a résumé of research results with formulas or curves where such may be readily given, and to report results of non-extensive researches which in the opinion of the investigators do not warrant a paper.

Air A3–22. A STUDY OF AIR-STEAM MIXTURES. This investigation was conducted by LeRoy A. Wilson, Research Associate in Mechanical Engineering, under the general direction of Dean C. R. Richards. It is the outgrowth of an investigation of the reheating of compressed air by Dean Richards, and J. N. Vedder, Research Assistant in Mechanical Engineering, the results of which have been published. In this earlier investigation the employment of steam as a reheating agent was found to result in an increased thermal efficiency for the mixture of air and steam, as compared with the use of either air or steam separately, in an engine operating expansively. The purpose in operating a reciprocating engine with a working medium composed of a mixture of air and steam was to determine the possible advantages in thermal efficiency resulting from the use of such mixtures having different proportions of the two components and with different initial temperatures of the compressed air.

The results of this experimental work have just been published as Bulletin No. 131 of University of Illinois, Engineering Experiment Station, Urbana, Ill. This bulletin treats the subject of air-steam mixtures in considerable detail, by both means of a theoretical discussion, and by reporting actual tests made with different proportions of air and steam at different initial air temperatures and under various load conditions. The thermal properties of various mixtures are presented in the form of Mollier charts which will greatly simplify the solution of problems connected with the subject. The bulletin contains 96 pages and its price is 75 cents per copy.

Steam Power A5–22. A STUDY OF AIR-STEAM MIXTURES. See *Air A3–22.*

Iron and Steel A6–22. THE PREPARATION AND PROPERTIES OF PURE IRON ALLOYS. Scientific Paper No. 453 of the Bureau of Standards, entitled The Preparation and Properties of Pure Iron Alloys, deals with fundamental principles involved in the manufacture of steel products. To protect life and property it is necessary that the architect and engineer know the kind of steel which should be specified for each use. To know what composition a steel should have in order to withstand a certain amount of strain or to meet necessary requirements, the effects on the steel of each of its constituents must be known. The general effects of each of these constituents have long been familiar, but technical difficulties have hindered really thorough studies of the specific and exact effects of each of the elements. Very pure iron is difficult to prepare, and it is even more difficult to add a controlled amount of some one constituent of steel to pure iron without some contamination.

In this investigation iron of practically 100 per cent purity was prepared by an electrical method similar to the method of silver plating in which the metal is deposited from a solution by the passage of an electric current. The iron is plated out, leaving the impurities behind. This iron was then melted in a vacuum to exclude the effects of gases which would be taken up from the air if melted in contact with it. The heating was done electrically, and the containing crucibles were made of chemically pure magnesium oxide.

This paper will be ready in a short time and may be obtained from the Superintendent of Documents, Government Printing Office, Washington, D. C., at 10 cents per copy.

Photography A2–22. PHOTOMICROGRAPHY OF PAPER FIBERS. This paper describes some of the more important factors in the photomicrography of vegetable fibers, especially those used in the paper industry. As regards illumination it is shown that the carbon arc can be advantageously replaced by an incandescent stereopticon lamp. Different types of objectives are discussed, and it is shown that the working qualities of most objectives may be greatly improved by the use of proper light filters, three types of which are discussed. It is shown that where an object lying in different planes is to be photographed, an objective of comparatively long focal length will give better results than one of shorter focal length, and that this arrangement requires a longer bellows extension. Different types of photographic plates are described and suggestions as to the best type of plate to use for photomicrographic work are given. Suggestions for staining and preparing the material to be photographed are included, as well as some regarding the value of photographs for permanent records and in the study and control of materials and mill processes. A short bibliography on photomicrography and related subjects is given.

This very timely paper, known as Bureau of Standards Technologic Paper No. 217, was prepared by R. E. Lofton, Associate Physicist at the Bureau of Standards. Address Superintendent of Documents, Government Printing Office, Washington, D. C. Price 5 cents.

Wood Products A5–22. PHOTOMICROGRAPHY OF PAPER FIBERS. See *Photography A2–22.*

B—Research in Progress

The purpose of this section of Engineering Research is to bring together those who are working on the same problem for coöperation or conference, to prevent unnecessary duplication of work, and to inform the profession of the investigators who are engaged upon research problems. The addresses of these investigators are given for the purpose of correspondence.

Corrosion B9–22. SOIL CORROSION OF IRON AND STEEL PIPE. The damage to buried pipe structures due to the corrosive action of soil is known to run into enormous sums annually. In order to throw further light on the ways and means of reducing losses from this source, the Bureau of Standards instituted, about a year ago, a very comprehensive investigation into the entire subject. This investigation has been undertaken first, to determine what types of soils throughout the country are especially corrosive to iron and steel; second, which kinds of iron and steel pipe are most resistant to the corrosive action of particular types of soils, and, third, the most practical means of reducing damage from this cause.

The work is carried on with active coöperation of the principal manufacturers of iron and steel pipe, the large public-utility corporations throughout the country as the principal users of pipe, and the Bureau of Soils of the Department of Agriculture. The steel and public-utility interests are incurring the major part of the expense of the investigation. The Bureau of Standards plans and directs the work. Approximately 9000 specimens of pipe have been furnished free of charge by pipe manufacturers.

Owing to the very urgent demand from many sources, it is planned to increase considerably the scope of this investigation. The brass manufacturers have requested that numerous brass specimens be included in the test, particularly of fixtures designed to be used with wrought-iron and cast-iron pipes. It is planned also to include a considerable number of specimens of pipe coated with various types of protective coatings. These will include some additional specimens of pitch-treated pipe, but will more particularly refer to metal-covered pipe, such as those covered by the various processes of galvanizing, also lead-covered pipe for which rather strong claims have recently been made. Arrangements have been made with the manufacturers of galvanized pipe and lead-covered pipe to furnish the necessary samples. These will be buried at the various locations when the first inspection of the iron pipes is made. Address Director of the Bureau of Standards, Washington, D. C.

Iron and Steel B9-22. Soil Corrosion of Iron and Steel Pipe. See *Corrosion B9-22.*

Radiation B1-22. Emissivity of Cotton Cloth. Attention has been previously been called to an investigation which the Bureau of Standards is conducting to discover a roofing material which will keep the inside of a balloon hangar at a minimum temperature when exposed to the sun. It was shown that the most efficient means for reducing the heating of the interior of the building by solar radiations is by covering the outside of the roof with a highly reflecting substance, such as white paint or asbestos, and painting the inside of the roof with aluminum paint which is a poor radiator of the low-temperature long-wave-length radiation emitted by the roof.

During the past month a similar study has been made of white cotton cloth such as it used for tents. As is well known, when a tent is exposed to the sun the interior becomes uncomfortably warm from the sunlight which is diffusely transmitted through the cloth, and in particular as a result of the heat rays emitted by the cloth. By covering No. 10 duck on the inside with aluminum paint it was found that the heat radiation into the interior of the tent reduced 86 per cent. If the aluminum coating is on the outside the arrangement is less efficient, the radiation into the interior being reduced by only 78 per cent. While No. 4 duck would be too heavy for tents, it is interesting to note that by applying a coating of aluminum paint to the interior the heat radiation is reduced from 78 to 81 per cent. It is obvious that while such a tent would be more comfortable in the daytime, during the night the use of the coating of paint would act in the opposite way and retain the heat generated within, thus maintaining a higher temperature.

Welding B2-22. Test of Welded Rail Joints. An investigation is being conducted at the Bureau of Standards on the strength of rail joints in coöperation with the committee on welded rails, and six preliminary tests have been made of typical rail joints used on street railways. For this purpose the large horizontal Emery testing machine has been employed. Two specimens of thermit-welded joints, 1 riveted fishplate joint, and 1 standard 7-in. railroad rail section, as well as 2 specimens of electric butt-welded joints submitted by the Lorain Steel Company have been tested. The preliminary tests showed wide variations in the strength of the joints made by the different methods, but sufficient information was obtained concerning the method of test to determine the best means for gripping the specimens as well as the most satisfactory design therefore.

D—Research Equipment

The purpose of this section of Engineering Research is to give in concise form notes regarding the equipment of laboratories for mutual information and for the purpose of informing the profession of the equipment in various laboratories.

Instruments and Apparatus D1-22. Sprague Dynamometers. The Division of Engineering, Brown University, has recently installed in oneof its laboratories two Sprague dynamometers each having a capacity oe 200 hp. These dynamometers may be used either separately or tofgether and are completely equipped with all the necessary auxiliary apparatus. With this apparatus power tests from 15 to 600 hp. may be made and the authorities of Brown University desire to make it known that these facilities are available. Those interested may address Prof. William H. Kenerson, Division of Engineering, Brown University, Providence, R. I.

CORRESPONDENCE

CONTRIBUTIONS to the Correspondence Department of Mechanical Engineering are solicited. Contributions particularly welcomed are discussions of papers published in this journal, brief articles of current interest to mechanical engineers, or comments from members of The American Society of Mechanical Engineers on activities and policies of the Society in Research and Standardization.

The Accuracy of Boiler Tests

To the Editor:

I have read with very great interest the correspondence under this heading, and I am afraid that fear of taking up too much space in your columns prevents me from joining in the discussion on all the very many different points that have been raised. I will content myself, therefore, with the question of the amount of steam or power used auxiliary to the production of steam.

A very serious defect in the revised A.S.M.E. Boiler Test Code, which applies still more forcibly to the British Institution of Civil Engineers' Code, is the scanty attention given to this question of steam or power used auxiliary to the production of steam. The simplest boiler plant, merely for the sake of illustration, can be taken as one boiler only, without any accessories, evaporating say, 5000 lb. of water per hour, and working with an injector, in which case the real steam output of the plant—apart from the infinitesimal amount of energy used by the injector—is 5000 lb. of steam per hour, and the real net working efficiency of the plant can be calculated on this evaporation. If now we use any appliance whatever auxiliary to the production of steam, which consumes steam to work it, then this amount of steam must be deducted in calculating the net working efficiency of the plant. If, for example, we install a steam-jet furnace taking 10 per cent of the production of the plant, that is, 500 lb. of steam per hour, then the real net working efficiency has to be calculated on an evaporation of 4500 lb. only, since this is the amount of useful steam that passes the stop valve into the factory. This sounds so elementary as to be hardly worth mentioning, but practically every boiler test that has been carried out in the world for the last century ignores this simple fact.

In my book, Boiler Plant Testing, I have given the exact detailed figures for the performance of 400 steam boiler plants in Great Britain, representing 1513 boilers in 41 different industries, and with a total coal bill of 3,250,000 tons per annum. In these boiler plants, which are thoroughly representative of British practice, and probably also, in fact, of steam generation throughout the world, a very large amount of auxiliary steam is used for coal conveyors, ash conveyors, mechanical stokers or mechanically moving bars, steam nozzles, mechanical forced or induced draft, boiler-feed pumps, water-softening plants, driving of economizer scrapers, in the electrolytic treatment of feedwater for the prevention of corrosion, soot cleaners, and for various other purposes, so that I should estimate that the amount of steam used in cylindrical boiler-plants under average good conditions can very easily reach $12^1/_2$ per cent of the production, and in the case of water-tube boilers $4^1/_2$ per cent. The worst example is that of the use of steam nozzles, and out of the 400 plants tested, 153—that is 38 per cent—were fitted with steam nozzles, the average amount of steam consumed by these being $6^1/_2$ per cent of the production, and varying from 0.5 per cent to no less than 21.5 per cent in individual plants.

It is of course absolutely necessary to deduct this auxiliary steam in calculating the real net working efficiency of the boiler plant, but the general lack of understanding on this point is seen by the fact that we have today firms making appliances for steam generation advertising broadcast figures of tests in which 75 to 80 per cent boiler efficiency is shown, while at the same time the fact that their own appliance may be wasting from $2^1/_2$ to 20 per cent of the steam production is coolly ignored.

The A.S.M.E. Revised Code only considers this matter of sufficient importance for a footnote, and merely states that such auxiliary steam ought to be determined and a record made if it has been included in the calculations or not. There is not the slightest indication given that this question of auxiliary steam is just as important as recording the amount of coal used and water evaporated, and that without such proper record, boiler testing is worthless. As I have stated in my book, the whole question of boiler-plant testing is a most complicated one, being a combination of technical chemistry and engineering quite outside ordinary practice, and it is high time, in my opinion, that we have an International Code devised which will put the matter upon a sound and practical basis.

David Brownlie.

Manchester, England.

Commercial Aviation in America

Howard E. Coffin

Any fair discussion of commercial aviation in our country today must of necessity consist largely of prophecies. For, to be frank, with certain notable exceptions there is little of commercial aviation worthy of consideration either as a transportation business or a production industry.

But we must not confuse frankness with pessimism. Just the same kind of statement might just as truly have been made twenty years ago with reference to the automobile business, and yet in these few years we have seen the motor-car industry achieve its present great place in the world's commercial affairs. What may not aviation, profiting by the experience of its automotive brother, be expected to do in a similar time? For here we have fulfilment of man's age-old dream, and here again the desires and needs of humanity are being served.

We are, in my own opinion, just upon the threshold of a remarkable expansion in the aeronautical-transportation art. Civilization, since the beginning of time, has never turned its back upon the newer, speedier, and more luxurious forms of locomotion and will not fail to grasp flying and develop it as an important adjunct to existing agencies of traffic and travel. The possibilities so far overshadow the problems that a successful commercial development of considerable magnitude seems beyond question.

A consideration of the many things to be done before we can expect aviation to become a dividend-paying agency in the commercial service is important. Listed in the order of pressing need they are:

First, control. An authoritative federal agency must be established by legislative action and charged with the regulation, encouragement, and control of air navigation. Federal inspection of all ships for airworthiness must be provided. All pilots and mechanics must be examined and licensed. A bureau for such work in the Department of Commerce is proposed in the Wadsworth-Hicks Bill now before Congress. The enactment of such legislation is essentially fundamental to any healthy growth of our aviation art.

Second, public confidence. Stunting at the county fairs, deviltries, and flights in poorly constructed and uninspected planes or by inexperienced pilots have occasioned far too many crashes. These accidents, emblazoned upon the front pages of our newspapers in the most sensational manner, have firmly instilled in the public mind the idea that all aviation is dangerous. Not until a convincing background of safe, sane flying history has been written in American air annals, covering a period of several years, will this fear be supplanted by confidence and faith. Time, energy, and skill expended in engineering achievement and in safeguarding air performance will slowly but surely overcome this handicap.

Third, governmental coöperation. Our nation, as a whole, is vitally concerned that commercial aviation shall progress rapidly. For such development constitutes an essential and fundamental basis upon which rest all plans for the future military-naval defense of our country. Perhaps the greatest single need of the moment is the adoption by our Government of a definite, comprehensive, and continuing program for the encouragement of our American aeronautical progress.

To illustrate, no direct subsidy is needed, but there is essential that same federal coöperation and assistance that is given our water-borne agencies of commerce. The Government has for many years indirectly subsidized shipping by the provision of ports, the charting of sea routes, the maintenance of bureaus for the disseminating of weather forecasts or meteorological data, the coast guard, the lighthouse service, and many other aids to water navigation. For our railroads there have been land grants and concessions, rights of condemnation, and elaborate federal bureaus governing labor and rates. The same kind of general aid must be extended aviation in the provision and maintenance of landing fields, wireless and radio signaling stations, beacon lighthouses for night flying, in scientific research, the charting of air routes, a code of air regulations, and in many other practical details.

Fourth, laws. Today the only law governing aviation in America is Newton's law of gravity. Forty countries have national air laws regulating the operation of civilian aircraft, designed specifically to encourage and regulate aviation as well as to eliminate flying accidents through reckless piloting or the operation of unsafe machines. Twenty-six nations have ratified the International Air Convention drawn in Paris in 1919. The United States of America is not among either class but is listed with Abyssinia, Persia, Bhutan, Nepal and Oman as countries which are not yet sufficiently forward-looking to enact legislation safeguarding life and property in air commerce.

The four needs enumerated are paramount. There are many other items in the catalog of aviation's requirements which can be met when time and experience permit. But, for the enthusiast of today, these four are immediately pressing and afford ample objective toward which our initiative and energy may be directed.

To aid in the settlement of these questions of commercial aviation, as well as to lend a hand in military and naval preparedness in the air, a new national body has recently come into being—the National Aeronautic Association. Born of the desire among thousands of our citizens for a channel of expression on aviation affairs, representative of every section of the country and of every element of our population, wholly without selfish ends, this association fills a well-recognized need and its formation marks one of the brightest spots in American aeronautic annals.

We have had for some time the Aeronautical Chamber of Commerce, representing the manufacturer and the operator; we have had the Society of Automotive Engineers, representing the designer and the inventor; and now we have that essential third member of the triangle, the National Aeronautic Association, representing the people themselves.

Thus, the picture is not empty of accomplishment. Even though we are in the infancy of commercial aviation, we have achievements to our credit of which we may well be proud. America holds all principal air records of the world: speed, endurance, altitude, long distance, all of which stand to the credit of American engineers, designers, pilots, and mechanics.

We have in the phenomenal performance of our transcontinental Air Mail the world's greatest application of commercial aviation. Every day except Sundays and holidays this service covers a round trip of 5360 miles, an annual flying schedule of 1,800,000 miles. From July 16, 1921 until September 7, 1922, this service flew ap-

proximately 2,000,000 miles without a fatal accident. During the fiscal year ending June 30, 1922, an efficiency of 94.39 per cent was maintained. That is, during that year out of every 100 trips scheduled, 94.39 were finished on schedule time. And remember that this route crosses three mountain ranges, the Alleghanies, the Rockies, and the Sierras.

Of almost equal importance has been the record of the Aeromarine Airways Company, specializing in passenger transportation. During the past three years this company has flown more than 1,000,000 miles, carrying more than 15,000 passengers and without a single mishap. It is only by an actual showing or promises performed that the public confidence can be gained and retained, and the wonderful records being made by the Air Mail Service and the few commercial companies operating are doing much toward this end.

We may well be optimistic. For, with all these records of achievment to the credit of our air industry, and with a strong national patriotic body dedicated to the furtherance of this new transportation art, it lies easily within our hands to put "America First" among the world's air powers.

Let's do it.

Howard E. Coffin.[1]

The A.S.M.E. Annual Meeting and the Power Exposition

THE holding of the first National Exposition of Power and Mechanical Engineering following the recent Annual Meeting of The American Society of Mechanical Engineers resulted in an instructive combination that should do much to inspire the members of the A.S.M.E. The meeting with its broad, diversified program and well-balanced sessions established a new precedent, and its supplement this year with a technical exhibit added an element of appeal that will be strengthened as the scope of the Exposition grows.

The Committee on Meetings and Program is somewhat concerned about the intensity of the past meeting with its twenty-four professional meetings, four entertainments and several excursions and industrial visits. Under the present conditions of great activity and diversity of members' interest it cannot be relieved, and the Committee must rely on its ability to arrange a program with the least amount of conflict between sessions with related papers. The problem will grow more severe as the Professional Divisions of the Society increase in activity. However, wealth of material for meeting programs is an embarrassment to be welcomed and one that can be overcome by the provision of more meetings or the diversion of material to regional meetings.

Notwithstanding the intensity of the Annual Meeting program, members have asked that the Power Exposition be arranged to parallel the meeting rather than follow it so that those from a distance may have more time to attend the meeting sessions they desire and also to spend the necessary amount of time at the Exposition. The Committee on Meetings and Program is giving consideration to this arrangement which is desirable and seems practical. The increase over last year in the number of out-of-town members who registered at the meeting this year is one reason why careful thought should be directed to the parallel plan.

The announcement that the Power Exposition will be continued next year will be greeted with pleasure by those who visited the Grand Central Palace this year and enjoyed the collection of latest devices, the mass of instructive data, the complete program of interesting educational moving pictures and the remarkable opportunity for broadening acquaintances. Although some important classes of power-plant equipment were not thoroughly represented, and it is hoped this omission will be corrected as the Exposition becomes established; the general character of the exhibits was excellent and every one who visited the Show carried away some ideas.

One important function of the Exposition must not be neglected. It is visited by many individuals who may not be informed about the problems of generating, distributing, and using power. In fact only a small percentage of people do understand the variety and severity of the engineering phases of the power problem. As Dean Kimball pointed out in his presidential address, the engineer has a grave responsibility in maintaining civilization. A more general appreciation will assist the engineer in shouldering this responsibility, and an exhibit such as this will assist greatly in extending general knowledge if the coöperation of the exhibitors is secured.

[1] President, National Aeronautic Association.

Improvements in The Engineering Index

THE Committee on Publication and Papers takes great pleasure in announcing two changes in The Engineering Index which it is hoped will greatly increase its service value to the readers of Mechanical Engineering. One of these is the placing of the Index items on one side of the sheet only so that items may be clipped, and the second is the addition of one page of items from technical journals received up to three days before going to press.

The Committee has been encouraged in making these changes by the increased demands on the Library for information, especially about articles from the current technical press. These requests come not only from research organizations but from individuals who are anxious to broaden their knowledge and who rely on The Engineering Index as their guide to the many excellent publications in the engineering field. This increased demand is also an encouraging symptom, indicating that the engineering public is becoming appreciative of the sources of recorded experience. For a long time we have felt that engineering libraries were not appreciated or used as widely as they should be by engineers, but the increase in use of the Index is an encouraging indication.

Perhaps a word should be said in explanation of the page of late items. The operation of setting the main portion of the monthly Engineering Index in type is laborious and requires painstaking proof reading. It is desirable to get this completed before the remainder of the text pages is ready and the Index is therefore closed a considerable time before the date of mailing. The inclusion of late items on a separate page will thus bring the Index more nearly up to date.

The Engineering Index must of necessity be selective, as the inclusion of all articles in all technical publications is obviously impossible. The annual volume of The Engineering Index includes all items that have been indexed from the publications that come to the Engineering Societies Library, but Mechanical Engineering contains only those of particular interest to mechanical engineers.

Engineers from Egypt and Czechoslovakia Study American Methods

ILLUSTRATIVE of the growing recognition of the internationality of engineering is the mission of ten graduates of the engineering schools of Egypt who have been sent to America by the Egyptian Government to study manufacturing methods in this country. Their expenses during the two years that they will remain here will be paid by the Egyptian Government. They have been placed in various factories by the Department of Commerce and will work as employees while they are acquiring a knowledge of American methods and machine-shop equipment. Subjects which will be studied by them are interchangeable manufacturing, railroad transportation, telephone systems, marine engineering, and internal-combustion-engine construction.

A young Czechoslovakian engineer is in this country on a similar mission in regard to the building trades. Through the aid of the Czechoslovakian Minister and the General Contractors' Association he will be enabled to obtain a thorough acquaintance with methods, equipment, and material used in construction in this country.

Undoubtedly these young engineers will have great influence upon the industries of their native countries in the near future. It is to be expected also that the introduction of American methods will increase the demand for American tools and equipment. But farther reaching still are the benefits accruing both to them and to us by the personal contacts thus established between members of the profession in those countries and in the United States.

The Monroe Palace—Administration Building of the

Brazilian Centennial Exposition, Opened in September, 1922

Calvin W. Rice Reports on South American Trip

Envoy to International Engineering Congress in Brazil Visited Eight Pan-American Countries—Standardization Work Pledged by Resident U. S. Engineers

YOUR Secretary sailed from New York for Rio de Janeiro on August 24 on the S. S. *Pan America*, the United States Shipping Board boat which carried the Secretary of State, Mr. Hughes, and his party to the Brazilian Centennial Exposition. I sailed as the official representative of The American Society of Mechanical Engineers and the other principal engineering societies of the United States and Canada, to the International Engineering Congress at Rio de Janeiro scheduled for September 17 to 30, and as the representative to the Brazilian Centennial Exposition of several civic bodies and of President D'Olier of the Sesquicentennial Exposition Association of Philadelphia of 1926.

When advised of my appointment, I saw an opportunity to link up membership on one of the sub-committees of the Inter-American High Commission with my relationship to the Engineering Congress and possible visits to associations of engineers in the several South American countries. Convinced of the beneficial results that might arise from such contacts, Herbert Hoover and Dr. L. S. Rowe, respectively president and secretary-general of the Commission, gave me letters to the corresponding officials of the Section of the Commission in all the South American countries I was to visit. Inasmuch as standardization of product in each country will promote the welfare of that country from both an industrial and commercial viewpoint, Mr. Hoover wrote me that—

> If his Excellency, the Minister of Finance,[1] finds it possible to hold a meeting of his Section of the Inter-American High Commission, I trust that it will be possible for you to discuss with some of the members the problem of standardization.

At that time, in all of South and Central America there was no such thing as a standardization committee or bureau. The need for work in this direction had long been apparent. This gave me a practical message to take to associations of both native engineers and members of United States and Canadian Societies in the countries I was to visit, for they, with their special training, could render a great service in such a work to the countries of their adoption.

With this in mind I purposely booked passage on the *Pan America*, for, knowing Secretary Hughes' personal admiration for Mr. Hoover, I wished to obtain, if possible, the official interest and support of the Secretary of State for Mr. Hoover's message. In several interviews on board ship I found Mr. Hughes enthusiastic over this particular activity of the Inter-American High Commission. He gave most helpful advice as to the method of presentation. He further gave his support in every way, and when I later presented my program to officials and engineering organizations I was able to say freely that it had the whole-hearted approval of our Secretary of State.

The high place which the engineer holds in South American affairs is indicated by the fact that outside of the government, the Club de Engenharia of Rio de Janeiro was the only organization that presented Secretary Hughes with an address during his first visit to Brazil. Mr. Hughes' recognition of the high place the engineer is to hold in world development is seen in his epoch-making address delivered at the dedication of the site of the monument which the United States is to give to Brazil. He said:

> The resources of science are marshaled under efficient direction to meet the peculiar increasing needs of civic life. . . . . But this fortunate land of Brazil is one of constant revelations and today more than ever before we are appreciating the limitless possibilities of its development, of the prosperity the future has in store for its people, and the extraordinary promise of their service to humanity. . . . . The various organizations now gathering here remind us that science has no frontiers. . . . . . . We have also gathered here the engineers for whose precise knowledge and trained hands Nature has long been waiting.

I arrived at Rio de Janeiro on September 5. The two weeks between that date and the opening of the Congress were spent by United States engineers in Rio in daily meetings to coöperate with the Club de Engenharia under whose auspices the Congress was being held. Our meetings, while not official in character, were a

[1] In every country but ours, the Minister of Finance is Ex-Officio Chairman of the Inter-American High Commission of his country. This work in the United States was transferred from the Treasury Department to the Department of Commerce after Mr. Hoover became Secretary of the Department of Commerce.

great aid in preparing for the Congress. Most of the papers that made up the program, lantern slides, and several motion-picture films on industrial matters were coming from the United States, and much patient and discouraging work was done in getting everything through the red tape at customs and ready for the meetings.

At a formal afternoon reception the Board of Management of the Club de Engenharia received my credentials together with those of Verne L. Havens, Editor of *Ingenieria Internacional* and delegate of the American Society of Civil Engineers. At another reception credentials were received from A. W. K. Billings, F. H. Shepard, and Dr. T. T. Read, representing civil, electrical and mining engineers.

The Congress itself was formally opened on Sunday evening, September 17. Dr. Pires do Rio, Honorary President of the Congress, who made the opening address, is Minister of Public Works and one of the most influential men of Brazil. He said in part:

> The word "engineer," builder of engines or machinery, as defined by the dictionaries, has actually a large significance in view of the magnificent industrial movement caused by the invention of the steam engine and its application to the industries of transportation and manufacture. . . . . The new industrial civilization, characterized by the use of the steam engine as a prime mover, and steel machinery as the instrument of operation, crowded the years of the last century with such a procession of important events that all that has gone before the Watt steam engine appears to be of but petty importance. . . . . . . The engineering profession responded to the call of this new state of industrial activity, and engineers ceased to be merely military officers, entrusted with the management of the crude machinery of warfare. They have become men of high technical education, accustomed to directing the work of exploitation of mines for the recovery of minerals, to designing and constructing blast furnaces, building railroads, laying pipe lines which supply cities with water and protect them from floods, and finally, to designing and building electrical machinery in all its modifications of shape and construction.

The address of Dr. do Rio was one of the high spots of the Congress. A brilliant banquet at the Jockey Club was given later in his honor and that of the officers of both the Congress and the Club de Engenharia, by engineers from the United States. It was an occasion which cemented the friendship of the engineers of the two continents.

Sessions of the Congress continued through October. The South American Railway Congress was scheduled to meet at the same time and place, and in order to avoid conflict the International Congress postponed some of its sessions so that it did not close on September 30 as had originally been planned. The attendance was not large. It consisted mainly of local engineers with a few from Chile, Argentine, and Peru. There were eight sections holding meetings. Four of these had for their presidents engineers from the United States. A fifth section had a United States engineer for its secretary. The sections and their presidents were:

1 Overland, Maritime, Fluvial and Aerial Transportation. The Pan-American Railway. Practical Means for Its Construction. (*President*, Dr. Santiago Vicuna)

2 Iron Metallurgy. (*President*, Col. C. H. Crawford)

3 Fuels. (*President*, Dr. Heitor Escardo)

4 Hydraulic Power, Its Utilization as Motive Power. (*President*, A. W. K. Billings)

5 Sanitation, Dams, and Irrigation. (*President*, Dr. Francisco Saturnino de Brito)

6 Maritime and Fluvial Ports. (*President*, Calvin W. Rice)

7 Machinery for Agricultural and Industrial Purposes. (*President*, Dr. Barbosa Goncelves)

8 Standardizing of Statistical Methods in Ports and Railways. (*President*, Verne L. Havens)

The actual accomplishments of the Congress are shown in three resolutions which were passed. The first was one to effect a permanent organization to carry out the resolutions of the Congress. The second recommended legislation in every Pan-American country to establish a standardization bureau as suggested by Mr. Hoover. The third was a resolution to call a meeting of the nations to develop the dream of the Transcontinental Railway. Minor C. Keith, of Costa Rica, the only living member of the committee which originally recommended the building of this railway, has been asked to call this meeting to order.

A specific piece of standardization work has already been undertaken by a group of United States engineers in South America who have pledged themselves to develop a list of all technical words and phrases used in Portuguese. As neither Spain nor Portugal has ever developed a technical vocabulary, technical words and phrases often have different meanings in different localities. Mr. Havens, as a representative of the McGraw-Hill Publishing Co., promised to publish this commendable work when it is completed. It is quite possible that a similar vocabulary of Spanish words and phrases will be compiled later.

As to the Exposition, I attended the opening session as the representative of civic bodies and of President D'Olier. However, the Exposition was not in readiness and had been postponed until December. As a personal representative of Mr. D'Olier and of the Societies, including the Engineers' Club, of Philadelphia, I gave a formal invitation to South American engineers to attend and participate in the International Engineering Congress to be held in Philadelphia in 1926. I was a guest at several receptions in connection with the Centennial Exposition, and certain others given in Mr. Hughes' honor. No one knows better how to entertain than our South American neighbors. The two largest receptions I attended, one given by the President of Brazil in the Catette Palace and the other given in the Itamaraty Palace by the Minister of Foreign Affairs, excelled in setting and magnificence anything ever given in the United States and remind one of the court functions of Europe.

I left Brazil on September 28, and between that time and my return to the United States on November 13, I visited Uruguay, Argentina, Chile, Peru, Panama, Costa Rica, and Cuba. In each country I had a uniform method of approach. I called first at the American Legation. The next step was to call upon the president of the local engineering society, and with him I then called upon the members of the Inter-American High Commission with

Interior View of the Jockey Club of Buenos Aires

my letters from Mr. Hoover and Dr. Rowe. In each country I urged—

1 That every professional man from the United States affiliate with the local engineering society of the country where he is residing, even if only temporarily;

2 That they form within or under the auspices of the local society groups of members of the National Engineering Societies of the United States for purposes of service to the local society;

3 That the local society link up with its government;

4 That the organization of engineers—members of U. S. Societies—link up—

a With their country's government through the embassy and commercial attaché and with the Inter-American High Commission;

b With the National Engineering Societies of the United States.

This, briefly, is the program suggested, and in several countries I was able to bring engineering organizations together with their governments for the first time. But in one country at least they are ahead of us in such matters: I refer to Cuba. If you will examine the census of Cuba for 1919 you will find that the National Board of the Census consists of three members, one chosen by the Civil Division of the Supreme Court, one by the Council of the University of Havana, and the third, an engineer chosen by the general council of the Cuban Society of Engineers. Furthermore, a law was passed in Cuba in October last providing for a commission of three to investigate Cuba's outstanding indebtedness, and this commission is to be similarly chosen: one by the Supreme Court, one by the Minister of Finance, and the third an engineer chosen by the Cuban Society of Engineers. Such participation in national affairs is an ideal toward which we may all strive.

In all the Pan-American countries I was impressed by the high regard with which the people hold those in the engineering profession. In all South America they are addressed as "Doctor" and are correspondingly respected. A man aspiring to a public career finds that an engineering education and training best fits one for political positions of responsibility and honor. Further, a South American is a world citizen with a keen grasp on international affairs. The newspapers of South America devote much space—especially preferred-position space—to international news and discussions, and murders and divorces are relegated to unimportant positions if published at all.

Without a single exception in my three months' travel of 15,000 miles everything was characterized by infinite patience and courtesy. So marked are these traits that it is essential that our official and commercial representatives to these countries have these qualifications and instincts. The ideals of our people are not truly represented if our representatives lack these qualifications.

The work of furthering international good feeling between our nation and the Pan-American countries will have the aggressive support of the South American engineer. The results of the International Engineering Congress are a foundation on which effective, permanent work may be built. Nothing less than a program devoted to the public good will form a basis for future work acceptable to the ideals of the engineers of the two continents.

Calvin W. Rice, *Secretary,*
The American Society of Mechanical Engineers

Engineer Heads Italian Embassy

Prince Gelasio Caetani, an engineer of international reputation and a member of one of the oldest families of Europe, has been appointed Italian Ambassador at Washington. He succeeds Senator Ricci who resigned when the Fascisti came into power.

The new Ambassador is a graduate of the School of Mines of Columbia University, class of 1903. Following his graduation he went West where he worked his way in true American fashion as miner, trammer, timberman and millhand. He later opened offices in San Francisco as a consulting engineer and became a member of the firm of Burch, Caetani and Hershey. The World War found Caetani still in this country but he returned to Italy immediately and became a Captain in the Engineer Corps.

The War record of Prince Gelasio is an enviable one. He was advanced to the rank of Colonel and three times decorated for bravery. It was Caetani who laid the mine that, with a single blast, blew up the whole top of the Col di Lana which destroyed an Austrian fort and opened the way for the Italian Army through the Cordevole Pass in the Upper Trentino. This feat was made possible by the practical experience which he had acquired in engineering studies in the United States. To accomplish it he designed a gallery under the fort nearly 2000 feet long.

After the war Prince Gelasio returned to the vast estates of the Caetani family near Rome where he combined a life of politics and business. He was one of the first of the Roman aristocracy to enter the political fight against socialism and communism. He became actively affiliated with the Nationalist Party when it was decidedly the unusual and unpopular thing for a man of his rank to do so. In December, 1920, Prince Gelasio enrolled himself among the original ninety Fascisti organized as a Roman cohort. At the last electoral campaign he was chosen a Deputy on the Nationalist ticket. He now comes to Washington as the first representative of the Mussolini Government there.

Underwood & Underwood
Prince Gelasio Caetani

The choice of Prince Gelasio Caetani to this important post is indeed a happy one. He is a true representative of the Italian people. The finest of Roman blood and traditions belong to him by inheritance; the right to represent Italy he has earned by personal service to her. For a thousand years the Caetani family has been closely identified with the history of the Eternal City. It has given several Popes and a number of Cardinals to the Holy See. The grandfather of Prince Gelasio, the thirteenth Duke of Sermoneta was a bitter enemy of the church and took an active part in bringing about the fall of the temporal power of Pope Pius IX.

Caetani himself has devoted his efforts since leaving the army to the stabilization of his war-stricken country in its dangerous period of reconstruction. Unemployment became a terrific problem. Communistic ideas took root and grew rapidly. For at least six centuries the Caetani family had owned a large part of the Pontine Marshes, celebrated in literature by Pliny the Younger. The land was unproductive. A low-lying lake with no outlet had over-flowed for centuries making marsh land that was of no commercial value. Returning from military life, Prince Gelasio planned and soon began the construction of a canal leading from Lake Caprolace to the Mediterranean. This mammoth undertaking, completed in 1920, reclaimed hundreds of acres of land for Italy. It was a big step in the solution of Italy's food and unemployment problems.

Although Ceatani is but in his forty-sixth year his wide experiences admirably fit him for the important post for which he has been chosen. He considers America his second home and his many friends here, who think of him just as "Gelasio Caetani," know that he is a personage as well as a Prince, a man who comes to Washington with a trained scientific mind and an understanding of the two countries whose immediate future relations lie largely in his hands.

Caetani is a member of the American Institute of Mining and Metallurgical Engineers. His friends in the National Engineering Societies are planning a dinner in his honor after his arrival in this country and the presentation of his credentials in Washington.

News of The Federated American Engineering Societies

National Board of Jurisdictional Awards

SPEAKING at a session of the A.S.M.E. Annual Meeting on December 6, L. W. Wallace, secretary of the F.A.E.S. characterized the activities of the National Board of Jurisdictional Awards as one of the most important and far-reaching pieces of work in which the Federation is engaged. Rudolph P. Miller, who is the representative of American Engineering Council on this Board, later addressed the membership on the organization, the activities, and the value to the nation of the Board. His chief purpose was to acquaint the engineers present with the salient facts concerning the organization, for despite the fact that it has been in existence since March, 1919, and has arbitrated a large number of jurisdictional strikes, comparatively few of the engineering profession appreciate or are even aware of its great influence on the building industry. Mr. Miller's address, together with supplementary details, is presented in the following paragraphs.

Practically since building-trades unions have been organized there have been from time to time disputes as to which group of mechanics should do certain work in connection with building construction. The development of asphalt shingles or strip shingles for roofing purposes, for instance, has been the cause of dispute as to whether such shingles shall be placed by the carpenter, whose jurisdiction over wooden shingles has never been questioned, or by the roofer, who has jurisdiction over other forms of roofing. Such disputes lead to strikes on building operations and the losses incidental to them fall directly on the mechanics and contractors, indirectly on the owner who must foot these bills, and ultimately on the general public.

The waste in industry due to such jurisdictional strikes has been estimated to run into millions of dollars. E. J. Russell, vice-president of the American Institute of Architects, and chairman of the Board, estimates that previous to the establishment of the Jurisdictional Board the cost of building operations was increased from seven to eight per cent unnecessarily because of jurisdictional strikes.

These considerations prompted the calling of conferences, about four years ago, of representatives from the American Institute of Architects, Engineering Council, the Building Trades Department of the American Federation of Labor, the Associated General Contractors of America, the National Building Trades Employers' Association, and the National Association of Builders' Exchanges. The purpose of these conferences was to organize a board to which jurisdiction in the building industry might be referred. It was a momentous step that was taken when these participating organizations voluntarily agreed to organize such a body and to accept and abide by its decisions.

The Board as now organized consists of eight members, one representative of the American Institute of Architects, one of the F.A.E.S., three representatives of the contractors' organizations, and three of the Building Trades Department of the A. F. of L. It is felt that such an organization is fairly representative of the building industry at large for the purpose of settling jurisdictional disputes.

Mr. Russell, who is an architect of St.Louis and the representative of the American Institute of Architects, has been the chairman of the Board ever since its formal organization in August, 1919. William J. Spencer, secretary of the Building Trades Department, A. F. of L., has been its secretary.

Complaints with regard to jurisdiction to be considered by the Board must be submitted in writing through the officials of one of the organizations that are parties to the agreement. A brief statement with regard to the complaint is forwarded to those who are immediately interested in the matter, and a time is set for the hearing of the case. Not only are the unions immediately affected given an opportunity each to present its claims and arguments, but frequently manufacturers and contractors who have an interest in the controversy are invited to present facts and evidence that they may wish to submit. For instance, in the dispute between the elevator constructors and the electrical workers over electrical work on elevators, the elevator manufacturers were given an opportunity to present their views. In that case the Board, in its endeavor to master the situation fully, went so far as to invite an elevator expert who had no interest in the dispute to give testimony on the technical questions involved.

Cases have also arisen where the manufacturers in offering a new material in building construction found difficulty in marketing their product because the mechanics of different unions claimed jurisdiction over the placing of that material, and architects hesitated to specify it for fear of starting a strike on the building. Such a case was that of Bestwall plaster board, in which case the matter was brought to the attention of the Jurisdictional Board through American Engineering Council.

A two-thirds vote of those members entitled to vote is required to render an award in all cases. That means ordinarily six votes are required. But according to the constitution, a member of the Board is not entitled to vote or to participate in discussion in executive session when the decision is fixed if he is immediately interested in the result of the controversy. In such cases provision is made for the appointment of an umpire whose decision shall be final.

Since its organization the Board has had about four meetings a year. It has rendered thirty-eight decisions, including fourteen confirmations of agreements that had been entered into some time previous to being presented to the Board, or that were the result of a suggestion in the course of a hearing. Generally a controversy was between two unions, but in six cases, three unions appeared as claimants for the same work, and in one instance four unions were involved in the dispute. Of the seventeen unions that constituted the Building Trades Department when the Jurisdictional Board was first established, thirteen have appeared as claimants before the Board.

Mr. Miller enumerated these unions, which include plumbers and steam fitters, iron workers, wood, wire and metal lathers, bricklayers and plasterers, painters, electrical workers, carpenters, roofers, sheet-metal workers, and elevator constructors, and stated that the decisions of the Board have been well observed and supported in practically all cases. The work of the Board was highly commended at the Cincinnati convention of the American Federation of Labor, in June, 1922, and at a recent meeting of the Executive Council of the A. F. of L. a resolution was passed condemning the jurisdictional strike and threatening drastic action against such unions as refused to join in any movement to avoid such strikes.

Mr. Miller felt that engineers and architects in many cases failed to support the work of the Board through lack of knowledge of its existence. What they are more especially asked to do in support of this movement was expressed in the resolution of the Board at a meeting in March, 1922, as follows:

Resolved, That the members in the American Institute of architects and The Federated American Engineering Societies insert in all specifications and contracts for building operations a stipulation that the decisions of the Jurisdictional Board shall be observed.

Mr. Miller cited a number of cases in which the decisions of arbitrary bodies have been upheld by the courts and stated that he believes that such decisions indicate that the courts would heartily support any movement, such as the work of the Jurisdictional Board, that would tend to eliminate dispute and trouble.

Referring again to the extra expense of building operations because of jurisdictional strikes, Mr. Miller stated that while it is practically impossible to get definite figures, an estimate made by Mr. Russell places the present cost at about-one-half of one per cent of the total.

Topographical Mapping

AMONG the important questions which will be discussed at the annual meeting of the American Engineering Council to be held at the Cosmos Club, Washington, D. C., January 11 and 12, is that of topographic mapping. Secretary Wallace, at the Business Meeting of the A.S.M.E., said that topographic maps of only about 34 per cent of the area of the United States have been completed. At the present rate of progress it will take from 80 to 100 years to complete the topographical survey of the country and the production of the necessary maps.

Realizing the pressing need for such maps, the Federation will give its active support toward the passage of the Temple Bill which provides a plan whereby the work may be completed in from 20 to 25 years. Efforts will be made to have this bill brought up for hearing in the near future. Meanwhile the state administrative committees of the F.A.E.S. are coöperating with the state geologists throughout the country in an educational campaign on this subject. Information is being assembled as to the progress of topographical work in the various states and existing and proposed legislation thereon so that senators and congressmen may know the respective requirements of their states.

The necessity for such maps is said to be just as pressing in the East as in the South and West. They are essential to highway and railway construction, to the location of barge canals, feeders and reservoirs, to flood control, hydroelectric development, and to land drainage, which latter affects not only the productivity of the land but also, through problems of municipal water supply and sewage disposal, the health of the nation.

Government reorganization, the Muscle Shoals investigation, letting of Government contracts, flood control, elimination of waste, and the 12-hr. shift in industry, together with other matters which have been part of the F.A.E.S. program during the past year, will be reported upon at the Annual Meeting.

Code for Identification of Piping Systems

IDENTIFICATION of fluids carried by pipes has in the past engaged the attention of many managers of industrial plants and superintendents of power stations. Five systems of color identification were published in the July, 1921, issue of MECHANICAL ENGINEERING. One of these systems had been developed by a Special Committee of The American Society of Mechanical Engineers.

We can now report that the Sectional Committee there announced has completed its organization with twenty-six members who represent twenty-four organizations. A. S. Hebble, the representative of the Society of Naval Architects and Marine Engineers, was elected chairman of the Sectional Committee at its first meeting held June 14, 1922, and I. G. Hoagland, the representative of the National Automatic Sprinkler Association, was elected secretary. The principal business of the organization meeting after the election of officers was the appointment of the Plan and Scope Committee.

This Committee was headed by W. S. Morrison as chairman and consisted of E. J. Cole, Crosby Field, W. J. Venning, H. P. Weaver, W. S. Morrison, A. S. Hebble, and I. G. Hoagland. It held a series of meetings during the summer and early fall and on November 10 presented a very carefully prepared report to the Sectional Committee. After a very thorough discussion the report on Plan and Scope was unanimously adopted with a very few minor changes. An abstract of this report is given below.

PART I

General Limitations of Plan and Scope

The plan and scope of the Sectional Committee on Code for Identification of Piping Systems shall be confined to the code of identification of piping systems in industrial and power plants, not including pipes buried in the ground

Definitions

Piping systems for the purpose of this code, in addition to pipes of any kind, shall include fittings, valves, and pipe coverings. Note that there shall be specifically excluded therefrom supports, brackets, or other accessories. Note also that the definition of pipes shall be hollow conduits for the transport of gases, liquids, semi-liquids or plastics, but does not include solids, as pipes carrying solids are more properly believed to come under the general classification of conveyors. Note also, that electric conduits are specifically excluded.

By "power plant" is meant any plant producing any of the following substances: steam, gas for heating or lighting purposes, electricity, compressed air, vacuum, water pumping, refrigeration and ice, air conditioning; but specifically not plants for the production of various chemicals or in which operations are performed for other purposes than the transfer of units of heat from one form into another more readily usable form. Note that "power plants" specifically includes heating plants.

Identification

It is obvious that to attempt to outline a code in which every product liable to be transported would have its identification, would result in a system so comprehensive that even should the supply of colors and identification symbols hold out, adoption of it would be automatically rendered impossible in those industries which do not have a major group of colors allocated to its products. It is found, however, upon investigation, that any materials transported in pipes in a plant fall in one of the following classifications:

(a) *Safe Products.* This represents a majority of the products that are handled through a plant. These products may be defined as having no hazard in their handling and no extraordinarily high value, so that a workman in approaching a piping system to make repairs will run no undue hazard in breaking into a pipe bearing a safe material, even though that material had not been emptied by previous arrangement.

(b) *Extra Valuable Material.* This might be classified as a part of the safe materials above mentioned, but inasmuch as cases came to your committee's attention where those products would have a very high value, it appeared preferable to give them a separate major classification.

(c) *Dangerous Materials.* These materials are those which inherently in themselves are hazardous to life or property by virtue of being easily flammable or productive of poisonous gases or are in themselves poisonous. They include of course materials that are known ordinarily as fire producers and explosives.

(d) *Protective Materials.* Under this class fall materials which are piped through plants for the express purposes of being available to prevent or minimize the hazard of the dangerous materials above mentioned. Thus, a plant may have certain special gases which are antidotes to poison fumes, which gases are piped through their plants for the express purpose of opening or breaking the pipe in cases of danger.

(e) *Fire-Control Equipment.* This might properly be called a division of the Protective Materials just mentioned above, though the hazard of fire and the use of sprinkler systems and other fire-fighting equipment having become so universal, it would appear better to make it a special major classification.

These five classifications, or subdivisions thereof, if necessary, in the opinion of your committee should be each given a major color, and the various subdivisions that a plant may need can be obtained by the use of numbers, names, or the like, painted in white or black upon the background of the color selected.

Machinery for Further Work

It is suggested that this work be carried on by four committees, having not over five members each, appointed by the chairman, and having the following duties:

(a) *Executive Committee.* It is felt that the size of the entire committee is so great as to render it very difficult to transact any work other than that of approving and modifying codes presented to it. It is therefore suggested that an Executive Committee be appointed to act for the Main Committee subject to its approval, and to receive the reports of the other Sub-Committees. It is recommended that the personnel of this Committee consist of the Chairman and Secretary of the Main Committee and the Chairman of each of the three Sub-Committees mentioned immediately hereinafter.

(b) *Sub-Committee on Identification by Colors.* It is felt that there should also be a sub-committee whose function it shall be to present to the Executive Committee suggestions for various colors and confirmatory evidence that those colors can be used universally. It must be here interjected that some of the members having had the largest experience in this matter have found it almost impossible to use paints when subjected to various fumes, etc. The selection of the basic colors, therefore, should be those that are most nearly resistant to the ordinary acids met with in commercial practice. It shall also be the duty of this Sub-Committee on Paints to prepare specifications for the paints selected.

(c) *Sub-Committee on Classification.* It is obvious that there are a great variety of requirements in the large number of industries to be represented and yet unless practically all industries are included prior to the issuance of the code it becomes extremely likely that certain industries will find their needs have been overlooked. It is therefore suggested that a Sub-Committee on Classification be appointed, whose function it shall be to communicate with representatives of the various industries, obtaining from each industry a list of the materials piped through their plants, classified according to the classification given under paragraph five of this report. It shall also be the duty of this Sub-Committee to combine the data received from the various industries, placing all the materials under one of the five major classifications. When these data have all been compiled, the Sub-Committee on Classification shall meet jointly with the Sub-Committee on Identification Markings Other Than Color hereinafter mentioned, for the purpose of assigning the markings selected by that Committee to the various materials under the five major classifications as compiled by this committee.

(d) *Sub-Committee on Identification Markings Other Than Color.* It is also felt that a Sub-Committee on Identification Markings Other Than Color should be appointed, whose duty it shall be to investigate the various form and shape methods of identification and make recommendation as to the most practical method of marking. Upon agreement as to the best method of identification other than color, this Sub-Committee shall meet jointly with the Sub-Committee on Classification above mentioned, for the purpose of applying definite markings to the list of materials submitted by that committee.

PART II

In this part of its report the Committee transmitted two important items of information under the heads (*a*) Number of Pipes to be Identified and (*b*) Colors.

(a) *Number of Pipes to be Identified.* It came to the Committee's notice that the number of fluids which need to be identified varies greatly in the various plants. In some only one or two are employed, in others, as many as one hundred are to be found. One chemical plant was found to have twenty-four pipes carrying gases and twenty-three liquids.

(b) *Colors.* The use of red for fire fighting or fire control appears to be

universal, and it is therefore believed that a separate classification for fire-fighting equipment should be made, and that its color should be red, which is at present accepted. In addition to the use of this color for sprinkler lines, it is believed it should be extended to include various pipe lines such as those for Firefoam, etc.

In addition to red, the experience of the members of the Committee is that the following colors are obtainable in permanent or acid-resistant form: black, green, yellow, and aluminum.

In addition to these may be mentioned the possibility of soon obtaining white, gray, and brown.

In view of these conditions and referring to the classifications in the paragraph on Identification, it is suggested that the following be the basic colors for the classification of materials given:

a Safe Products.................. Yellow
b Extra valuable materials.......... Aluminum
c Dangerous materials.............. Black
d Protective materials.............. Green
e Fire-control equipment........... Red

Complying with the provisions of the report on Plan and Scope, Chairman Hebble made the following appointments:

F. P. Ingalls or E. J. Cole, *Chairman*, Sub-Committee on Identification by Colors
Crosby Field, *Chairman*, Sub-Committee on Classification
W. S. Morrison, *Chairman*, Sub-Committee on Identification Markings Other Than Color.

Sectional Committee on Colors for Traffic Signals Organized under A.E.S.C. Procedure

THIRTY-NINE men—representing as many administrative bodies, trade associations, scientific or technical societies, and Government departments—make up the Sectional Committee on Colors for Traffic Signals which was organized at a meeting in New York City on November 9 under the auspices of the American Engineering Standards Committee.

The committee elected as its officers the following representatives of the three sponsors for the code: Chairman, Charles J. Bennett, State Highway Commissioner of Connecticut, representing the American Association of State Highway Officials; Vice-chairman, Dr. M. G. Lloyd, representing the United States Bureau of Standards; Secretary, Walter S. Paine, Research Engineer, Aetna Insurance Company, Hartford, Conn., representing the National Safety Council.

The sectional committee by resolution invited the Aeronautical Chamber of Commerce of the United States to participate in the work of the committee. It was also decided at the organization meeting of the sectional committee to appoint a sub-committee to investigate the efficiency of all color signals now in use as traffic signals, and where possible to ascertain the reasons for adopting certain colors for specific uses. This committee will investigate the use of various types of semaphores and silent policemen. Another committee will make an original study of specific colors for definite uses as a check upon previous researches and to establish certain colors for traffic signals. A third committee will study non-luminous signs and signals (excluding luminous signals) and after a thorough research propose signs of definite colors and shapes for highways and also for railroad crossings.

Automobile Headlight Testing Specifications Approved by A.E.S.C.

ONE of the tribulations of the touring motorist—the hopeless attempt to comply with the automobile headlighting regulations of all the states through which he passes on his trip across the continent—will be removed as soon as the various state motor-vehicle departments have all adopted the Specifications of Laboratory Tests for Approval of Electric Headlighting Devices for Motor Vehicles which has just been approved by the American Engineering Standards Committee.

Even before these specifications had been formally approved by the A.E.S.C., nine of the states indicated that they would adopt the specifications; in three states they are already in effect.

These specifications were submitted to the A.E.S.C. by the Illuminating Engineering Society. This organization and the Society of Automotive Engineers have been appointed joint sponsors for any revision and further development of the code which may be necessary.

NEWS OF OTHER SOCIETIES

Taylor Society

The recent meeting of the Taylor Society was a particularly practical one in that the papers presented at its sessions were chiefly descriptions of actual conditions and problems in various concerns, and that ample time was allowed for discussion on each of them.

The first of the six addresses at the convention, which was held in New York, November 23 and 24, 1922, was by Percy S. Brown, works manager of The Corona Typewriter Company, Groton, N. Y. His address dealt with a specific type of manufacture, the continuous production of portable typewriters, their cases and a few accessories, for which it has been found expedient to departmentalize highly and to standardize operations. The functions of the various departments and their relation to each other were discussed in some detail by Mr. Brown, who also told of research work to develop standard operations. The Corona Company stimulates the interest of its foremen by holding bi-monthly conferences at which the management presents information on sales costs, items of expense, and other matters not usually brought to the attention of foremen, and gives an opportunity for discussion of all major factory problems. Reduction of manufacturing costs by the study of routing operations and precise control through the planning system has been effected to a large degree in the plants of the Corona Company. The discussion upon Mr. Brown's paper was led by L. Herbert Ballou, of the Lewis Mfg. Co., Walpole, Mass., and R. H. Lansburgh, Wharton School, University of Pennsylvania.

Dr. H. S. Person, managing director of the Taylor Society, speaking at an evening session on Thursday, November 23, on Shaping Your Management to Meet Developing Industrial Conditions, reviewed conditions during the last few years and showed the effect of the recent business depression upon various enterprises. He stated as his belief that there are still many difficulties to be met, particularly by those establishments which continue to employ conventional management methods.

Dr. Person said that he did not believe that future conditions could safely be forecasted from the present industrial activity and went on to point out some of the facts which have been learned from studies of business cycles and analyses of industrial conditions. He called attention to the fact that demand is going to be less than the productive capacity and said that the way out for the successful competitor seems to be to develop an inclusive system of management which will more than compensate for high prime costs by cost savings elsewhere, thereby effecting lower factory costs and making possible lower selling prices.

Among his suggestions for the new management Dr. Person emphasized the need of more thought being given to policy and general plans and advocated that definite master plans, budgets, and schedules of operation be devised for a considerable period ahead. Organizations should have units to analyze the market and interpret industrial statistics. Improved production methods should be more generally utilized and advertising should bear on the quality of staple merchandise rather than on the creation of new wants. The coöperation of the personnel is essential and the forceful, acquisitive type of executive should be balanced by the thinking, investigating, planning type.

A session on statistical compilation was particularly welcome as many business organizations seem to find it difficult to determine what statistics are essential and what are non-essential, and to establish a statistical technique which secures results precisely and economically. Harry B. Horwitz and H. J. Hutkin, chief speakers at this session, discussed some of the uses of statistical compilation as a function of scientific management, presenting a description of the organization, methods, results, and equipment of the planning department of the statistical and methods divisions of the Joseph and Feiss Company of Cleveland, with which both are connected.

The methods of the Hood Rubber Co. and those of the Dennison Mfg. Co. in analyzing the market and establishing coördinated schedules of sales production and finance on the basis of that analysis were described by representatives of those companies, W. W. Duncan and E. E. Brooks, respectively.

Philip J. Reilly, associate director of the Retail Research Association, New York, addressed the convention on November 24 on the subject of the reduction of waste through research studies in the

operating departments of retail stores, summarizing the results of recent studies that have been made by his association.

The closing symposium dealt with the supervision of personnel. It reviewed the development of personnel departments and the elimination of many of them during the period of depression following the war, pointing out the durable features of personnel work.

American Society of Refrigerating Engineers

The eighteenth annual meeting of the American Society of Refrigerating Engineers, one session of which was held in conjunction with the A.S.M.E. Annual Meeting, took place in New York, December 4 to 6, inclusive. The opening session was devoted to a business meeting, which included discussions of the Mechanical Refrigeration Safety Code and the Code for Unfired Pressure Vessels. New officers elected at this session were William S. Shipley, Brooklyn, N. Y., president, Van R. H. Green, New York City, vice-president; L. Howard Jenks was reëlected treasurer, and William H. Ross, secretary.

The joint session with the A.S.M.E., held on the afternoon of December 4, included two papers, one on the Economic Thickness of Insulation in the Refrigerating Field, by Percy Nicholls, Pittsburgh, Pa., contributed by the A.S.R.E.; and one on the Design of Cooling Towers, by C. S. Robinson, of the Department of Chemical Engineering, Massachusetts Institute of Technology, contributed by the A.S.M.E.

Mr. Nicholls, who is connected with the Research Laboratory of the A.S.R.E., defined the economic thickness for a heat insulation as that which will reduce to a minimum the sum of the expenses due to the heat passed through it plus the expenses of prevention. He interpreted this definition for such cases as the walls of ice and storage houses, pointing out the factors of monetary expense, and also for tanks, pipes, and cylinders. Mr. Nicholls stated that it was not his purpose to recommend a definite thickness, but rather to establish a standard of reference, and to set forth a basis of argument on which the figuring of the thickness may be done.

In Mr. Robinson's paper it was pointed out that engineers have designed cooling towers in the past on empirical information and in accordance with the experience of previous successful designs. Wide departure from standard designs is difficult because of the lack of scientific basis for the design. Mr. Robinson therefore established the general principle applicable to cooling-tower design and derived equations for the use of the designer. He presented a quantity of experimental data to substantiate the validity of his formulas and showed by an actual experiment how these formulas are applicable to the design of a counter-current cooling tower.

The presidential address, delivered by Harry Sloan of Milwaukee, Wis., retiring president of the society, at an evening session, December 4, was on the subject of educating and training the engineer. Other addresses at this session were by C. S. Cragoe, of the National Bureau of Standards, Washington, D. C., giving the physical properties of ammonia as determined by that bureau, and by H. J. Macintire, Urbana, Ill., on the Flexibility of Cast-Iron Radiators for Direct Expansion of Ammonia.

Two technical sessions were held on the second day of the convention at which four papers were presented and the commercial value of hydrocarbon refrigerants was discussed. George A. Horne, of New York City, described tests made at the Tenth Avenue plant of the Merchants' Refrigerating Co., New York, to determine the horsepower for varying condenser pressures of a single-acting simple ammonia compressor, and tubular condensers. The machine on which the tests were made is a vertical three-cylinder, single-acting, simple compressor of the enclosed type with pistons 18 in. in diameter and a 20-in. stroke. The machine is direct-connected to a synchronous motor and is operated at 164 r.p.m. The condensers are shell and tube, open type, in which the water is pumped over the top and flows through the tubes by gravity into an open pan. The condenser liquid is cooled in a double-pipe liquid cooler from which it passes to a shell-and-tube brine cooler. Mr. Horne's paper contained tables giving test data, power calculations and volumetric efficiencies, condenser calculations and data, and calibrations of the ammonia meter. He called particular attention to this method of measuring the refrigerating output of the compressor, which he said was a distinct refinement over any method of simply weighing or gaging the liquid during the tests.

A paper by W. G. Croll, of Wellington, New Zealand, described the design of several air batteries installed in a plant in southern New Zealand for use in the refrigeration of meat. Desirable features of this method are clean, dry freezing rooms and purer air, and although the first cost is expensive, the power factor is high.

There were also presented at this session papers on the Compresion Refrigerating Cycle, by W. H. Motz, Chicago, Ill., and the Reliability of Fluid Meters in Refrigeration Tests, by L. S. Morse, York, Pa.

The closing technical session was held on Wednesday, December 6, and included papers entitled Heat Waste in Ammonia-Compression Refrigerating Machines, by J. H. H. Voss, New York, and An Oscillating Compressor for Ammonia, by H. J. Macintire, Urbana, Ill., together with discussions of new things in refrigeration and other topics suggested by the membership.

Inspection trips were made to the Tenth Avenue and North Moore Street plants of the American Refrigerating Company, to the Hellgate Station of the United Electric Light & Power Co., and to the Carrier Engineering Corpn., of Newark.

Society of Naval Architects and Marine Engineers

The thirtieth general meeting of the Society of Naval Architects and Marine Engineers was held in New York during American Marine Week, November 8 and 9, 1922. Twelve technical papers were presented, a number of which dealt with subjects of interest to mechanical engineers.

Elmer A. Sperry, president of the Sperry Gyroscope Co., Brooklyn, N. Y., in a paper on Automatic Steering, described the method of operation of the "iron quartermaster" and its auxiliaries. Although best results can be obtained with this instrument, an experienced quartermaster, with the aid of a gyro-compass repeater conveniently located, can obtain a high degree of accuracy in steering. Mr. Sperry also discussed steering by magnetic compass and described separate and unit systems for automatic steering.

Edwin A. Stevens, Jr., vice-president of the Hoboken Land & Improvement Co., showed the results of applying Dyson's method of analysis to propellers of ocean-going merchant vessels. Three groups of ships were considered, namely, single-screw vessels; vessels fitted with two or more screws, the wing screw being carried in struts; and vessels fitted with two or more screws, the wing screws being carried in bosses or spectacle frames.

Results of wake tests performed upon different models by means of a current meter filled with wheels of varying diameter, were given by E. M. Bragg, professor of naval architecture and marine engineering at the University of Michigan. The study showed that any complete system for determining wake values must take account of the diameter of the screw relative to the draft of the ship; the draft of the ship relative to the breadth of the ship; the fore and aft position of the screw; the transverse position of the screw; the vertical position of the screw relative to the keel; and the vertical prismatic coefficient of the ship.

In a paper entitled Some Experiments on Propeller Position and Propulsive Efficiency, Rear-Admiral David W. Taylor, U. S. N., enumerated the factors affecting hull efficiency and described experiments upon a single-screw low-speed vessel to determine the propeller position.

A. D. Stevens, naval architect and consulting engineer, Jacksonville, Fla., gave a description of how a Government sub-chaser was converted into a 1650-hp. gasoline fire boat for Jacksonville.

Prof. William Hovgaard, Massachusetts Institute of Technology, presented a paper containing a brief description of the principal features of a ship of the Zeppelin type. He also took up the problem of the calculation of stresses and compared the method of transverse shears and of bending moments, giving reasons for the superiority of the latter method.

Points to be considered in the selection of propelling machinery from the point of view of the ship owner were given by J. L. Ackerson, vice-president of the Merchant Shipbuilding Corporation, Chester, Pa. Reliability, economy in operation, and weight were the factors emphasized.

The fact that the Second Annual Marine Exposition was held in New York during the week of November 4–11 gave those attending the convention an opportunity to see the latest developments in hull construction, propulsion machinery, particularly the Diesel

engine, and safety devices, and such modern equipment as the radio direction finder, the mechanical quartermaster described in Mr. Sperry's paper on Automatic Steering, and sounding apparatus.

National Personnel Association

The first annual convention of the National Personnel Association was held at Pittsburgh, Pa., November 8–10, 1922. This association was recently formed through the merger of the National Association of Corporation Training and the Industrial Relations Association of America.

Immigration was a principal topic of the convention. The effect of existing immigration laws on labor and industry, training immigrant workers, the social and economic effects of our immigration policy, and the immigrant's point of view were subjects discussed. Among the speakers were Michael I. Pupin, professor of electromechanics, Columbia University, and Magnus W. Alexander, managing director of the National Industrial Conference Board.

The Committee on Trade Apprenticeship Progress recommended that a system for developing sufficient training courses be centralized under a national organization that would embody representatives from the manufacturing, educational, and publishing institutions, and sub-organizations to introduce and supervise the work in different sections throughout the country.

The report of the Committee on Employment and Labor Turnover emphasized the need for coöperation between employment and operating departments, and for careful consideration on the part of the management in hiring, training, and discharging employees.

The Committee on Economics for Employees reported on an investigation of methods of training in industrial economics, touching particularly on the gathering of data illustrating the economic principles as they are working out through the various jobs and every-day relationships of the employee with his job, his fellow-employees, with the firm, and with his employers.

The Committee on Shop Training, headed by R. L. Sackett, dean of engineering, Pennsylvania State College, presented a report calling attention to the shortage of skilled workmen and outlining different types of training.

Discussing the development of men for executive positions, a committee headed by C. R. Dooley, manager of personnel and training, Standard Oil Company of New Jersey, said that "companies having had training courses for several years invariably report that the effort and expense involved are justified by the results."

The report on foreman-training methods stated that foremanship training to be really effective must be a continuous process, and prophesied that the work of the next few years will be not so much the development of new methods as better application of the methods already outlined to the conditions for which they are best suited.

The Committee on Personnel Problems of Small Offices reported that the chief fact discovered "is the almost total lack of a definite, planned training program in the majority of companies. Training in small offices has been left to take care of itself."

An especially important report was that on relations with engineering colleges, prepared by a committee of which W. E. Wickenden, American Telephone & Telegraph Co., New York, is chairman. The report enumerates ways and means by which assistance, through the Personnel Association, can be rendered by industries to engineering colleges.

Reports were also heard on health education, pensions for industrial and commercial employees, employee publications, and industrial and public-school relations, industrial motion pictures, and job analyses.

Other addresses at the convention were by W. W. Kincaid, Niagara Falls, president of the Association, on Nationwide Coöperation in Personnel Work, and by E. K. Hall, vice-president of the American Telephone & Telegraph Co., on Management's Responsibility for and Opportunities in the Personnel Job.

Inspection trips were made during the convention to the East Pittsburgh works of the Westinghouse Elec. & Mfg. Co., the Duquesne works of the Carnegie Steel Co., the Colfax power plant of the Duquesne Light Co., the American Window Glass Co., Arnold, Pa., and the Mellon Institute of Industrial Research of the University of Pittsburgh.

Lincoln New Dean of Electrical Engineering School of Cornell University

Paul M. Lincoln

On November 1, 1922, Paul M. Lincoln assumed his duties as director of the electrical engineering school of Cornell University, replacing Prof. Alexander Gray who died some months ago. Since 1919 Mr. Lincoln has been associated with the Lincoln Electric Co., organized by his older brother in 1904. Mr. Lincoln was graduated in 1892 from Ohio State University with the degree of M.E. in E.E., and then entered the employ of the Short Electric Co., Cleveland, Ohio. Later he was connected with the Westinghouse Electric & Manufacturing Co., Pittsburgh, Pa., and after two and a half years with that concern became electrical superintendent of the Niagara Falls Power Co., Niagara Falls, N. Y., where he was located for seven years. In 1902 he returned to the Westinghouse Co., where for about seven years he had charge of the power division of the engineering department. In 1910 he was appointed a general engineer with the company and remained with them until 1919, when he resigned to become associated with the Lincoln Electric Co. From 1911 to 1915 Mr. Lincoln acted as head of the electrical school of the University of Pittsburgh, while still carrying on his work with the Westinghouse Co.

Mr. Lincoln is a member of both the A.S.M.E., and the A.I.E.E., and was president of the latter society in 1914. In 1902 he invented the synchroscope, for which he was awarded the John Scott Medal by the City of Philadelphia on recommendation of The Franklin Institute.

Boston Gives M.I.T. Students Unusual Opportunity

STUDENTS at the Massachusetts Institute of Technology have been given an opportunity to assist in solving some of Boston's municipal problems in a recent offer made by that city through its mayor, James M. Curley. Four prizes of $500 each will be given for the best reports and working plans for solving certain problems connected with street traffic, street cleaning, malodorous and unsanitary nuisances, and fire-protective building construction.

The competition is open to any student enrolled at M.I.T. in 1922–1923 and is to be concluded May 1, 1923. The conditions of the contest stipulate that the recipients of such prize awards relinquish full rights, without further payments, to the use of the devices or methods proposed. One judge is to be selected by the mayor, one by the head of the Department of Civil and Sanitary Engineering at the Institute, and the third by the two so selected.

Chinese Board Specifies A.S.M.E. Boilers

In a recent communication Mr. Wm. Althoff, Asst. Chief, Industrial Machinery Division of the Department of Commerce, Washington, D. C., states that the Department has received copies of specifications for tenders invited by the Min River Conservancy Board, Foochow, China, for a steam-operated river-type hydraulic dredge for improving the channel of the Min River; tenders to be in the hands of the Board not later than February 15, 1923. These specifications include the following clauses:

> *Boiler.* The boiler shall be constructed in accordance with the specifications of the Boiler Code Committee of the A.S.M.E.—or other equivalent specifications.
>
> *Hull.* The steel used in the hull shall meet the requirements of the specifications for structural steel for ships of the American Society for Testing Materials—or other equivalent specifications.

The Min River Conservancy Board, although a Chinese Government organization is, through their representation on it, under the virtual power and control of the commissioner of customs and the foreign consular representatives and representatives of foreign commercial bodies. Its funds are supplied by a surtax on the regular customs tariff and the funds are administered by the Board though collected by the customs. The engineer in chief is an American.

LIBRARY NOTES AND BOOK REVIEWS

American Malleable Cast Iron. By H. A. Schwartz. First edition. Penton Publishing Co., Cleveland, Ohio, 1922. Cloth, 6 × 9 in., 416 pp., illus., diagrams, $7.

This book, the only American one on the subject now in print, is the work of a metallurgist with long experience in the industry. The volume opens with a historical account of the development of the malleable industry in the United States from its inception in 1820. The various phases of manufacture are then discussed, including the plant, materials, fuels, refractories and melting practice with air, electric, cupola and open-hearth furnaces. Succeeding chapters treat of annealing, molding and pattern-making, cleaning, finishing, inspecting and testing. The final section of the book is a study of the physical, thermal and electrical properties of malleable castings, in which is given much hitherto unpublished material. A selected bibliography of nearly 200 references is given.

A.S.T.M. Tentative Standards. 1922. American Society for Testing Materials, Philadelphia, 1922. Cloth, 6 × 9 in., $8.

The 1922 issue of tentative standards contains 163 specifications for engineering materials, such as metals, cement, lime, gypsum and clay products, preservative coatings, petroleum products, road materials, coal and coke, waterproofing, insulating materials, containers, rubber goods and textiles. These specifications are tentative, that is, they are distributed prior to definite adoption, for the purpose of eliciting criticism.

Anthracite and the Anthracite Industry. By A. Leonard Summers. Isaac Pitman & Sons, New York, 1922. (Pitman's Common Commodities and Industries.) Cloth, 5 × 7 in., 126 pp., illus., map, $1.

A brief non-technical account of anthracite mining, and of the advantages of anthracite as a fuel, with special reference to British conditions.

Belt Conveyors and Belt Elevators. By Frederic V. Hetzel. John Wiley & Sons, New York, 1922. Cloth, 6 × 9 in., 333 pp., illus., diagrams, tables, $5.

This book, the author says, is not a mere restatement of trade literature nor a collection of descriptions of installations of conveying and elevating machinery. It aims rather to explain principles and the reasons for doing things. The present volume deals with belt conveyors and belt elevators, and uses these machines, which are so widely useful, to illustrate some of the general principles that underly the design and use of conveying and elevating machinery. The author has had thirty years' experience in the design, manufacture and erection of machinery of this kind.

Berechnen und Entwerfen von Turbinen-und Wasserkraft-Anlagen By I. Holl. Third edition. R. Oldenbourg, Munich, 1922. Paper, 7 × 10 in., 181 pp., illus., 225 mk.

Holl's Calculation and Design of Turbine and Water-Power Plants was written with the intention to furnish all who are interested in water-power plants with a convenient assistant in solving the various problems that arise in calculation and design. To facilitate calculation, the author invented a turbine slide rule, the use of which is explained in this book.

In this edition, which is thoroughly revised, the book is planned to give the designer a concise introduction to all the structural and mechanical details of water-power plants, which will not only enable him to determine the turbine system for any projected plant, but will also give information upon the construction required in connection therewith.

Dyke's Automobile and Gasoline Engine Encyclopedia. By A. L. Dyke. Thirteenth edition. Goodheart-Willcox Co., Chicago, 1922. Cloth, 7 × 10 in., 1226 pp., illus., $6.

The new edition of this well known reference and instruction book has been entirely rewritten and rearranged. The number of pages has been increased from 960 to 1238, and the illustrations from 3362 to 4143. Intended for owners, repair men and students, the book is a remarkably comprehensive,compendium of information on automobile construction, operation and repair.

Electric Power-Plant Engineering. By J. Weingreen. Third edition. McGraw-Hill Book Co., New York, 1922. Cloth, 6 × 9 in., 511 pp., illus., diagram.

Intended to provide information on practical problems connected with the control of the generation and distribution of electrical energy. Theoretical discussions are reduced to a minimum, the book being primarily a record of current American practice in power-plant engineering. This edition has been thoroughly revised. New material has been added on oil switches, open-air switches, lightning arresters and outdoor sub-stations, and reactive coils and synchronous condensers have been discussed in greater detail.

Elektrische Oefen. By Oswald Meyer. Vereinigung Wissenschaftlicher Verleger, Berlin and Leipzig, 1922. Boards, 4 × 6 in., 133 pp., illus., $0.30.

This little book opens with a short historical review of electric-heating processes. Next are discussed the physical foundations, methods of measuring furnace temperatures, structural elements and materials for electric furnaces. This is followed by a chapter devoted to the various types of furnaces, classified by methods of heating. The remaining chapters discuss the use of electric furnaces in various industries, domestic electric apparatus for heating and cooking, electric boilers, etc.

Handbook of the National District Heating Association. D. L. Gaskill, Sec'y-Treas., Greenville, 1921. Fabrikoid, 5 × 7 in., $5.

Prepared by the Educational Committee of the Association, and intended as a working manual of district-heating practice, particularly with respect to engineering problems. The material is published in loose-leaf form, arranged in two general divisions, Steam and Hot-Water Heating. Each of these divisions is subdivided into the following groups: General, Generation, Distribution, Utilization, Metering. In addition to engineering data, commercial information supplied by manufacturers of apparatus is included.

Hutte. Hilfstafeln zur I. Verwandlung von Echten Bruchen in Dezimal-Bruche, II. Zerlegung der Zahlen bis 10,000 in Primfaktoren. Third edition. Edited by the Akademischen Verein Hütte. Wilhelm Ernst & Sohn, Berlin, 1922. Paper, 5 × 8 in., 83 pp., tables, 2 mks.

Two convenient mathematical tables, for the use of calculators and designers are given in this little book. Table I is a series of common fractions arranged in an increasing series and accompanied by their decimal equivalents, calculated to eleven places. It can be used to translate any decimal fraction into a common fraction, neither term of which will be greater than 100. Table II gives the simplest factors of all numbers not divisible by 2 or 5, from 1 to 10,000 and also shows the prime numbers in this range.

The tables are intended primarily for determining gear ratios for lathes, milling machines, etc., but are adapted for other uses as well. Examples of their use for various purposes are given.

Manufacture and Uses of Abrasive Materials. By Alfred B. Searle. Isaac Pitman & Sons, New York, 1922. (Pitman's Technical Primer Series.) Cloth, 4 × 6 in., 118 pp., illus., $0.85.

Brief description of abrasive materials and their preparation and of the manufacture of abrasive wheels, papers and polishes, together with advice upon the selection and testing of abrasives, and the erection and operation of grinding machines. Should be useful to those called upon to deal with grinding problems without any very extended experience in the art.

Manufacture of Dyes. By John Cannell Cain. Macmillan & Co., New York, 1922. Cloth, 6 × 9 in., 274 pp., $4.50.

This volume seems intended as a supplement to the author's earlier work, The Manufacture of Intermediate Products for Dyes. It describes methods for making a large number of commercial dyes,

giving details of the processes and referring to the English, American, French and German patents concerned, as well as to descriptions in books and periodicals.

Theory of Wave Transmission. By George Constantinesco. Second edition, revised. Walter Haddon, London, 1922. Cloth, 5 × 9 in. 209 pp., tables, 10s. 6d.

A detailed mathematical exposition of the theory underlying the method of power transmission invented by the author. In this system energy is transmitted from one point to another by means of periodic variations of pressure which produce longitudinal wave pulsations in a column of liquid enclosed in a system of piping connecting the wave generator and the tool or machine. Many advantages are claimed for the method, which has been applied practically to rock drills and other percussive tools and to trigger control in machine guns, and is now being adapted to the production of rotary motion.

Treatise on Bessel Functions. By Andrew Gray and G. B. Mathews. Second edition. Macmillan & Co., London, 1922. Cloth, 6×9 in., 327 pp., $12.

This book has been written in view of the great and growing importance of the Bessel functions in almost every branch of mathematical physics; and its principal object is to supply in a convenient form as much of the theory of functions as is necessary for their practical application, and to illustrate their use by a selection of physical problems, worked out in some detail. This new edition has been thoroughly revised. The earlier chapters have been rewritten, examples have been appended and additions have been made to the tables. A bibliography is included.

Welding Encyclopedia. By L. B. Mackenzie and H. S. Card. Second edition. Welding Engineer Publishing Co., Chicago, 1922. Fabrikoid, 6×9 in., 388 pp., illus., tables, charts, $5.

A reference book on the theory, practice and application of the four processes for autogenous welding. The first half of the book is a dictionary of the words, terms and trade names used in the industry. Included in this are instructions for the common types of repair and production work, descriptions of tests, specifications for rods and wires, and descriptions of the application of welding in various industries. Following the dictionary are separate chapters on the four processes for welding, giving detailed descriptions of each and instructions for its use. Chapters on boiler tank, pipe and rail-joint welding are then given, followed by a section on the regulations of federal and state authorities, and insurance companies, and a chapter on the heat treatment of steel. A collection of charts and tables and a catalog section are also provided.

TESTING INVOLUTE SPUR GEARS

(Continued from page 34)

ing gears. No matter how accurately a gear may be cut, if it is carelessly forced or keyed on its shaft or if the shafts are not in line in both planes, satisfactory operation cannot be obtained.

Discussion

B. F. Waterman[1] submitted a written discussion in which he said that the reason gears had not been inspected with quite the precision employed in the case of other and simpler pieces, was because gears were not the easiest pieces of mechanism to understand and measure.

In most shops if a pair of gears was noisy it was immediately assumed that the cutter was not right or, if the cutters had cut other gears that had run quietly, that the gear-cutting machine was at fault, when it was probably neither of these but rather carelessness on the part of the operator in setting up the machine, and perhaps improper mounting of the gears or, last but the least considered, the design of the gears or the machine upon which they were finally mounted to run.

If, however, proper care was taken in using the machines and cutting tools, and means were at hand for testing the gears, much trouble could be avoided. In all up-to-date shops an effort was made to check the first pair of gears taken off the cutting machine and, if they were not correct, steps could be taken to correct the trouble in so far as the gears were concerned.

In most shops the gear-testing machine first mentioned in the paper was sufficient, as it was a very easy one to use.

The Saurer machine seemed to have considerable merit and undoubtedly would find a place in many gear shops, but it was perhaps too exacting for most gears. With gears, as with everything else used in machinery, tolerances of greater or less degree had to be employed, and in most cases they were sufficiently great to make the use of charts unnecessary.

Charles H. Logue[2] wrote that the study of irregularities in pitch-line velocities was a study of the entire gear problem, and the paper was therefore of vital importance.

It might be claimed that there was little use in locating and measuring errors in the formation of gear teeth—that what was required was a means for producing gears free from error. The fact of the matter was that there was little chance for securing the means by which more perfect gears might be produced, until the nature of the errors encountered could be located, measured and understood. This must serve as a guide in the production of better cutters and hobs, as well as in the design of the teeth themselves. Again, to attain the highest quality or to maintain any uniform quality with the means at hand, facilities must be immediately available for a measurement of quality. In all other branches of machine-shop practice this was a recognized principle: it was only in the cutting of gear teeth that this principle was ignored.

The testing machine described by Mr. Estabrook furnished a definite means by which the accumulative error of a *pair of gears* might be measured, leaving no opportunity for a difference of opinion as to relative operating quality.

The service which might be expected of a pair of gears depended primarily upon their operating quality, or upon the correctness of the formation and spacing of the teeth. The trade, sooner or later, would specify this quality and accept or reject gears on percentage of error in pitch-line velocities—that is, they would ask for a definite measure of attainment.

Earle Buckingham[3] said that an inspection had two prime purposes: First, to see that the manufacturing facilities and processes were sufficiently accurate and reliable to produce the desired results; second, to test the results actually obtained—to sort out the good work from the bad. To test the tools required a great variety of equipment, which in many cases was laboratory equipment. Any facilities for testing the product itself should be extremely simple. The so-called feeler test was an extremely good one when the man who gave it understood what he was doing; but after he had sorted the good from the bad, he knew but very little as to why the bad ones were bad. That was where the more elaborate laboratory instruments came in.

F. E. Cardullo[4] said that after a gear had been tested by all of the processes which had been described, there still remained to be dealt with gears which were noisy. He believed that a part of the noise might be attributed to the fact that in the action of the gear during the angle of approach the effect of friction between the teeth was to increase the pressure angle, but after the recess the effect was to reduce the pressure angle. That meant each time the tooth passed the center line, there would be an alteration to some extent in the amount, and to a considerable extent in the direction, of the forces acting between the teeth.

Now, if these forces, which were absolutely independent of the form of the gear, were dependent only on the smoothness of action and the quality of lubrication, fell into natural synchronism with any of the natural vibration periods of the body in which the gear was mounted, a noisy set of gears would result, no matter how perfect the forms of the teeth and all the other features might be. He believed that a great many mysterious gear troubles had been due to something of that nature. There was a very wide field still for investigation in the action that went on in a pair of running gears, and the possibilities of trouble.

THE ENGINEERING INDEX

(Registered United States, Great Britain and Canada)

Exigencies of publication make it necessary to put the main body of The Engineering Index (p. 137-EI of the advertising section) into type considerably in advance of the date of issue of "Mechanical Engineering." To bring this service more nearly up to date is the purpose of this supplementary page of items covering the more important articles appearing in journals received up to the third day prior to going to press.

AIRPLANES

All-Metal. The Modern Airplane and All-Metal Construction, William B. Stout. Soc. Automotive Engrs.—Jl., vol. 11, no. 6, Dec. 1922, pp. 495–500 and (discussion) 500–504, 11 figs. Outline of structural problems followed by progress of development of thick-wing and all-metal airplanes with which author has been identified. Author believes that future commercial airplanes will have all-metal construction.

ALLOYS

Light. Some Points of Contact Between Metallurgy and Engineering, Owen W. Ellis. Eng. Jl. (Eng. Inst. of Canada), vol. 5, no. 12, Dec. 1922, pp. 576–581, 1 fig. Early development of iron and steel industry; research on alloys; economics of alloys of aluminum for structural work; composition and mechanical properties of duralumin; tests on a duralumin channel; important alloys recently investigated; possibility of use of light alloys in structural field.

AUTOMOBILE ENGINES

Moderate vs. High-Speed. The Low-Compression Low-Speed Engine for Motor Vehicles, F. Strickland, and The High-Compression High-Speed Engine for Motor Vehicles, H. R. Ricardo. Engineering, vol. 114, no. 2968, Nov. 17, 1922, pp. 627–630, 8 figs. Contributions to debate before Instn. Automobile Engrs. See also Automotive Industries, vol. 47, no. 22, Nov. 30, 1922, pp. 1079–1081.

Reciprocating Parts, Light-Weight. Advantages of Light-Weight Reciprocating Parts, L. H. Pomeroy. Soc. Automotive Engrs.—Jl. vol. 11, no. 6, Dec. 1922, pp. 508–515 and (discussion) 515–519, 1 fig. Influence of weight of reciprocating parts on chassis in general and engine in particular is emphasized as being of greater importance than actual saving in weight of parts themselves; tabulation of specific strengths of various materials used in automotive engineering shows advantages of aluminum as compared with steel; comparison of steel and aluminum connecting rods; advantages of using aluminum in connecting rod to secure stiffness.

BOILER PLANTS

Improvements. Plant Improvement Shows Large Saving. Power, vol. 56, no. 21, Nov. 21, 1922, pp. 790–794, 11 figs. Changes at plant of Int. Motor Co. made it possible for three boilers operating at 200-per cent rating to do work of eight used originally; large saving was effected by doubling evaporation per lb. of coal, resulting from change of boiler baffling and application of hand stokers. Plant, instead of consuming 50 tons of coal daily, averaged 50 tons last winter.

BOILERS

Electrically Heated. Electric Steam Boilers for Using Surplus Water Power. Elec. World, vol. 80, no. 23, Dec. 2, 1922, pp. 1211–1212, 3 figs. High efficiency, negligible attendance, small floor space and flexibility of operation claimed for electrically heated boilers; relative merits with essential requirements; three methods of heating water are available, indirect, direct and electrode system. Based on information from Hackethal Nachrichten.

CASTING

Centrifugal. Casting Steel Ingots Centrifugally, L. Cammen. Iron Age, vol. 110, no. 23, Dec. 7, 1922, pp. 1494–1496, 3 figs. Results from using horizontal bottle-neck mold; comparison with earlier attempts; excellence of ingots and their cost.

CRANES

Traveling. 100-Ton Overhead Electric Traveling Crane. Engineer, vol. 134, no. 3491, Nov. 24, 1922, p. 562, 3 figs. partly on p. 554. Four-motor electric crane, capable of lifting 100 tons, constructed for Japanese Navy by Vaughan Crane Co., Manchester, England.

CYLINDERS

Automobile Engines. Ford Engine-Cylinder Production, P. E. Haglund and I. B. Scofield. Soc. Automotive Engrs.—Jl., vol. 11, no. 6, Dec. 1922, pp. 463–471, 21 figs. Principles governing intensive quantity production; sources and methods of handling basic materials that compose Ford engine cylinder; fundamental plan of River Rouge plant.

DIE CASTING

Developments. Developments in Die-Casting Practice, Charles Pack. Machy. (N. Y.), vol. 29, no. 4, Dec. 1922, pp. 281–283, 3 figs. Die-casting dies; location of parting line; draft required in dies for castings made from different alloys.

Equipment. Equipment for Making Die-castings, A. G. Carman. Machy. (N. Y.), vol. 29, no. 4, Dec. 1922, pp. 261–263, 5 figs. Applications of die castings; general principles of die-casting machines; points on design of parts to be die-cast.

EVAPORATORS

Flash. The Flash Evaporator. Power, vol. 56, no. 22, Nov. 28, 1922, pp. 834–835, 3 figs. New type of apparatus for producing distilled makeup water.

Triple-Effect. How a Lillie Evaporator Operates. Power, vol. 56, no. 21, Nov. 21, 1922, pp. 802–804, 3 figs. Operation of triple-effect evaporator that operates on exhaust steam.

FOREMEN

Duties. The Rightful Place of the Shop Foreman, A. H. Rodrick. Indus. Management (N. Y.), vol. 64, no. 6, Dec. 1922, pp. 350–351 and 354. Tells how shop foreman can become most valuable link in management chain.

Training. Training Steelworks Foremen, B. M. Nussbaum. Iron Trade Rev., vol. 57, nos. 21 and 22, Nov. 23 and 30, 1922, pp. 1407–1408 and 1491–1492. Points out that management should participate in training; instruction and fundamentals of industrial management given in iron and steel industry with successful results; club idea failed.

FREIGHT HANDLING

"Veri-Direct" Method. The "Veri-Direct" Method of Handling L.C.L. Freight. Ry. Age, vol. 73, no. 23, Dec. 2, 1922, pp 1053–1057, 6 figs. Method of loading freight from freight houses into cars in use in Ohio region of Erie R. R., which has reduced errors and losses due to wrong loading about 70 per cent as compared with former conditions.

FURNACES, ANNEALING

Continuous. Continuous Annealing Furnaces for Sheets. Iron Age, vol. 110, no. 21, Nov. 23, 1922, pp. 1342–1343, 3 figs. Car-type furnaces with daily capacity of 125 tons each at Ashtabula steel plant; pulverized coal used as fuel. See also article by E. L. Shaner in Iron Trade Rev., vol. 71, no. 21, Nov. 23, 1922, pp. 1423–1427, 8 figs.

GAS PRODUCERS

Mechanically Agitated. The Stein-Chapman Gas Producer with Mechanical Agitator. Engineering, vol. 114, no. 2967, Nov. 10, 1922, pp. 597–598, 8 figs. Embodies Chapman floating agitator and new form of automatic ash extractor.

GEARS

Involute Curve. The Law of the Involute Curve, O. G. Simmons. Am. Mach., vol. 57, nos. 21 and 22, Nov. 23 and 30, 1922, pp. 801–803 and 837–839, 6 figs. Determining lead of involute curve; how right- and left-hand involutes may be generated; finding length of involutes; developed principles applied to generating gear teeth; adapting milling machine to cutting gear teeth with true involute.

HOBBING MACHINES

Testing. Testing Gear-hobbing Machines, D. Vaughn Waters. Machy. (N. Y.), vol. 29, no. 4, Dec. 1922, pp. 304–306, 5 figs. Testing fixtures used by Gould & Eberhardt, Newark, N. J.

HOBS

Manufacturing. Simmons Method of Hob Making, Charles O. Herb. Machy. (N. Y.), vol. 29, no. 4, Dec. 1922, pp. 255–260, 11 figs. Method of simultaneously generating and relieving teeth of gear hobs with revolving cutter resembling spur gear.

INDUSTRIAL MANAGEMENT

Instructions, Illustrated. Illustrated Instructions, Joseph Spielvogel. Management Eng., vol. 3, no. 6, Dec. 1922, pp. 365–369, 5 figs. Shows how, by use of illustrations in connection with such items as assembly drawings, bills of materials, stock, estimating, inventory and cost records, etc., it is possible to apply quantity production principles to manufacture of complicated machinery during plastic stage of development.

Tool Purchasing and Storage. Ordering and Storing Small Tools, W. J. Sansom. Am. Mach., vol. 57, no. 23, Dec. 7, 1922, pp. 869–872, 4 figs. Things to do and to avoid in ordering small tools; inspection and storage methods; systems of getting tools to workmen.

LATHES

Semi-Automatic Multi-Cut. New Semi-Automatic Multi-Cut Lathe, William O. Strauss. Machy. (N. Y.), vol. 29, no. 4, Dec. 1922, pp. 276–278, 4 figs. Machine developed by R. K. LeBlond Machine Tool Co., Cincinnati, turns work up to 12 in. in diam. and is made in various bed lengths giving max. center distances of 18, 26, 34, or 42 in.

LOCOMOTIVES

Power Reverse Gear. All-Service Locomotive Power Reverse Gear. Ry. Age, vol. 73, no. 23, Dec. 2, 1922, pp. 1051–1052, 4 figs. New non-creeping power reverse gear equally adapted to passenger, freight or switching service. Designed by Transportation Devices Corp.

MACHINE TOOLS

Selection. Selection of Machine-Tools, A. J. Baker. Soc. Automotive Engrs.—Jl., vol. 11, no. 6, Dec. 1922, pp. 520–528. Investigates problem of determining when to make change of equipment by substituting new machine tools for old, or special machines for standard.

Standard. Standard Machines Increase Production, L. S. Love. Iron Age, vol. 110, no. 21, Nov. 23, 1922, pp. 1335–1338, 9 figs. Savings effected in use of fixtures rather than in special machines; case of quintupled production. Changes made in production-plant layout at Gray & Davis Division of Am. Bosch Magneto Co.

Standard vs. Special. Standard versus Special Machine-Tools for Automotive Production, R. K. Mitchell. Soc. Automotive Engrs.—Jl., vol. 11, no. 6, Dec. 1922, pp. 472–473. Points out disadvantages attending use of special machines and benefits of using standard equipment whenever possible; possibilities of special jig-and-fixture design that would meet needs of manufacturers of standard parts.

METALS

Behavior under Stress. A Mechanical Model Illustrating the Behavior of Metals under Static and Alternating Loads, C. F. Jenkin. Engineering, vol. 114, no. 2968, Nov. 17, 1922, p. 603, 3 figs. Model is said to be capable of illustrating most of phenomena which metals exhibit when tested in any way under mechanical stresses not exceeding their yield points.

NICKEL-CHROME STEEL

Segregation. Ingot Corner Segregation in a Nickel Chrome Steel, T. Henry Turner. Engineering, vol. 114, no. 2969, Nov. 24, 1922, pp. 662–664, 9 figs. Experiences encountered in examination of large and medium-sized steel forgings which had been received for machining at some of most important engineering works in England. Paper read before Staffordshire Iron & Steel Inst.

POWER PLANTS

Economy in. The Cost of Power Per $100 of Pay-Roll, P. F. Walker. Management Eng., vol. 3, no. 6, Dec. 1922, pp. 339–342. Discusses economizing in power by (1) saving in fuel through greater efficiency at source, and (2) saving by eliminating losses in transmission and application within establishment.

PULVERIZED COAL

Equipment. Rochester Plant Installs Pulverized Fuel Burning Equipment, R. D. DeWolf. Power, vol. 56, no. 22, Nov. 28, 1922, pp. 845–847, 2 figs. Furnaces of two 8750-sq. ft. boilers converted to burn pulverized fuel; pulverizing equipment and coal bins located directly above boilers; no conveyors or driers used; one operator handles both boiler and pulverizer.

Power Plants. Modern Industrial Plant Burns Pulverized Coal. Power, vol. 56, no. 23, Dec. 5, 1922, pp. 868–874, 8 figs. New plant of Eline's, Inc., Milwaukee, contains complete fuel-preparation plant; special ventilation of furnace walls; economizers and hot-process water-softening system.

RAILWAY MOTOR CARS

Requirements and Future of. Motor Cars on Rails. Soc. Automotive Engrs.—Jl., vol. 11, no. 6, Dec. 1922, pp. 481–490, 5 figs. Contains following papers: The Field for the Rail Motor-Car, Roy V. Wright; Some Requirements for the Rail Motor-Car, W. L. Bean; Automotive Rail-Cars and Their Future Development, L. G. Plant.

REFRIGERATING PLANTS

Equipment Specifications. Value of Specifications in Purchasing Refrigerating Equipment, A. C. Bishop. Power, vol. 56, no. 23, Dec. 5, 1922, pp. 884–886. Paper read before Nat. Assn. Practical Refrig. Engrs.

STEAM ENGINES

Standard Extraction. Tandem Extraction Engine for Combined Power Production and Exhaust Steam Heating. Engineering, vol. 114, no. 2967, Nov. 10, 1922, pp. 584–585, 5 figs. partly on p. 558. Tandem compound engine, in which steam required for heating purposes is drawn from receiver between two cylinders.

Uniflow. Unaflow Valve Gear of American Design. Power, vol. 56, no. 23, Dec. 5, 1922, pp. 880–881, 6 figs. Describes several valve gears used on Filer & Stowell uniflow engines. Method of setting valves.

STEEL

Carbon, Manganese Effect on. Effect of Manganese on Carbon Steels, Henry S. Rawdon and Frederick Sillers, Jr. Iron Age, vol. 110, no. 21, Nov. 23, 1922, pp. 1357–1361, 7 figs. Their structure as affected by varying percentages; manganese as strengthening factor in low and medium steels. Published by permission of Bur. of Standards.

STEEL, HEAT TREATMENT OF

Case-Hardened Articles. Heat Treatment of the Core of Case Hardened Articles, H. B. Knowlton. Forging & Heat Treating, vol. 8, no. 11, Nov. 1922, pp. 526–528, 5 figs. Study of effect of carburizing heat upon core and of structure and strength of article carburized after various heat treatments.

Acceptance for mailing at special rate of postage provided for in section 1103, Act of October 3, 1917, authorized on January 17, 1921.

Contributors and Contributions

Methods of Ash Handling

John Hunter

Methods of removing ashes from boiler rooms, and systems of conveyance are described and illustrated in an article by John Hunter and Alfred Cotton, chief engineer and chief of the research department, respectively, of the Heine Boiler Company of St. Louis. Mr. Hunter was born in Scotland. He became a seagoing engineer at the age of twenty and during the Spanish-American War was chief engineer of the *St. Paul*, operated by the U. S. Navy. In 1905 Mr. Hunter became chief engineer for the Union Electric Light and Power Co., of St. Louis, and later aided in the development of the hydroelectric station which supplies this company with 60,000 hp. over a 100,000-volt transmission line.

Alfred Cotton

Mr. Cotton received his technical education through university-extension courses and private tuition in England while serving an apprenticeship in marine engineering. In 1903 he came to America where he developed the Cotton furnace. He manufactured and installed these furnaces until the war, when he entered the employ of Colt's Patent Fire Arms Manufacturing Co.

Stresses in Electric-Railway Motor Pinions

The results of a scientific study undertaken by the General Electric Company for the development of superior electric-railway motor pinions are reported in this issue by Dr. Paul Heymans and A. L. Kimball, Jr. Dr. Heymans, who is research associate in industrial physics at M.I.T., was born in Belgium in 1895 and educated at the University of Ghent, L'Ecole Spéciale des Travaux Publics in Paris, and the University of London.

A. L. Kimball, Jr., has been research physicist at the research laboratory of the General Electric Company since 1918. He was graduated from Amherst College in 1908 and from the Harvard Engineering School in 1914. He spent the year 1919–1920 in London studying Dr. Coker's method of stress analysis by the use of transparent models.

Torsion of Crankshafts

Dr. S. Timoshenko, who has recently become consulting engineer for the Vibration Specialty Co. of Philadelphia, presents a paper which discusses how the torsional properties of a crankshaft with a single throw may be determined. Dr. Timoshenko came to the Vibration Specialty Co. from St. Petersburg, where he occupied at the Polytechnic Institute the chair in the Theory of Elasticity as Applied to Ships.

Design of Cooling Towers

Prof. C. S. Robinson of the Massachusetts Institute of Technology has established a general principle applicable to cooling-tower design and derived equations for the use of the designer. In his paper in this issue he shows by actual experiment how these formulas are applicable. Professor Robinson was formerly a chemist in the employ of the Sherwin-Williams Co., the Rosseler and Hasslacher Co., and the Walworth Manufacturing Co.

Size Selection of Dry-Vacuum Pumps

A rapid and practically accurate method for determining the size of dry-vacuum pump to employ under any set of conditions is described by Edward W. Noyes and Harold V. Sturtevant, sales engineers for the Sullivan Machinery Company of Claremont, N. H., and Chicago, Ill. Both Mr. Noyes and Mr. Sturtevant are graduates of the Massachusetts Institute of Technology, class of 1921.

Feed Heating for High Thermal Efficiency

Linn Helander, a Junior Member of the Society, presents the results of an investigation made for the purpose of determining the correct feed-water temperatures for conditions of high thermal efficiency. Mr. Helander, after his graduation from the University of Illinois in 1915, was steam and hydraulic engineer for the Pittsburgh Crucible Steel Co. During the war he was supervising engineer of tests for the Ordnance Department in the Montreal district. Since 1919 he has been with the Westinghouse Electric and Manufacturing Co.

Lumber Dry Kilns

Thomas D. Perry, vice-president and manager of the Grand Rapids Veneer Works, believes that scientific kiln drying offers engineers a splendid field for research work. His paper pays particular attention to the several classes of ventilated kilns. Mr. Perry received his A.B. degree from Doane College in 1897 and his B S. in Mechanical Engineering from M.I.T. in 1900.

German Submarine Diesel-Engine Clutch

During the five years spent as supervising draftsman for the U. S. Navy Department, W. H. Nicholson had an opportunity to study the German types of submarine equipment. His paper gives to American builders of Diesel engines facts about German Diesel-engine clutches. Mr. Nicholson has done engineering drafting and designing for the New York Shipbuilding Corporation, the National Aniline Co., and the Newton Machine Tool Works. At present he is with the Westinghouse Electric and Manufacturing Co.

MECHANICAL ENGINEERING

Volume 45 February, 1923 No. 2

Methods of Ash Handling

By JOHN HUNTER[1] and ALFRED COTTON,[2] ST. LOUIS, MO.

Various methods of handling ash are described and illustrated in this paper, the greater part of which deals with stationary practice, beginning with rudimentary and progressing to the most modern installations, of which schematic and actual examples are given

Methods of removing ashes from basement boiler rooms are followed by a discussion of the design, construction, and capacity of hopper ashpits, including their doors and water seals. Systems of mechanical conveyance and elevation are described, comprising ash cars, skip hoists and bucket conveyors. Fluid conveyance, as represented by water sluicing and steam-jet conveyors, is discussed in general, and typical examples of both are illustrated and described in detail. Particulars of ash bunkers and settling basins are also given.

ASH HANDLING is just as important as coal handling. It was originally accomplished entirely by hand, but with the growth of the size of boiler plants it is now either partly or entirely mechanical. There are three general methods of conveyance in use; air, water, and purely mechanical.

The great development of the central electric generating station has compelled operating engineers to give much attention and thought to ash handling. It is only a few years since boilers of 600 hp. were considered large, while today 2000-hp. units are not at all uncommon and some 3000-hp. boilers are in use. Furthermore, while boilers were usually operated at about their rating of 10 sq. ft. of heating surface to the boiler horsepower, they are now commonly operated at twice their nominal rating; and in the larger central stations it is common practice to run them for short intervals at three or even

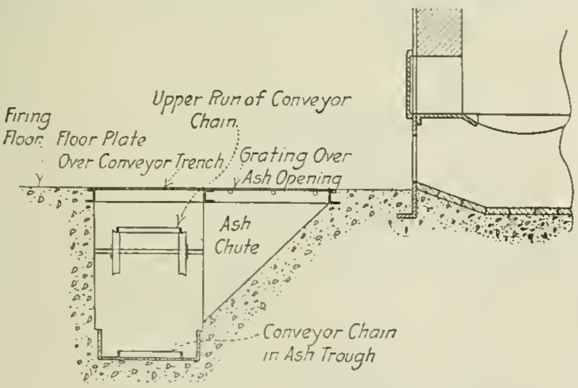

Fig. 1 Chain and Cross-Bar Conveyor

four times their rating. The bearing of this development on ash handling may be strikingly seen when we remember that a 250-hp. boiler running at rating and burning coal with 15 per cent of ash would make 150 lb. of ash per hour; while each 2000-hp. unit at 200 per cent of rating makes well over a ton of ash per hour.

While the complete paper deals with both stationary and marine practice, the present abstract is limited to the former, although definite progress in ash handling was first made on shipboard.

Except that there are several standardized types of conveyors, classification of methods of ash handling is not convenient and would serve no useful purpose. Therefore no real classification will be attempted, but several different schemes and installations will be described.

The most rudimentary method is that in which the ashes are hoed out of the fire doors and ashpits on the firing floor and shoveled into wheelbarrows. In some cases the ashes are shoveled into industrial railway cars, which are then pushed to the dumping point. The wheelbarrow can be replaced by either a mechanical or air conveyor.

Fig. 1 is a cross-section of a block-chain conveyor running in a trench under the firing floor. The ashes are hoed on to the grating through which they fall down the chute to the bottom of the trench. They are then drawn along by the chain, discharging into a bucket elevator as illustrated in Fig. 2, or on to an inclined chain conveyor carrying the ash into an elevated storage hopper.

Where there is a plentiful supply of water, a flume may be car-

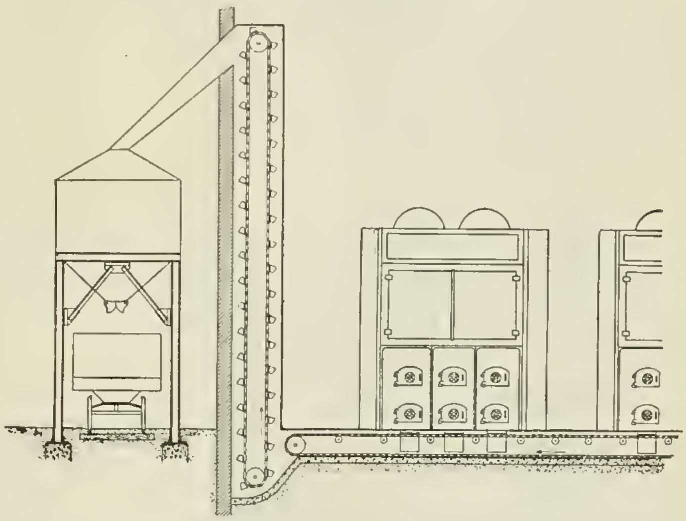

Fig. 2 Chain and Cross-Bar Conveyor with Bucket Elevator and Ash Bunker

ried along under the firing floor and the ashes raked into it through openings.

The problem is more complicated when the boiler room is considerably below the ground level, as in office buildings, hotels, etc. Whatever the final disposition may be, the ashes are invariably removed from the vicinity in motor or horse-drawn trucks. Here, the important consideration is principally that of hoisting the ashes from the boiler room to the street. In the isolated heating plants of the Union Electric Light and Power Company in St. Louis, the ash trucks are equipped with a davit just like a regular boat davit on shipboard. A small winch with a 4-in. barrel geared to a $^1/_4$-hp. electric motor is mounted at the side of the truck. A $^3/_{16}$-in. steel wire rope is attached and wound on the winch barrel, and passed through a pulley block hanging from the head of the davit with a hook at the free end. Current for the motor is conveyed by a flexible cord from a socket in the plant and snapped to the motor when the ash truck arrives. Opening the sidewalk cover, the hook is dropped and the first ash can attached, quickly hoisted to the davit head, the davit swung around and the ash can dumped into the wagon, and then returned to the basement. The whole operation is completed in a few minutes.

In some instances the air conveyor (the so-called steam-jet conveyor) has been used very advantageously in hospitals, hotels,

Contributed by the Materials Handling Division and presented at the Annual Meeting, New York, December 4 to 7, 1922, of The American Society of Mechanical Engineers. Abridged. All papers are subject to revision.

and office buildings in crowded parts of cities, but it is not always applicable.

Another method is the "post box" elevator. The ashes are stored in the boiler room until the arrival of the ash truck. The elevator, which is of the bucket type, has a telescopic housing which is pushed up through the sidewalk opening and the chute extended to discharge into the truck.

The first opertion where labor can obviously be saved is in avoiding hoeing and shoveling ashes at the outset. This leads naturally to a consideration of the hopper ashpit.

Hopper Ashpits

The hopper ashpit is regular practice in the modern plant. Its

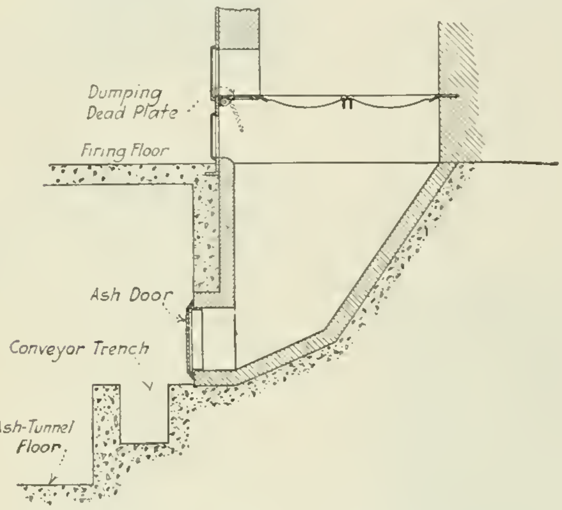

Fig. 3 Hopper Ashpit for Hand-Fired Furnace

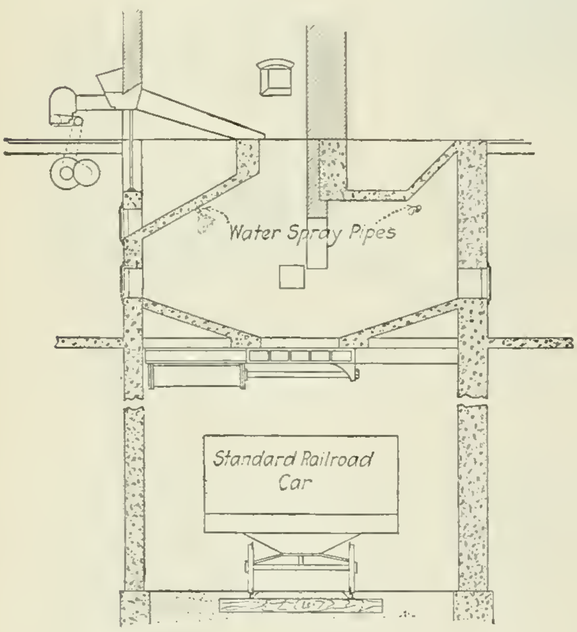

Fig. 4 Large-Capacity Hopper Ashpit

size and general design will depend primarily upon the manner in which the ashes flow into it, the method of removal, and also upon the system of draft. The design begins at the top to suit the stoker.

In hand-fired, forced-draft anthracite plants the top of the hopper will conform to the whole grate area. With stationary grates fine ash is falling constantly over the whole area. As the fires are hand-cleaned, a dumping deadplate will keep the ash away from the firing floor and allow it to fall directly into the hopper, the forced draft being temporarily shut off. With dumping grates the ash will also fall from most of the grate surface. The discharge door must be airtight to avoid increasing the cost of generating the forced draft and the possible reduction of ashpit pressure's lowering the boiler capacity. If it can be dumped directly into railroad cars the basement being deep enough for this purpose, the hopper can be quickly dumped through bottom doors. Where conveyors are installed it is usual to use a side door and work the ashes out gradually into the conveyor to avoid choking it, as would happen with a straight dump. Fig. 3 illustrates a layout of this kind. The conveyor will occupy the trench in front of the ash door. It may be mechanical, bucket or chain, or air or water, and is therefore shown schematically only.

With forward-travel underfeed stokers, chain-grate stokers, front-feed inclined stokers, and others the ashes are dumped at the rear of the furnace and the top of the hopper will be the width of the fire but of small dimension from front to rear to accord with the stoker dump. This reduces the capacity for storage as is seen by

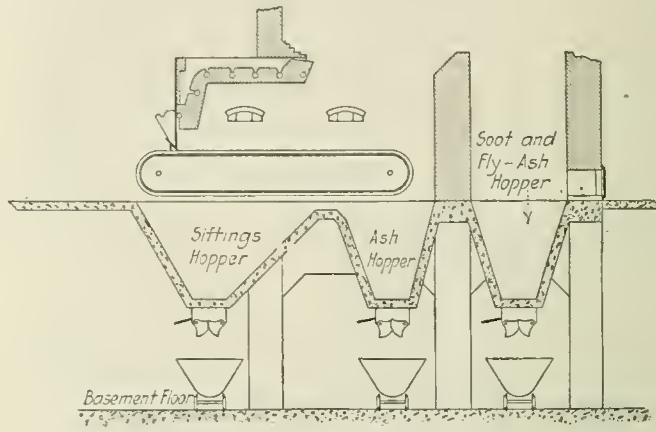

Fig. 5 Hoppers for Ashes, Coal Siftings, and Soot

examining Fig. 5. Where large storage is imperative, the ashpit may be designed as in Fig. 4, which is drawn from an illustration appearing in *Power* of January 17, 1922. Owing to the flatness of the bottom, some hand labor is necessary to effect complete discharge when desired.

With chain-grate stokers a hopper should also be provided for fine coal which shifts through the grates before ignition. Such an

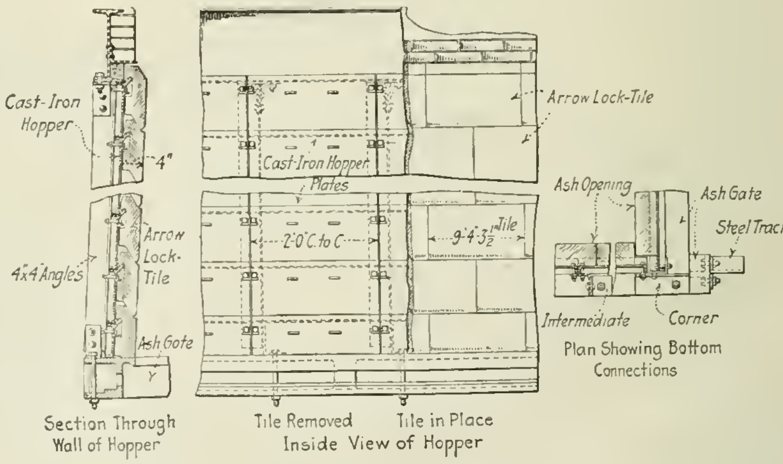

Fig. 6 Baker-Dunbar-Allen Ashpit

arrangement is shown in Fig. 5. This coal is dumped into some means of conveyance to be returned to the stoker coal hoppers.

Side-travel underfeed stokers dump at each side of the wind box for the whole depth of the fire. Hopper ashpits for this type of stoker may therefore have greater storage capacity since the top of the hopper extends to the front of the boiler.

Capacity. In some instances very little capacity may be sufficient, owing to storage being taken care of outside the ashpit. The method of conveyance from the ashpit will have considerable bearing on the ashpit capacity necessary. But 24 hours' capacity should usually be provided in case of breakdown of conveyors, etc.

Since the required capacity depends upon the amount of ash that accumulates between emptyings, it is controlled by the rate of

firing and the percentage of ash in the coal. Multiplying the weight of coal burned between dumpings by the percentage of ash and allowing 40 lb. per cu. ft. gives the storage space required. Allowance must be made for unburned coal coming in with the ash, for neglect to empty regularly, for possible increase in the load and consequently in the rate of combustion, and for possible change to dirtier coal. The careful engineer will make the capacity of his ashpits perhaps 50 per cent greater than the calculations show, or even more.

Design. The sides should slope at not less than 45 deg. in any case, and a minimum of 50 deg. with the horizontal is preferable. If one side is vertical the opposite side may have the minimum slope; but where two opposite sides slope, neither should slope less than about 55 deg. If the slope is too small, arching of the ash is likely to occur. Where the width of the hopper would necessitate too great height to get these required slopes, the ashpit may easily be divided so as to have a number of discharge openings. An excellent example of reversed slope which results in absolutely reliable dumping is illustrated in Fig. 13.

If a very small slope is used so as to get large capacity such as in Fig. 4, access doors should be provided at the top of the slope so that the ashes may be pushed to the dump doors with a minimum of labor, and ample space should be left so that long ash tools can be wielded with ease.

Large discharge openings should be used, though their size depends to some extent upon the method of firing. Modern practice requires 30 to 36 in. as a minimum, with many instances of clear openings 5 ft. square.

The bottom discharge is undoubtedly the least costly in labor and well repays the added expense of the greater height of basement needed. The height of the bottom of the hopper above the basement floor depends upon the system of conveyance adopted. It is greatest where standard railroad cars are used, about 8 or 9 ft. to clear the cars and about 17 to 18 ft. if a locomotive must pass under. With industrial cars 5 or 6 ft. is sufficient, though a clear headroom of 6 ft. 6 in. to 7 ft. is preferable. In any case there should always be sufficient vertical space to allow a bar to be pushed up into the hopper to clear away any obstruction. In designing new plants ample headroom should always be provided.

Where storage takes place in the ashpit, water spray pipes should be provided for quenching the ashes. These pipes should be near the top and sheltered from the incoming ash. Or a substantial spray ring such as illustrated in Fig. 9 may be used. Many prefer to make the hopper sufficiently large for the ashes to remain long enough to cool naturally. If too much water is used it will leak from the dump doors and flow about the basement; and as it contains much fine ash in suspension, it will clog sewers and necessitate cleaning them frequently.

Construction. Hopper shells made of sheet steel lined with firebrick are undesirable owing to rapid corrosion from sulphur in the ashes. Shells of reinforced concrete about 6 in. thick are common and satisfactory. The most modern construction, and probably the best method so far devised, is to use a structural-steel skeleton and make the shell of substantial cast-iron flanged plates bolted together.

Owing to the heat of the ashes and the possibility of the combustion of unburned coal, the hopper shells should always be lined with firebrick, which may be of second quality. With proper quenching of the hot ashes with water sprays a lining of well-burned hard paving brick is very satisfactory.

The method of construction of the Baker-Dunbar-Allen hopper ashpit is illustrated in Fig. 6. A suspended skeleton of structural steel carriers the hopper shell of heavy cast-iron flanged plates. The lining is of special firebrick blocks which will not spall under the temperature changes which occur. As seen in the left-hand view these blocks are hung from the shell and interlocked in a manner that prevents displacement but allows of easy renewal, and no mortar joints are used.

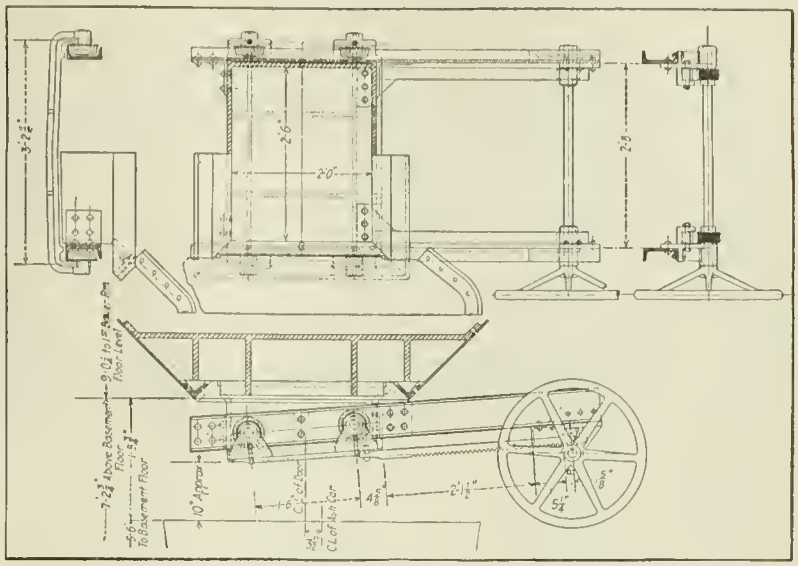

Fig. 7 Assembly of Ashpit Door and Frame

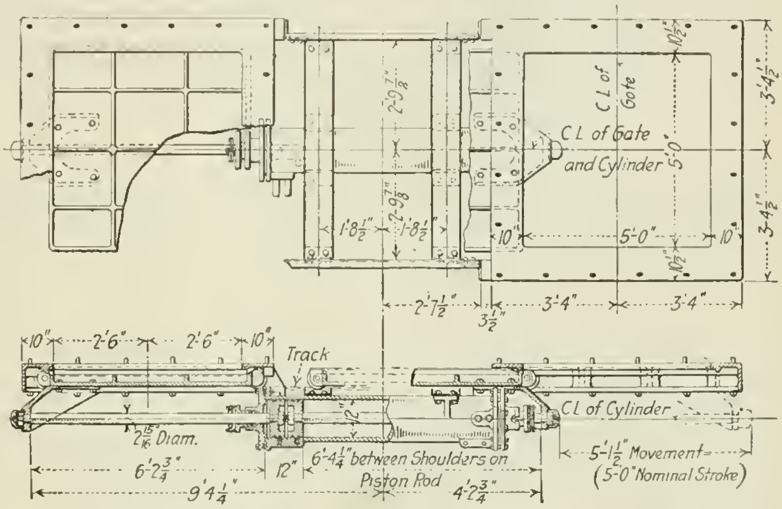

Fig. 8 Baker-Dunbar-Allen Power-Operated Ash Doors

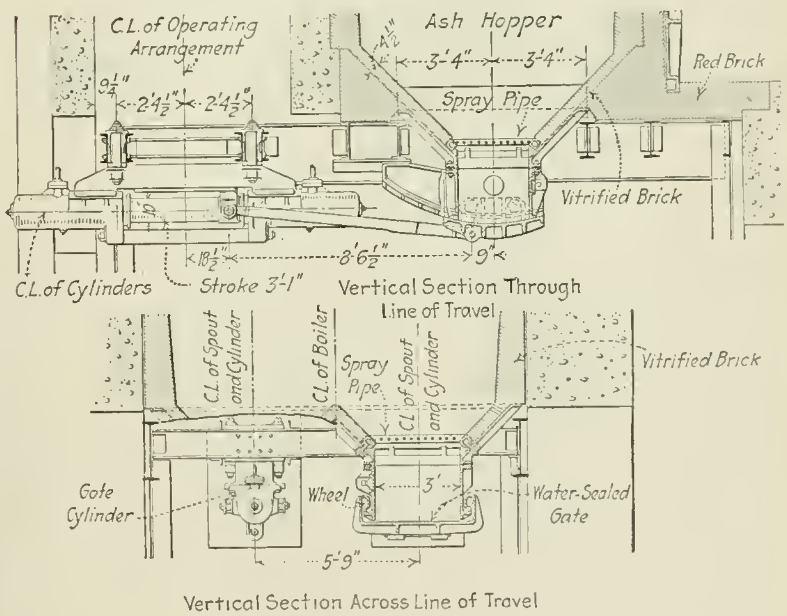

Fig. 9 Diescher Power-Operated Ash Doors

Closures. Hopper ashpits will usually be provided with doors to retain the ash and prevent the passage of air, and to allow of the ash being dumped or hoed out at intervals as desired.

Airtight ash doors are highly desirable in almost all cases. There are several ways in which the dump openings may be sealed. The

doors and faces may be machined, or the frame may be provided with a groove packed with asbestos rope, while the door has a rib or tongue which is squeezed into the asbestos packing by a crossbar and screw spanning the door. The latter method has been used with satisfaction in vertical doors like that of Fig. 3. The doors should usually be lined with firebrick to prevent warping due to hot ashes lying on them soon after dumping.

An example of ash door is illustrated in Fig. 7. These doors are of substantial construction, and are carried on rollers running on steel members. They are operated by hand with rack and pinion. Smaller doors are operated by hand, but when the openings approach 3 ft., power operation is advisable for speed. The larger hand-operated doors are worked by gearing, such as rack and pinion, while power operation may be hydraulic, compressed air, or electric.

Fig. 8 illustrates two Baker-Dunbar-Allen dumping doors arranged for compressed-air or hydraulic operation. The cylinder is worked between the openings and contains two pistons, one connected to each door. The doors are lined with firebrick.

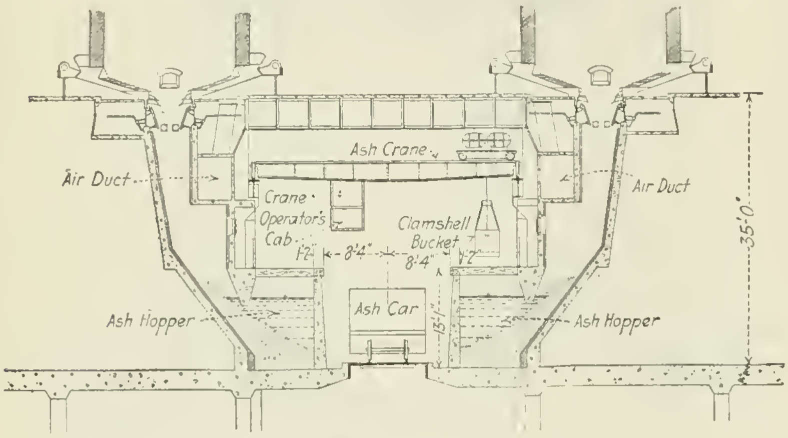

Fig. 10 Water-Sealed Ashpit

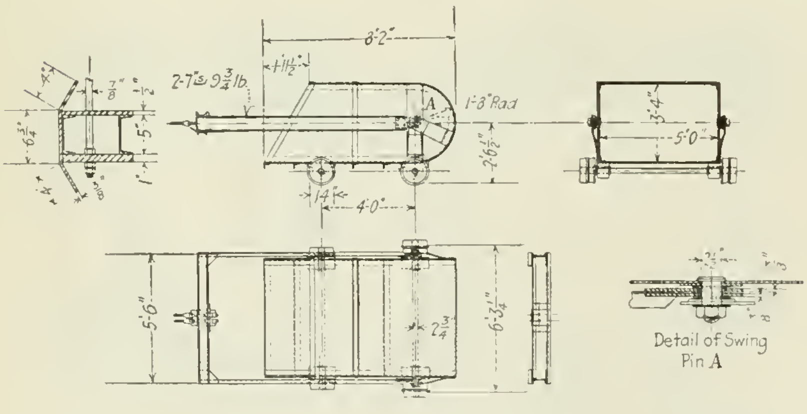

Fig. 12 Details of Skip-Hoist Bucket

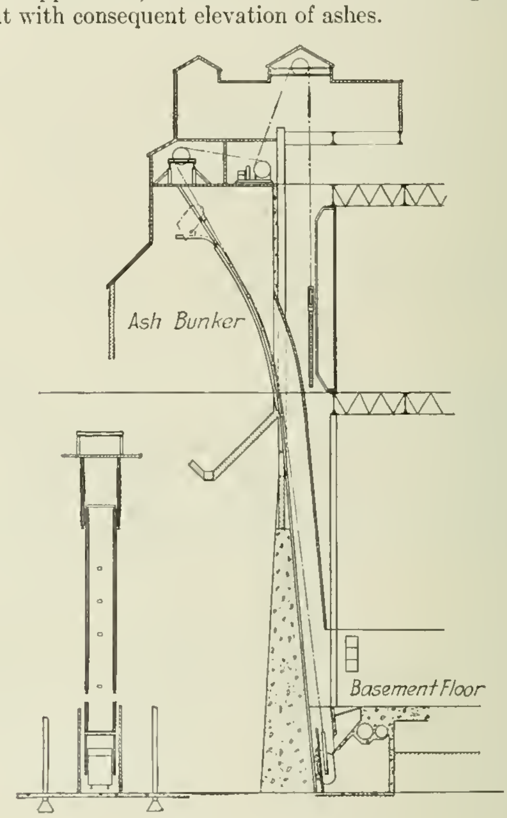

Fig. 11 Skip Hoist

The Diescher dumping door shown in Fig. 9 is provided with rollers which run on a curved track. Owing to the curvature of the door in conjunction with the flanges which carry the rollers, it retains water to form a seal and this water renders lining unnecessary. The door can be run off the track and another door run on if replacement is ever necessary by simply removing the pin of the driving connection. There is ample power and strength to shear easily through any clinkers which may get caught during closing.

Instead of using doors, closure may be effected by water seal. This method may be described as a U-tube with one leg forming the hopper ashpit while the other is open to the atmosphere and possibly to the entrance of a clamshell bucket. Water in the bend of the U-tube forms a seal and serves to quench the ashes.

An excellent example of this method is illustrated in Fig. 10, which is a cross-section of the boiler room of the Springdale Station of the West Penn Power Company. More than sufficient water for the seal is provided by the waste cooling water from the clinker grinders. The overflow is from one ashpit to the next, until it is finally discharged from the last ashpit. This system of ashpit requires considerable depth of basement—not less than about 30 ft. from firing floor to basement floor.

A further advantage of this method is that no combustible or corrosive gas escapes into the basement. When boilers are being pushed with heavy loads, gas often escapes from hopper dump doors. Apart from discomfort and danger to those in the basement, considerable corrosion of ironwork often occurs. Such troubles are entirely obviated with the water-seal ashpit.

Mechanical Conveyance

The method of conveying ash by emptying ashpits into small dumping cars has a great deal to recommend it. The cars are inexpensive, can be moved by men, animals, tractors, or locomotives, and can be run about the floor or on tracks, all according to the amount of ash to be moved and other conditions.

In the Ashley Street Station of the Union Electric Light and Power Company, St. Louis, Mo., a system of industrial railway and ash cars was installed in 1905. The basement floor of this plant is 30 ft. below the flood stage of the Mississippi River, and this necessitated a watertight basement with consequent elevation of ashes.

The boilers are equipped with chain-grate stokers discharging ash into hoppers having a capacity of 24 hours. These hoppers are of steel plate lined with vitrified brick laid in cement, and each has two large horizontal dumping doors which are illustrated in Fig. 7.

The railway is 30 in. gage and the dumping cars have a capacity of three tons each. The cars are lifted 120 ft. to an elevated ash bunker by a skip hoist installed in 1916 to replace the car elevators originally employed; a gasoline locomotive is used to haul the ash cars. The general arrangement is illustrated in Fig. 11. The details of the bucket are presented in Fig. 12.

The operation of the skip hoist is mainly automatic. When an ash car has been dumped into the bucket, a switch button is pressed. This starts the hoisting motor, which raises the bucket to the top of its travel where it turns over and discharges into the elevated bunker. A switch trip at this point reverses the motor and thus lowers the bucket to its starting point, where another switch trip stops the motor.

The operation of this new system is entirely satisfactory and it has given good service. It has reduced the labor cost of handling ash one-third and the cost of maintenance one-half.

In the system installed at the New Bedford Gas and Electric

Light Company's plant, the ashes collected in hopper ashpits are emptied into a storage-battery truck having a dump body of 40 cu. ft. capacity. An automatically controlled skip hoist with the skip car normally in a small concrete pit just large enough to hold the car, is installed about 39 ft. outside the boiler room. The truckman pushes a button switch which starts the elevator motor, and this raises the car, dumps it into the ash bunker, and returns it to the concrete pit ready for another load. Two men handle the ashes from the station, which has a load of about 38,000 kw. at the present time.

Fig. 13 illustrates a hopper ashpit arranged for dumping directly into standard gondola railroad cars which form part of the equipment of the station. The hoppers are lined with brick, not shown, and have a capacity of about 2500 lb. of ashes. The stokers are equipped with clinker grinders. The ash gates are of the sliding type and are operated by compressed-air cylinders. Water spray pipes are provided near the top of the hoppers for wetting down the ashes before dumping.

The present consumption of this station is 413,000 tons of coal per year. The yearly ashes from the station amount to 52,800 tons.

The ash cars are handled by an electric locomotive and are dumped into an outside pit, from which they are recovered by a crane and grab bucket and loaded into the purchaser's trucks. The proceeds very nearly pay the labor cost of handling the ashes.

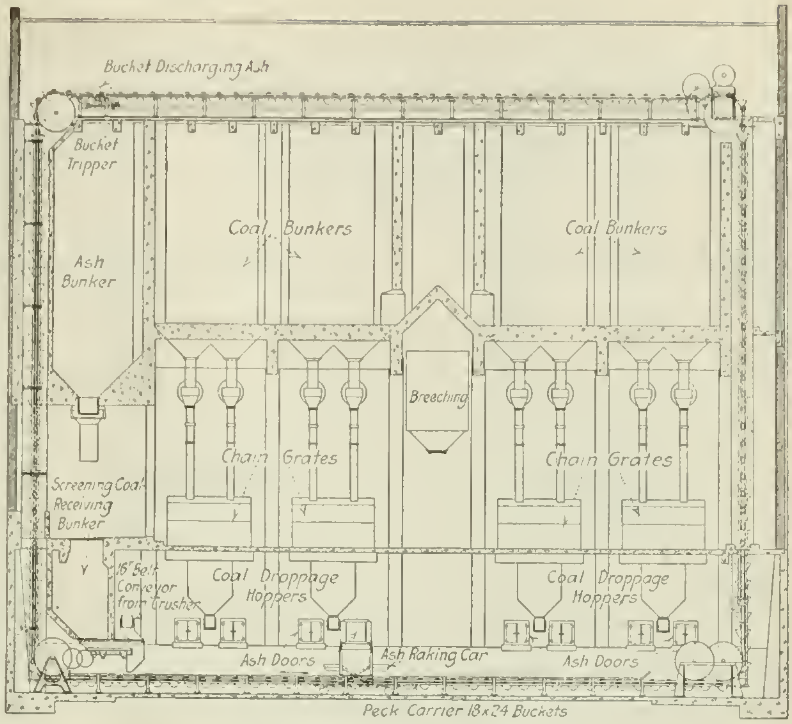

Fig. 14 Peck Carrier Ring System

It is estimated that 45 lb. weight of compressed air is required per day per boiler to operate the hopper-ashpit dumping doors. From recent tests it is found that 1030 gal. of water is used in spraying one ton of ashes, and this amounts to about 4 per cent of the total general-service water used by the station.

Bucket conveyors such as the Peck carrier have been extensively used. With the chain and buckets forming a ring system, the conveyor is often used for coal in the daytime and ash at night.

Fig. 14 illustrates a Pack carrier installation by the Link-Belt Company in a downtown heating station where coal and ash have be handled by motor truck. The building occupies the entire site, and no projections of any kind are possible. The basement floor is 12 ft. below the alley level, and as the alley is only 15 ft. wide it was necessary to build a recess where the trucks could drive in and dump coal, and then load up with ashes.

The conveyor is located centrally between the boilers and handles coal as well as ashes, and also the siftings from the chain-grate stokers. The run-of-mine coal is screened as it is dumped from the truck, the screenings going directly through the feeder to the conveyor, and the lumps passing through the crusher. The vertical lift is 66 ft. and the horizontal centers are 85 ft. The overlapping buckets are 18 in. wide and 24 in. on centers. A 7.5-hp. motor drives the conveyor at a speed of 45 ft. per min. The buckets are discharged into the overhead bunkers by a regular tripper on the upper run.

The coal bunker is continuous along the boilers. The ash bunker which has a capacity of 130 tons, is located in line with and immediately adjacent to the coal bunker and at the same elevation. Consequently the buckets discharge coal into the coal bunker or ash into the ash bunker according to the position in which the tripper is placed. Also, the ash-bunker discharge is immediately above the recess into which the trucks are driven, just as the coal-receiving hopper is immediately below it. Therefore the trucks, which have automatic dump bodies, drive into the recess over the coal-receiving hopper, discharge their load, and receive ashes without changing their position. Quick unloading and reloading therefore materially increases the road time of the trucks; and this is a considerable item in the downtown district where traffic is more or less restricted.

A novel method is employed for the removal of the ashes from the ash hoppers to the conveyors. A double raking apron is contrived as a car mounted on tracks and straddling the conveyor. It is movable the entire length of the boiler house and can be brought in front of each ash door, forming a continuous chute from the hopper door to the conveyor. The operator stands on one side of the car and pulls the ashes down into the chute. After a flow of ashes has been created, water under pressure is used to keep up the flow, and the ashes are removed in a very short time. The cross-section of the plant shown in Fig. 15 illustrates this clearly.

Owing to the abrasive nature of ash the maintenance cost of mechanical conveyors is high. The ashes grind away the connecting pins, and even with regular renewals the pins sometimes wear excessively and cause breakdowns.

The life of these conveyors is considered to be about seven or eight years, and extensive repairs must be made every two or three years. The excessive cost of maintenance has led to their replacement in some installations with electrically operated cars carrying the ashes to outside pits from which they are loaded into railroad cars with a bridge crane, and the cost of handling has been reduced by 50 per cent.

Hopper ashpits with large doors should not be dumped directly on to chain or bucket conveyors. With direct

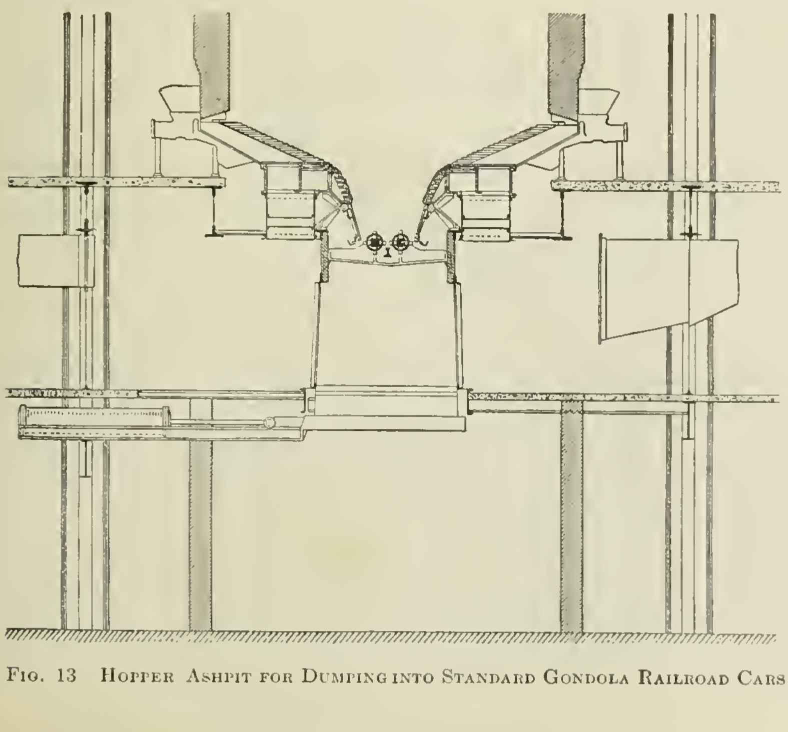

Fig. 13 Hopper Ashpit for Dumping into Standard Gondola Railroad Cars

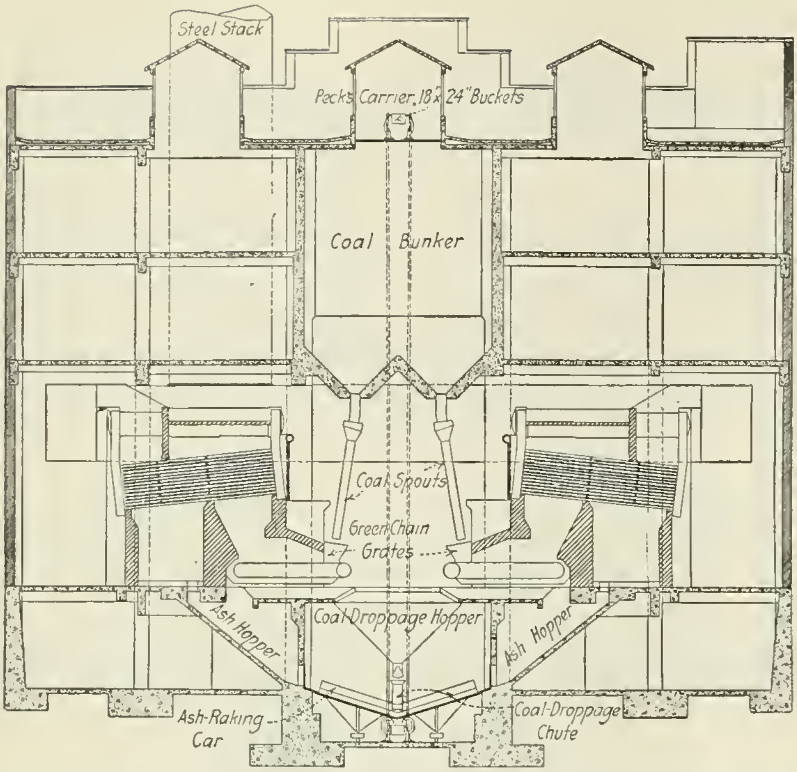

Fig. 15 Cross-Section of Boiler Room with Peck Carrier

dumping, large clinkers are liable to jam and cause breakdown, and opportunity should be given for breaking them.

The Fisk Street and Quarry Street stations of the Commonwealth Edison Company of Chicago are each equipped with bucket conveyors which handle both coal and ashes. There is an additional pair of ash conveyors at Quarry Street which carry the ashes to the train shed. The electrically operated ash cars now used in place of the apron conveyors formerly employed are dumped into a pit outside the building. A bridge crane takes the ashes from the pit with a grab bucket and loads them into railroad cars. The cost of maintenance as compared with the apron conveyors is almost negligible. The outside pit and crane were originally installed for and used with the apron conveyor.

At Northwest and Calumet stations, Chicago, the ash is dumped from hopper ashpits directly into railroad cars. The only maintenance required is upkeep of ashpit linings and dumping doors. The cost of the ash-handling system at these stations cannot well be estimated because there is none.

An example of a simple chain and cross-bar conveyor is illustrated in Figs. 1 and 2. The conveyor installed at one of the municipal plants of the Poplar Borough Council in England and illustrated in Fig. 16, may be considered as a development of this idea in combination with the water seal of Fig. 10, though there is no ashpit storage. In fact, there is no ashpit, only sheet-steel unlined chutes ending in cast-iron nozzles which dip below the water level in the conveyor trough, thus providing the water seal. The return of the chain is also below the surface of the water. The transverse centers of the chain are $19^1/_2$ in. apart and the cross-bars are $25^1/_2$ in. pitch. Therefore large clinkers easily fall between the upper run of the chains and cross-bars to the bottom of the trough. The end of the trough is carried upward at an angle of 41 deg. to its discharge into the ash bin, from which the ash is recovered by grab bucket.

No ash crushers are necessary as the space between chains and cross-bars is sufficient to allow large clinkers to fall through the upper run of the chain into the water; and the hot clinkers break up on falling into the water, the average size as delivered from the conveyor being about equal to that of a pea.

The length of this conveyor is about 140 ft. and it is designed for a chain speed of 20 ft. per min. One conveyor running at 9.5 ft. per min. and handling 3.25 tons of ashes per hour takes a little under 2 hp.

Air Conveyors

Air is passed through a pipe at a sufficiently high velocity to carry the ashes along with it. The air is admitted at one end and ash intakes are provided wherever required. There are two systems of generating the air current. In one, the pipe outlet is connected to an ash-storage tank in which a vacuum is caused by means of a steam-jet or mechanical exhauster. In the other, the air current is induced by a steam jet between the ash intakes and the outlet.

A typical layout of an air conveyor with vacuum storage tank is illustrated in Fig. 17. A steam-jet exhauster is attached to the top of the tank and may discharge into the atmosphere or into the chimney or a silencer to reduce the noise. It is claimed that ordinary gray-iron piping may be used, and a test is offered wherein a piece of conveyor pipe was replaced with light wrought-iron pipe which showed but little wear after a year's service carrying 5000 tons of ash.

An ash tank is not required as a part of the system. It is usual for the conveyor to discharge into an elevated ash tank supported on columns, so that carts, motor trucks, or railroad cars may be run underneath the tank and be filled quickly by opening the ash valve in the bottom.

The ash particles may momentarily attain velocities approximating to that of the steam jet at a little distance from the muzzle of the nozzle, and therefore local abrasion may be considerable. It is usual to locate the motor jet at an elbow, as it is then convenient to aim the jet in the new direction. When the conveyor pipe is very long, extra nozzles are installed in some cases. When the nozzles are arranged in straight pipe they are set at an angle to the axis of the pipe and are then not so efficient as they would be if coaxial. An air inlet is provided at the beginning of the pipe, for it must be remembered

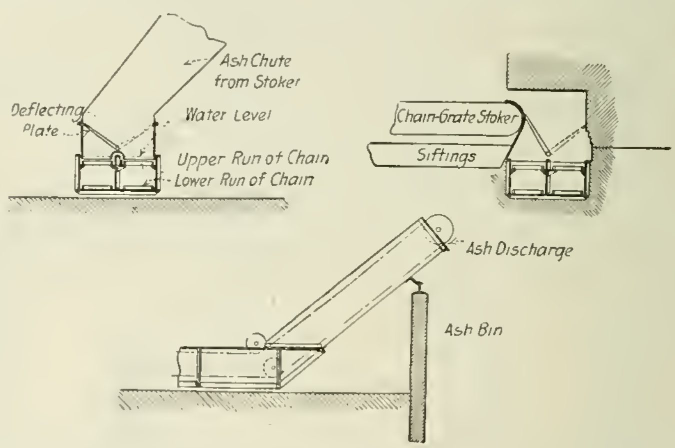

Fig. 16 Water-Seal Chain and Cross-Bar Conveyor at Poplar, England

that it is the velocity of a large body of air which carries the ash, and not the vacuum.

As an instance of the speed at which ashes can be handled, a plant may be cited containing fifteen 500-hp. boilers equipped with Murphy stokers, where the average amount of ashes in each pit ranges from 1000 to 1300 lb. One man cleaned out eight ashpits in 27 min. from the time steam was turned on until it was turned off.

Some stokers are provided with clinker crushers, and when this is not the case it is becoming increasingly necessary to add clinker crushers as part of the ash-handling equipment, so that the clinkers may be reduced to such size as the conveyors can handle without choking or breakdown.

The maximum capacity of a 6-in., conveyor is about four tons of ash per hour; that of the 8-in., six to nine tons; and of a 9-in. conveyor, ten to fifteen tons and even twenty tons in some cases. The capacity depends largely upon the size of the pieces. Ash should not be wet or quenched when fed to an air conveyor. Ashes can be conveyed

by air conveyors through a horizontal distance of about 500 ft. and through a rise of about 100 ft.

The cast iron used for pipes and elbows and other fittings is generally made of the hardest possible white iron, such as is not machinable and can only be ground, so that connections are commonly made by means of bolts slid into open lugs. The wear is greatest at elbows where the ash direction is changed, and it is usual to provide "wearing backs" of easily replaceable blocks.

Air conveyors use a large quantity of steam while running; but as they remove the ash very rapidly, the cost of steam per ton of ash removed is quite small when they are properly operated.

Considerable expense ensues if steam nozzles are allowed to wear excessively before renewal. Not only is the steam consumption greatly augmented, but the increased energy of the larger steam jet results in higher air and ash velocities with greater wear of pipes, elbows, targets, etc. Such wear of steam nozzles is greatest with wet steam.

In some instances the steam-jet conveyor is objectionable because the steam used represents so much water lost, and which must be replaced by "make-up." It is becoming increasingly general practice to distill all make-up water so as to prevent any scale-forming or foam-making salts from getting into the boilers. Condenser leakage is diligently looked for and eliminated. Therefore, owing to the care with which pure water must be conserved, it is obvious that any apparatus which removes water from the system, such as steam jets whose steam does not eventually reach the condenser, will usually be frowned upon by operating engineers.

One ton of steam will move four to eight tons of ash. With a coal containing 12 per cent of ash, two tons of steam would be used per 100 tons of coal. Taking an average evaporation of 9 lb. of water per pound of coal, the conveyor would use two tons of steam out of each 900 tons generated or nearly 0.2 per cent. To allow for careless operation or negligent maintenance and other contingencies, it would perhaps be advisable to allow, say, 0.3 or 0.4 per cent in arranging for extra distillation for make-up.

Air conveyors generally result in clean basements or firing floors because there is less spillage. The first cost is usually lower than that of a mechanical system, they take up very little space and can be installed in awkward positions, and require very little attention; but this is not always a good feature unless periodical inspection is conscientious, because steam nozzles may wear and leaks due to abrasion of pipes develop, and these may result in considerable waste of steam. The very convenience of the method may develop carelessness in allowing the steam to blow when ash is not being fed. It is safe to operate because there are no moving parts and this feature makes also for small expense of putting in renewals.

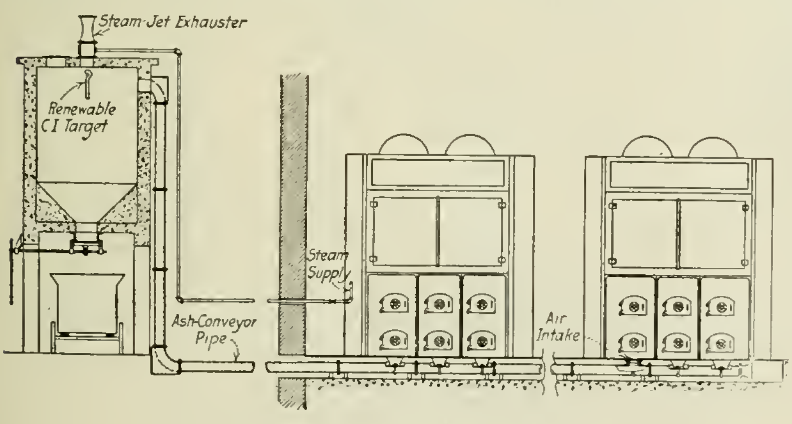

Fig. 17 Air Conveyor with Vacuum Storage Tank

The air conveyors which are being installed by the Conveyor Corporation of America at the New Milwaukee sewage plant are illustrated in Figs. 18 and 19. The plan in Fig. 18 shows the ash conveyor, which has a bore of 9 in., in conjunction with the four 734-hp. stoker-fired boilers. The hopper ashpits are dumped into auxiliary hoppers formed about the conveyor intakes, as will be seen in Fig. 19. This permits of rapid feeding of the conveyor

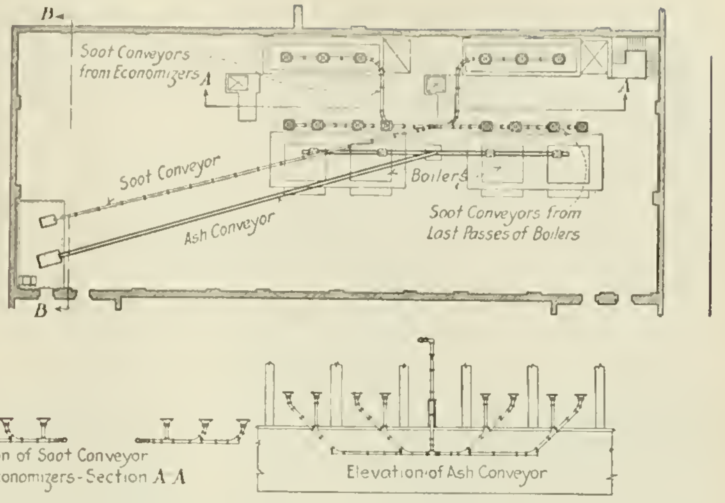

Fig. 18 Air Conveyor at Milwaukee Sewage-Disposal Power Plant. Plan

without smothering it. It is to convey a minimum of 12 tons per hour, with a steam consumption not exceeding 325 lb. of steam per ton of ashes.

The conveyor for soot and fly ash is independent of the ash conveyor and has a bore of 6 in. This arrangement usually increases both the capacity and the efficiency over that obtained with combination conveyors. It is connected to the later boiler passes and to the economizer, and discharges into a separate target box set upon the top of the ash bunker.

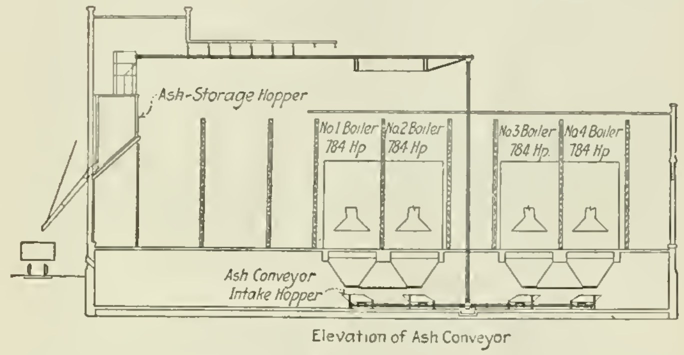

Fig. 19 Air Conveyor at Milwaukee Sewage-Disposal Plant. Elevation

The installation at the Lakeside plant of the Milwaukee Electric Railway and Light Company is of considerable interest because the boilers are fired with pulverized coal. See Fig. 20. There are eight boilers of 1333 hp. each—1306 hp. in the boiler proper and 27 hp. in the form of a water screen at the bottom of the combustion chamber. This water screen entirely prevents the formation of clinker or slag which was so troublesome in some of the earlier powdered-coal installations. Instead, the ash from the combustion chamber is a fine powder which is very easily handled by an air conveyor.

The air conveyors were installed by the Vacuum Ash and Soot Conveyor Company, have been in successful operation nearly two years, and practically no maintenance work has been required during that time; only one nozzle has been replaced.

To recover some of the fine ash which would otherwise be discharged from the chimney top, a smoke washer is installed in the main flue about twenty feet before it enters the base of the stack. It consists of two 4-in. pipes placed parallel to each other in the top of the flue. These pipes are provided with nozzles of $^1/_4$-in. pipe 1 in. long placed at 3-in. centers along each pipe, the nozzles of one pipe being staggered relatively to those of the other. The pipes are supplied with about 350 gal. of water per min. at a pressure of about 6 lb. per sq. in. The jets from the nozzles form a water curtain through which the gases must pass before entering the chimney.

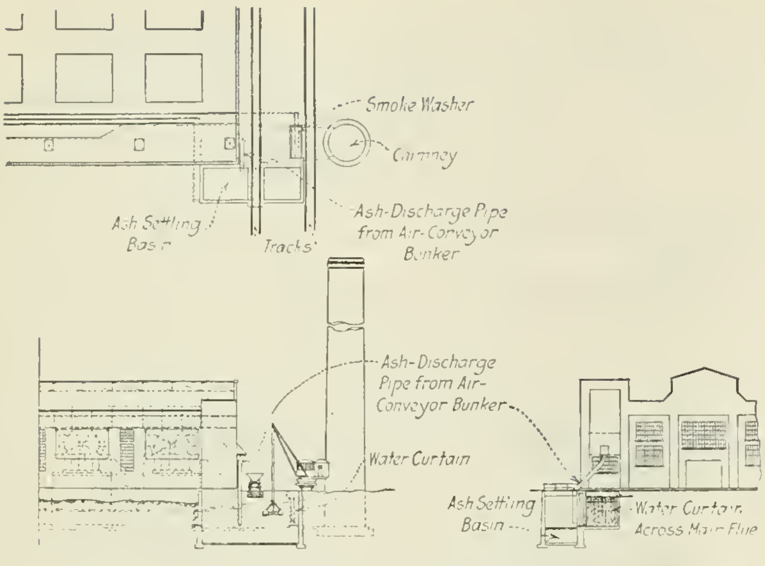

Fig. 20 Air Conveyor and Smoke Washer for Pulverized-Coal Firing at Lakeside Station, Milwaukee

Actual tests show that 50 per cent of the ash suspended in the flue gases is removed by this apparatus.

The boilers are arranged in two rows of four each, facing each other across the firing aisle. There are two conveyors, the main line of each being in the floor of the ash alley in front of the furnace ashpits. Each main line takes care of four boilers. Branch lines lead to the ash chambers at the rear of the boilers and also to the ashpits under the economizers.

All the conveyor lines are of 8-in. cast-iron pipe. The running length of the two main lines is approximately 200 ft. with a vertical rise of 65 ft. The lines from the ash chambers and the economizer ash hoppers are approximately 190 ft. long and have a vertical rise of 50 ft.

Ash Bunkers

Considerable choice of materials and design of ash bins and supports is available. A large number, perhaps most, are made of reinforced concrete. In some cases they are inside the boiler room and worked into the general design of coal bunkers, etc., such as illustrated in Fig. 14. They are occasionally built so as to span an alley, being supported by the buildings on each side.

Ash bunkers have also been built of brick, but unless very thick walls are used, they should either be buckstayed or have reinforcing bands laid up every five or six courses. The bricks should be hard and well burned, and laid in cement. The inner face of the walls should be of paving brick.

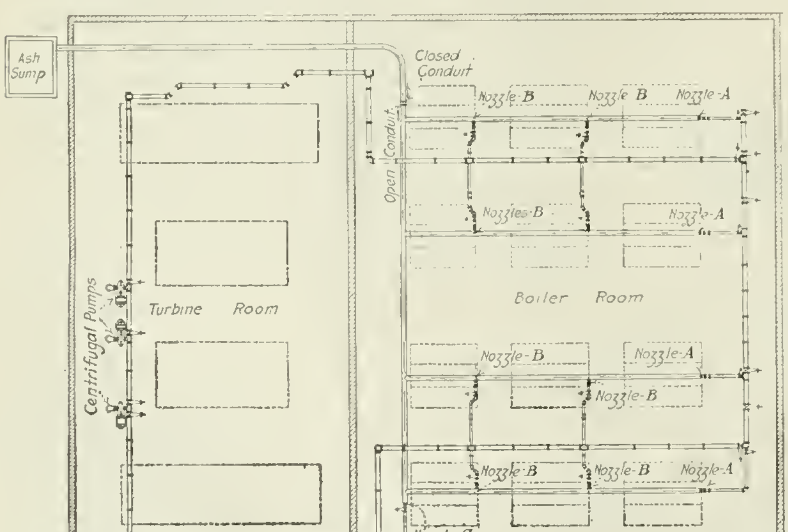

Fig. 21 Water Conveyor at Hell Gate Station. Plan

Hollow-tile ash tanks have several inherent advantages in that they are fireproof, prevent freezing of wet ash, are acidproof provide space for steel reinforcing rings within the wall, and have a smooth interior surface. The tiles are laid up in cement and are provided with key grooves on their joint faces.

Tanks may also be made up of a cast-iron skeleton filled in with cast-iron plates, the whole carried on a structural-steel framework. Cast iron, being much less subject to corrosion than steel, makes a durable tank for ash storage.

Water Conveyors

In systems of water conveyance the conduits carrying water are largely or wholly open. With a plentiful supply of water, this method has much to recommend it. There is no dust or heat and the ashes are carried away very quickly. Owing to the low velocity of the vehicle as compared with air, the wear is very small and usually is not troublesome. The conveyance, of course must always be down hill when open flumes are used, and a grade of 3 or even 4 per cent is desirable.

Where a natural supply of water from an elevator is not available a centrifugal pump may be used. The Hell Gate plant is an excellent instance of this kind, and the general layout is shown in Fig. 21. This is a system of open flumes within the boiler room continuing through a closed pipe to the ash setting tank. Tributary flumes are carried along below each line of boilers and empty into a main cross-flume which runs along the boiler room wall near the turbine room. This main flume then turns and becomes a full pipe or enclosed conduit leading to a pit near the river side into which it discharges. The ashes are recovered from this pit by a grab bucket operated by a locomotive crane running on a track laid on the pier, and discharged into scows. The scows are towed out and dumped at sea about five miles east of Sandy Hook, or about thirty miles from the plant.

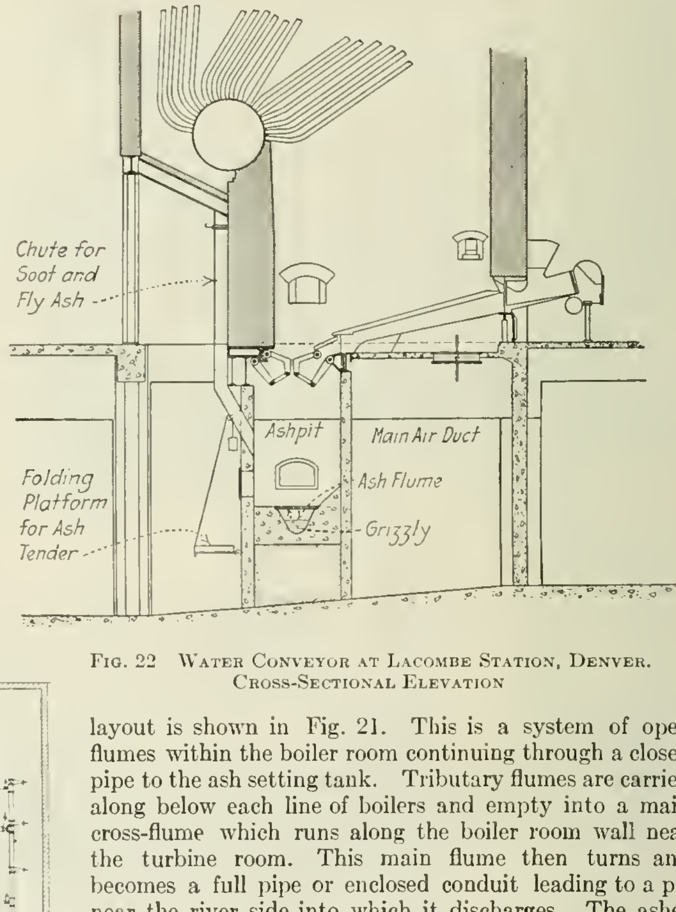

Fig. 22 Water Conveyor at Lacombe Station, Denver. Cross-Sectional Elevation

The flumes within the boiler room are of concrete with a bottom lining of vitrified earthen drain tiles or half-pipes. Those under the boilers are supported on structural-steel framework suspended from the firing floor, while the main cross-flume is carried on steel trestling.

A cross-section of the flume under the boilers is shown in Fig. 23. The ash as it leaves the clinker grinders drops directly into the water and is carried away. Access doors lined with common brick are provided so that any ob-

struction can be handled easily. These doors may be seen in Fig. 23.

The method of water supply is very interesting. There is a nozzle *A* at the head of each tributary flume, and an ingeniously arranged undercurrent nozzle *B* at the beginning of each succeeding ashpit. These undercurrent nozzles are at the bottom of the flume and are arranged to discharge horizontally downstream. They are placed to form steps in the flume so that the ash flows over them. At the head of the main conduit is a booster nozzle *C*.

The water for the various nozzles is taken from the circulating discharge tunnel and is supplied under pressure by 12-in. Lea-Courtenay centrifugal pumps direct-driven by 150-hp. Westinghouse motors. These pumps supply 5000 gal. per min. against a head of 75 ft., operating at 81.5 per cent efficiency.

The main pipe line which supplies the water nozzles has a bore of 16 in. and is arranged as a ring as clearly shown in Fig. 21.

Fig. 22 shows a cross-section of the flume under the boilers of the Lacombe station of the Denver Gas and Electric Light Company. The outstanding difference between this plant and the one at the Hell Gate station is that there are no clinker grinders. As a result, the flumes are protected by a "grizzly" composed of heavy bars set 6 in. center to center to withstand breaking up the large clinkers until they can drop between the bars into the flume. The water stream will easily handle clinkers about 12 in. square and 15 lb. in weight.

Water sprays cool the clinkers which are caught on the grizzly. Side-hinged doors 18 in. by 23 in. are provided through which the clinkers can be managed.

The station contains five boilers of 750 hp. each, operated at 250 to 300 per cent of rating. The coal is a sub-bituminous containing 6 to 7 per cent of ash. As the boilers are in line, the flume is single and straight. It is all of 2 per cent grade except the curve to the ash-settling tank, which is of 18-in. vitrified sewer pipe laid horizontally. The flume and sewer pipe is about 155 ft. total length. The capacity of the setting tank is 3000 cu. ft.

The water passes through a screen and is recirculated, and a 2-in. line is used to replenish occasionally the water in the system. The water is circulated by a 6-in. American open-runner centrifugal pump driven by a 20-hp. motor. The pump delivers about 1100 gal. per min. against a head of 25 ft. The system deals with about 33 tons of ashes in 24 hours.

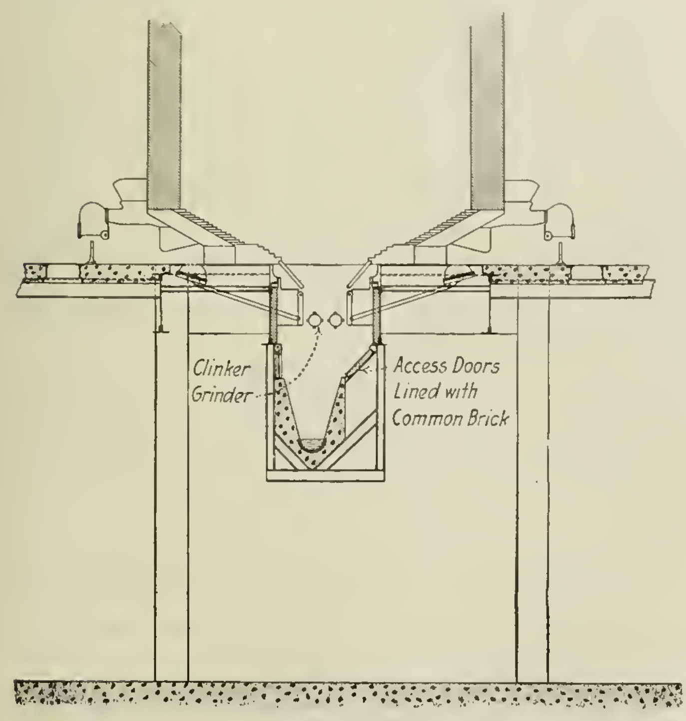

Fig. 23 Water Conveyor at Hell Gate Station. Cross-Sectional Elevation

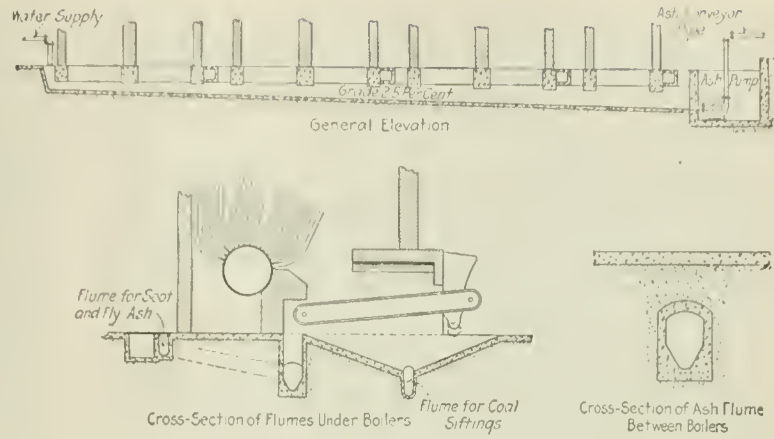

Fig. 24 Morrison's Water Conveyor at Great Western Sugar Refinery, Denver

An ingenious arrangement is that invented and patented by Mr. Morrison, of the Great Western Sugar Company of Denver, and installed in several of their plants. An example is partly illustrated in Fig. 24. A flume into which the ashes are fed is arranged under the boilers as in other water conveyors. This flume carries the ash-laden water into the suction connection of a centrifugal pump which discharges into the conveyor pipe. The conveyor pipe is of cast iron, 6 in. bore. Abrasion occurs slowly, but is confined to the bottom of the pipe. It is found that by rotating the conveyor pipes through an angle of 90 deg. every few years, maximum service is obtained out of each renewal.

In designing a water conveyor it must be borne in mind that while continuous dumping stokers such as chain grates or those equipped with clinker grinders may discharge dirctly into continuously running water, dumping stokers or any firing system where large clinkers are to be expected should discharge on to a grizzly of massive bars on which clinkers may be broken small. The water need only be running while dumping is in progress with stokers of the dumping type.

Concrete troughs, if carefully built, will be found to require very little repair. The inside lining should be smooth and free from pits. There should be a plentiful supply of water under a few pounds pressure. About 1000 gal. per min. should be supplied for each flume.

With natural draft, means should be devised to provide seals so as to prevent too great an excess of air from passing up through stoker dumps.

When the water is recirculated, the pump should be designed to handle gritty water, and occasional renewals due to this reason must be expected, though they will not be serious.

As there is often considerable dust and gas generated with stokers of the dumping type, it is advisable to provide the access doors with latches so that they cannot be blown open. Ample ventilation near where ashes are handled should always be provided.

In some localities in winter, trouble may be expected from water freezing in the bearings of grab buckets. In particularly cold situations the wet ash will freeze in the cars and cannot be dumped unless it is thawed out. Weather conditions may therefore prohibit water conveyors in some instances.

Discussion

In OPENING the extensive and extremely interesting discussion which followed the presentation of the paper, T. A. Marsh[1] said he would like to emphasize the serious effect of small ashpits and ash hoppers on stoker maintenance. Aside from the question of draft, he said, there was no one item which had caused more stoker failures than ashpit design. The cross-bar conveyor in water, shown in Fig. 16, had acquired great popularity in this country and he saw great possibilities for it. As the economic capacity of a man handling ash from an air conveyor was five to six tons, he saw no necessity of using larger than an 8-in. conveyor system. The remote-control steam valve for air conveyor systems, mentioned in the

[1] Chief Engineer, Green Engineering Co., East Chicago, Ind. Mem. Am.Soc.M.E.

paper, for shutting off the steam when the conveyor was not in use, was being received with great favor, and it appeared that the steam consumption of the average air conveyor might be cut in two by the use of this valve. It was very important, he said, to emphasize the author's caution in regard to keeping down the wear of steam nozzles in such systems.

F. B. Allen[1] discussed the design of ash hoppers which were bottom-dumped by means of power-controlled gates, discharging into some type of car beneath. It was essential for operating reasons, he said, to quench the ashes before dumping. The ordinary system of quenching by introducing one or two pipes perforated with holes was unsatisfactory as an excessive amount of water, with attendant difficulties, was essential for effective quenching. He then described, with the use of lantern slides, how better results could be obtained by running the quenching-water header outside of the hopper with a series of offtakes to quenching nozzles located through the hopper walls. Each quencher sprayed water in fine particles over the ash, and could be independently controlled and cleaned from the outside. He also gave particulars regarding the gates of this type of hopper.

R. H. Beaumont[2] said that in his opinion an ash-handling system should be capable of meeting the following conditions: (1) It must be capable of handling very large clinkers; (2) it must be of such design that abrasion has little or no effect on its parts, so that repairs are negligible; (3) it must not consume much power, nor waste it running idle; (4) it must be capable of lifting ashes to a good height without being subject to excessive wear by so doing; (5) it must handle either red-hot or dripping wet ashes with equal facility; (6) it must operate without making dust or exceptional noise; (7) it must have a high hourly capacity; (8) it must handle the general run of boiler-room refuse, such as soot, flue dust, broken bricks, grates, etc.; (9) it must accommodate itself to plant extension without complete remodeling; and (10) it must deliver ashes into a storage bunker so that they are acceptable as railroad freight. He described also the automatic electric skip hoist, which he considered the most important device used today in the handling of ashes.

Nevin E. Funk[3] said that ash-handling systems could be divided into two classes: those easy to operate and easily repaired without putting the entire apparatus out of commission; and those with no flexibility at all, which put at least one section of the boiler room out of commission in event of failure, and which cannot be aided by some crude makeshift in time of failure. In the first class he put the railroad car, the industrial railway with storage battery or trolley locomotives, and possibly the water-sealed ashpit of Fig. 10. In the second class he included all mechanical, air, and hydraulic conveyors. The use of railway cars did not mean raising the boiler room much more than required by many other schemes. He pointed out that even with a continuous ash-disposal system there must be sufficient storage to take care of periods of breakdown. He criticised a system which was used for both coal and ash because of the chance of getting ashes in the coal. He did not like the water-seal chain and cross-bar conveyor of Fig. 16 because of the liability to breakage. Even with two such systems parallel the breakage of one might easily result in the breakage of both; and it would not be easy to make repairs to such a system while the boilers were in operation. Speaking of the air-conveyor system with vacuum storage tank shown in Fig. 17, he said that there was danger of an explosion in such a system as gas might easily be generated in the tank. He was sure that hydraulic systems, even those depending upon flotation, would soon wear out due to abrasive action of the water and ashes.

Nixon W. Elmer[4] spoke of the problem of ash disposal in a powdered fuel plant.

I. E. Moultrop[5] said that of the three great handling problems in the power plant-handling water, coal, and ashes—that of handling ashes was the greatest. He spoke of the cost of disposing of the ashes after they had been removed from the power plant. A very large ashpit, he said, was absolutely essential. Ashes should be taken away with the use of as little machinery as possible, as one did not want machinery which, in case of breakdown, would interfere with the removal of ashes. He agreed with Mr. Funk that the best scheme was the industrial or steam railway because, in case of breakdown, the ashes could be dumped on the floor, later to be carried away.

[3] Operating Engineer, Philadelphia Elec. Co., Philadelphia, Pa. Mem. Am.Soc.M.E.

[4] Cons. Conveyor Engineer, Quincy, Mass. Mem. Am.Soc.M.E.

[5] Asst. Supt. Construction Bureau, Edison Elec. Illum. Co., Boston, Mass. Mem. Am.Soc.M.E.

T. Maynz[1] spoke of the necessity for ash storage space. In his plant an industrial railway with skip hoist to storage had been installed. In case of breakdown the ashes are dumped on the floor. The problem, he said, was not to cut down the head room of ashpits, but to give them all the room possible.

Sam H. Libby[2] spoke of some of the difficulties confronting the designer of hoists for ash-handling systems which resulted from incomplete or incorrect information about the details of what was expected of his designs.

E. H. Tenney[3] wrote in part: "In connection with the use of air ejector systems in downtown districts we found that, other things being equal, a great deal of consideration had to be given to the prevention of dust. In the particular installation in mind this was eliminated by the careful design of water spray rings and the proper installation of a standpipe vent on the ash-receiving tank. We have also found that where ash hoppers are located outside the plant so that trucks or other conveyances can drive beneath them, for loading purposes, considerable difficulty was encountered in the winter time, due to the ash gates freezing. This difficulty was easily overcome by the installation of small steam lines on all such ash-hopper gates for the purposes of thawing them loose. This point should not be lost sight of in building overhead ash hoppers where the question of hurried ash removal is necessary, as is the case with office-building or hotel power plants."

Rankin Eastin[4] sent in a description of the ash-sluicing system which he had installed at the Tell City Water & Light Company, Tell City, Ind.

Charles E. Prout[5] described the G. & G. telescopic hoist which is adaptable to ash-removal systems in hotels and office buildings when the ashes must be elevated to the street from a boiler room below ground level. This system was applicable, he said, to two conditions found with such types of building: those in which a wagon or railway car could be brought alongside and the cans emptied without removing them from the hoist, and those in which the cans could not be dumped without removal. The average can, he said, weighed about 150 lb. and could be elevated and returned to the basement at a speed of 60 ft. per min.

Eugene Hahn[6] presented an extensive discussion of the problem of removing ashes on shipboard.

George G. Bell[7] presented a written discussion in which he showed how the necessity of ash-handling equipment became acute when coal of high ash content and low fusing temperature was used for power purposes. He spoke also of the difficulty of proper quenching of the cinders and of the gases produced in the ashpit. He emphasized the need of a large ash-storage capacity to tide over difficulties with the ash-handling apparatus or with labor. He described, with lantern slides, the water-sealed type of ashpit originally proposed by Frederick Sargent for the Springdale plant and which was being installed in the extension of the Windsor plant of the West Penn Power Company.

In his closure to the discussion, John Hunter touched on some of the points brought up but said that he did not wish to enter into a detailed reply until he had an opportunity to do so in writing. He was sorry that his paper had been submitted to the printer before he had been able to include data on the G. & G. system which had been mentioned in the discussion.

Stresses in Electric-Railway Motor Pinions

Determination of Their Distribution by the Photo-Elastic Method

By PAUL HEYMANS,[1] CAMBRIDGE, MASS., AND A. L. KIMBALL, JR.,[2] SCHENECTADY, N. Y.

This paper embodies some results of a general scientific study undertaken by the General Electric Company for the development of superior electric railway motor pinions. The work described was performed at the Massachusetts Institute of Technology, using the General Electric Companys apparatus for stress determination in transparent models by the photo-elastic method. Some of the supplementary mechanical tests were made at Schenectady, and throughout the work close contact was maintained with the Railway Motor Department and the Research Laboratory at Schenectady. A brief description and discussion of the photo-elastic method is first given, following which the stress distribution in, and the causes of ruptures of, given types of gear pinions used in electric-railway motors, as investigated by the photo-elastic method, are reported upon and discussed.

THE state of stress at any point in a solid body is determined when the traction across every plane through the point is known. There exist at any point three orthogonal planes across which the traction is purely normal and which are called the planes of principal stress. The normal tractions across those planes are called the principal stresses. The state of stress at any point is completely determined by the direction and the magnitude of the principal stresses at the point under consideration. The principal stresses, given in direction and in magnitude, express in the most general and complete way the elastic state at any given point. The bending moment, the shearing forces, etc., are readily deduced from the direction and the magnitude of the principal stresses. Furthermore, one of the principal stresses always expresses the maximum stress.

The notion of principal stress may be illustrated as follows:

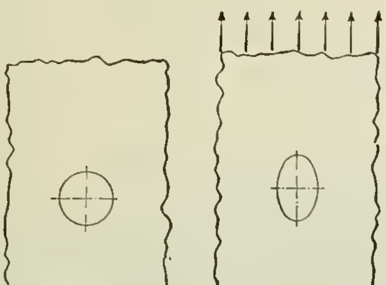

FIG. 1 ELLIPSOIDAL ELEMENT RESULTING FROM SUBJECTING A SPHERICAL ELEMENT TO STRESS

Consider a spherical element in a solid body. External applied loads will deform this spherical element into an ellipsoidal element (Fig. 1). The axes of this ellipsoid will correspond in direction and in magnitude to the direction and the magnitude of the principal stresses.

The orientation and the form of the ellipsoid and therefore the direction and the magnitude of the principal stresses, will define the state of stress at the point under consideration.

The axes of the ellipsoid represent the largest and the smallest deformation at the point under examination. Correspondingly, the principal stresses give the direction and the magnitude of the maximum and the minimum stress.

If the three principal stresses vary from point to point in the structure, the problem to be dealt with is a three-dimensional elastic one. If one of the three principal stresses vanishes throughout, it is a two-dimensional elastic or plane-stress problem.

Corresponding to the three- and two-dimensional elastic-stress problems there are also the three- and two-dimensional elastic-strain problems, when the deformations corresponding to the principal stresses are considered.[1]

A great number of structural problems (bridge, ship, airplane, plate, dam, etc., construction) are, or their stress analysis may be reduced to, two-dimensional elastic problems.

THE PHOTO-ELASTIC METHOD OF STRESS DETERMINATION

As set forth at the beginning of the paper, the state of stress at any point is most completely defined by the direction and the magnitude of the principal stresses. These are, therefore, the elements which we wish to determine for a complete analysis.

The photo-elastic method solves the two-dimensional elastic problems. It primarily takes advantage of the double refracting properties shown by isotropic transparent substances when put under stress. The stresses in the structure may therefore be determined from models made of a homogeneous transparent material, and ordinarily on a reduced scale. The stresses in a steel, cement, or any other structure, homogeneous throughout and obeying Hooke's law of linear proportionality between stress and strain, may be readily deduced from the values obtained by the analysis of the corresponding transparent model for the case of two-dimensional elastic problems.

FIG. 2 REPRESENTATION OF COLORED IMAGE WHEN BOTH NORMAL INSIDE PRESSURE AND MAXIMUM TORQUE ARE APPLIED

(The darkest portions of the image reproduced above are purplish in the original; the next lighter portions, bluish green; the next lighter, reddish orange; and the lightest, yellow.)

If plane polarized light is passed through a stressed specimen of celluloid and afterward through a second nicol prism whose principal section is parallel to the plane of polarization of the original beam of light, only the points where the principal stresses are respectively parallel and perpendicular to the principal sections of the crossed nicols remain dark. The result makes it possible to determine the directions of the principal stresses at any given point.

If now circularly polarized light be passed through the specimen, by interference of the two component rays, which in the double-refracting specimen have suffered a relative retardation at each point proportional to the difference in magnitude of the two principal stresses, a colored image is obtained. Practical considerations make it impossible to reproduce these colored images here, but an idea of their general appearance may be gained from Fig. 2.

By a comparison method, based upon the interposition in the proper direction of a comparison member of constant cross-section, put under uniform tension in a suitable frame (Fig. 3), the value of the difference of the principal stresses at any given point may be read on the dynamometer of the frame.

[2] General Electric Company, Research Laboratory.

Presented at the Annual Meeting, New York, December 4 to 7, 1922, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS. Abridged. All papers are subject to revision.

[1] A complete theory of stress and strain may be found in the Treatise on the Mathematical Theory of Elasticity by A. E. H. Love, 3rd ed , chapters i-iv.

Now, in the two-dimensional elastic problems the transverse deformation, i.e., the deformation along a normal to the plane of the two principal stresses, is proportional to the sum of those two stresses.

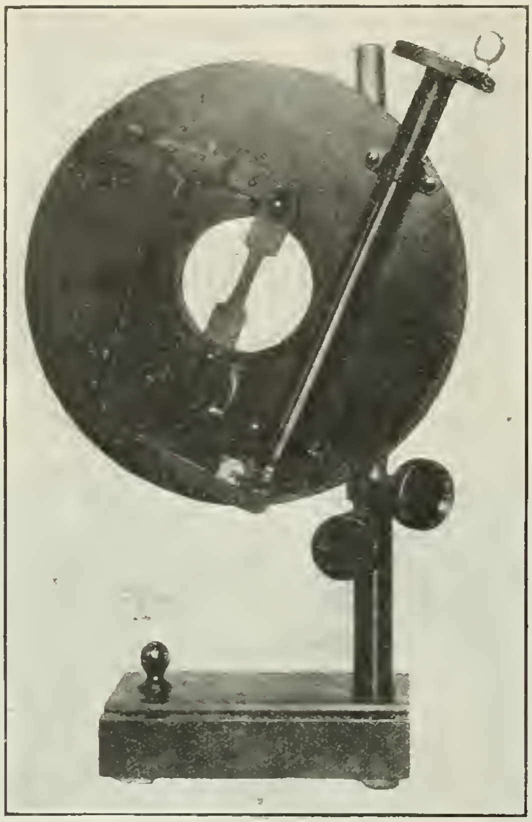

Fig. 3 Frame for Comparison Member Designed by E. G. Coker and A. L. Kimball, Jr.

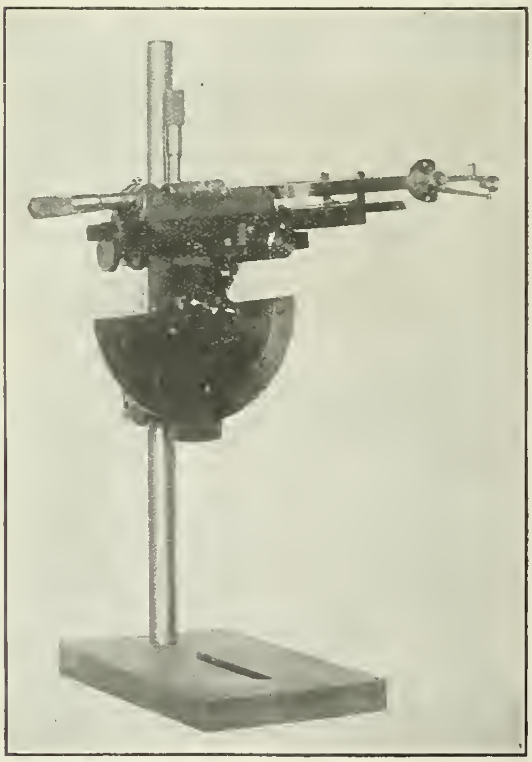

Fig. 4 Lateral Extensometer Designed by P. Heymans

By means of a lateral extensiometer, Fig. 4, we measure this transverse deformation. From the values of the differences and the sums of the principal stresses, the separate values of each of them are computed, thus determining completely the state of stress.

A question naturally arising is whether the results obtained on a transparent body such as celluloid hold for structural materials. It is shown by the general discussion of the equations of elastic equilibrium that in the case of strain or plane stress in an isotropic body obeying Hooke's law of linear proportionality between stress and strain, the stress distribution is independent of the moduli of elasticity and consequently of the material of which the body is made. Thus the stress distribution experimentally determined in the case of a celluloid body is the same as it is when the body is made of any other isotropic substance such as iron, steel, etc., obeying Hooke's law, in distribution, direction, and magnitude. Moreover these conclusions derived from the general theory of elasticity have been checked by experiment.

The photo-elastic method can be applied to the great majority of structural problems, not only in taking the place of mathematical computation, but particularly in solving those structural problems where mathematics becomes too involved to be of help. Moreover it has the great advantage of giving the maximum stress at each point throughout the whole structure, and it therefore offers an effective means of increasing safety and reducing superfluous material.

Stress Distribution in Gear Pinions

When accidents occur with gear wheels, besides the metallurgical question, three possible causes of failure suggest themselves:

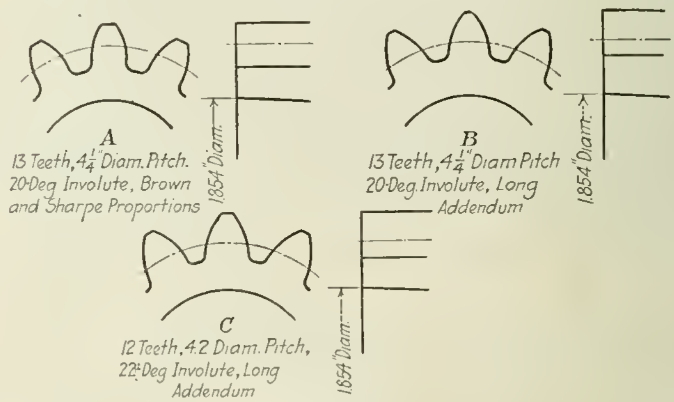

Fig. 5 Tooth Forms of Pinions Subjected to Photo-Elastic Analysis

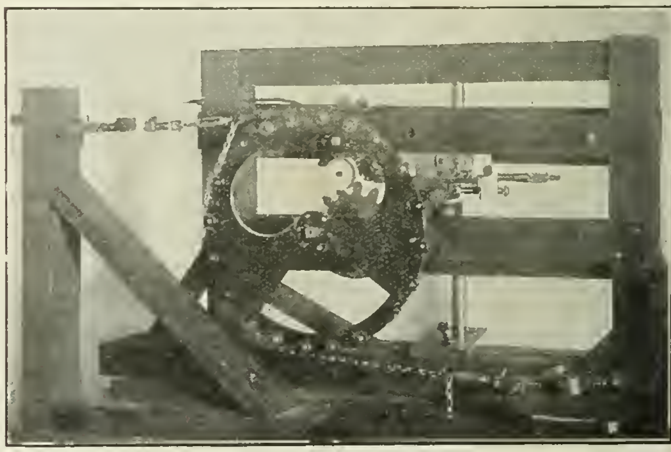

Fig. 6 Frame Used for Applying Loads to Celluloid Models of Pinions

a The gear wheel may not have been properly designed
b It may have failed under an excessive load
c When the pinion was shrunk hot or forced on to a tapered shaft, an excessive inside radial pressure may have been set up.

It is easy to see that the ordinary methods of resistance calculation of gear wheels, based on considering the tooth as a cantilever loaded at its end, would not be expected to give reliable and complete information as to stress distribution, not even for the root section of the tooth which is under consideration.

Fig. 7 Steel Rings Ruptured by Being Forced on to a Tapered Plug

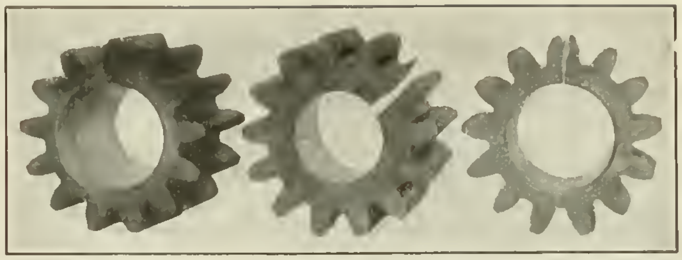

Fig. 8 Steel Pinions Ruptured by Being Forced on to a Tapered Plug

Indeed the shape of the tooth, the curvature at the root, the ratio of the diameter of the pinion bore to the root and outside diameter, the permanent stresses introduced by the placing of the pinion on the shaft, etc., all affect the stress distribution and the maximum stress. Photo-elastic analysis shows that these factors affect the stresses considerably more than would be expected from present methods of estimating. For standardized pinions the correction coefficients can only partially take account of these factors. For special pinions or for pinions of which more efficient running is required, a photo-elastic analysis seems to be the best if not the only effective way to determine the stress distribution and to locate the maximum stress.

Certain interesting points have been brought out by photo-elastic analysis which have been checked by tests carried out on steel sections. These are particularly interesting because they were unexpected.

Besides the stress distribution in the different sections of the pinions represented by Fig. 5 the photo-elastic analysis has given as maximum stress under normal inside radial pressure and normal torque:

80,000 lb. per sq. in. for tooth form *A*
70,350 lb. per sq. in. for tooth form *B*
60,900 lb. per sq. in. for the tooth *C*.

Moreover the 12-tooth pinion shows, besides a smaller maximum stress, a better stress distribution. Fig. 6 represents the frame used for the loading of the models. A tapered expansion ring is used to produce the radial inside pressure. The torque is measured by properly mounted dynamometers.

For steel pinions the maximum stress attained under normal conditions, although high, appears not to be excessive. *Tooth C appeared to be a better design* under normal conditions.

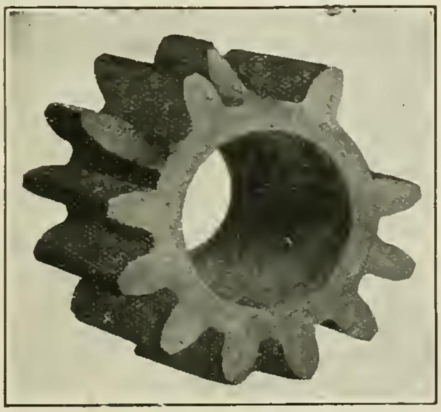

Fig. 9 Fatigue Failures of Teeth Produced by Experiment (with Radial Pressure in Bore)

The stresses due to shrinking or forcing the pinion on the shaft can only be estimated. The pinion may be assumed to be a plain circular ring, for which case the stresses may be mathematically computed. The stress at any point of the ring as well as the maximum stress in the ring depends upon the lengths of the inside and outside radii. The opinion generally expressed is that for the case of the pinion the maximum stress will be intermediate between the maximum values obtained for rings of which the outside diameters are respectively equal to the root diameter of the tooth and to the outside diameter of the pinion, the inside bore being the same.

Photo-elastic analysis shows that *the gear pinion is even weaker than the plain circular ring whose outside diameter is equal to the root diameter of the tooth.* The change of external profile, due to the presence of the teeth, although requiring an addition of material, weakens the structure.

Figs. 7 and 8 show the steel specimens after having been tested by forcing a tapered plug into the bore; and Table 1 gives the rupture load applied to the tapered arbor forced into the bore for the different specimens. These confirm the photo-elastic results.

Previous to the photo-elastic investigation of the stresses due to radial inside pressure in pinion sections, fracture due to pure radial inside pressure would have been expected to occur through the minimum radial cross-section.

From the color image obtained in the photo-elastic analysis when normal inside pressure alone was applied, it appears that *the regions under the teeth are under higher stress* and that the points at the inside boundary right under the teeth are points of maximum stress. The regions in question in the color image mentioned are similar in appearance to the region *A* in Fig. 2.

TABLE 1 RUPTURE LOAD ON ARBOR FORCED INTO SPECIMENS TESTED

	Inside diam., in.	Outside diam., in.	Root diam., in.	Rupture load, lb.
Ring	1.854	3.5	...	85,000
Ring	1.854	2.5	...	51,000
Pinion	1.854	3.5	2.5	47,000

Fig. 8 gives the fractures obtained on steel sections. Two of the sections show fractures right through the thickest layer of material, while all of them started at points where the photo-elastic analysis had revealed maximum stress. The uneveness of the material must account for the deviation of the fracture in one of the cases.

Can any statement be made as to the causes of the failure by inspection of the shape of the fracture? In the case in which the authors were interested, the photo-elastic analysis determined the best design. As before said, either the placing of the pinion on the shaft, if carelessly done, for instance by pounding the pinion heavily on the tapered shaft, or excessive torque and blows due to sudden meshing or the taking on of a heavy load, will set up dangerous stresses.

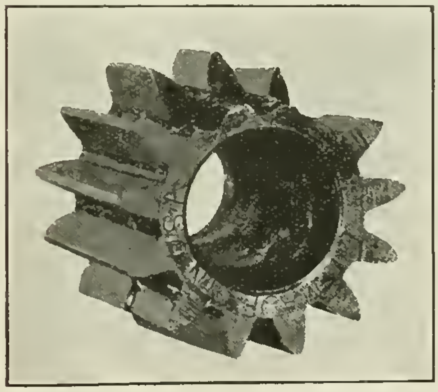

Fig. 10 Fatigue Failures of Teeth Produced by Experiment (with Heavy Radial Pressure in Bore). Note Fracture is of an Open V-Shape

The authors' photo-elastic analysis has shown that *the sections of dangerous stresses are different for different values of inside radial pressure and applied torque load.*

The fracture shown in Fig. 9 is of an *open* V-shape. Photo-elastic analysis shows that *the higher the inside radial pressure becomes,* for a given torque load, *the sharper becomes the V-shape of the section of dangerous stresses.* (Fig. 10.) If the fracture is due to too high a torque load the angle of the V will approach 180 deg. Tests on steel sections have been made with a specially built impact machine.

Without inside radial pressure the fracture obtained is a straight line through the root section of the tooth. With increasing pressures the V-shaped fracture becomes sharper. For an inside radial pressure exceeding the elastic limit, however, the observation does not hold. The reason for this departure from what the photo-

(*Continued on page 137*)

Torsion of Crankshafts

By S. Timoshenko,[1] Philadelphia, Pa.

In order to apply the dynamics of elastic systems to the design of engines it is necessary to determine the torsional properties of the crankshaft. In the present paper the author considers the case of a crankshaft with a single throw and establishes the mathematical relations for such a case. He investigates three conditions of such a crankshaft: (1) no constraint, corresponding to ample clearance in the bearings; (2) complete constraint, corresponding to no clearance in the bearings; and (3) partial constraint, corresponding to ample clearance in the halves of the bearings nearest the web and no clearance in the other halves.

Engine design no longer comprises merely the application of statics, more attention being now paid to the fact that in various types of engines there is not even an approximation of a state of equilibrium. If there are variations in the torque and in the magnitudes of the force, they are necessarily cyclic, and as such they produce cyclic changes in the state of motion and deformation of the parts. The problem is no longer one of statics, but concerns the dynamics of an elastic system. Variations in the state of motion are associated with inertia forces, and the stresses in the various parts of the engine are no longer due to the actually impressed forces alone. Obviously, calculations which consider only the impressed forces must lead to erroneous results, and frequently a break occurs where the designer thought there was an ample margin of strength. Moreover cyclic changes in the state of deformation of a crankshaft, for example, bring about a cyclic change in the orientation of the various cranks, and the balance of the reciprocating parts, which may exist without such changes, is totally destroyed. With reciprocating engines the cyclic changes in the state of motion, referred to above, concern principally changes of the velocity of rotation. In order to apply the dynamics of elastic systems to the type of engine just mentioned, it is necessary to determine the torsional properties of the crankshaft. This is the object of the present paper, which deals with the simpler cases and will be followed by another discussing the two- and three-cylinder two-bearing crankshaft, the multi-throw crankshaft, and the effect of clearances in the bearings.

On account of the very complex structure of reciprocating engines, the calculation of the torsional vibrations in their crankshafts is impossible without making some simplifying assumptions: namely, that certain parts, such as shafts, are considered to be elastic, and others, such as flywheels, armatures of generators, etc., are considered to be absolutely rigid. With these assumptions the engine may be reduced to a system of flywheels situated on a shaft of uniform diameter. This shaft is called the "equivalent shaft;" its diameter may be chosen arbitrarily, but its length between each two flywheels must be such that it is equivalent as to torsion to the actual shaft between corresponding parts of the actual engine. That is to say, a given twisting moment M must produce the same torsional deformation in both.

The length of the equivalent shaft is called the reduced length l_0. If we denote by the torsional rigidity C of a shaft the product of the modulus of shear G into the quantity which measures its resistance to twist, then by elementary mechanics we have for the twist δ of a straight shaft of length l of whatsoever cross-section (provided it is uniform),

$$\delta = \frac{Ml}{C} \quad [1]$$

In the above, as well as in the following, angles will be expressed in radians and all other units in inches and pounds.

For a circular cross-section,

$$C = G\theta \quad [2]$$

wherein $\theta = \pi d^4/32$ is the polar moment of inertia of the cross-section.

[1] Consulting engineer, Vibration Specialty Co.

Contributed by the Research Committee and presented at the Annual Meeting, New York, N. Y., December 4 to 7, 1922, of The American Society of Mechanical Engineers. Abridged. All papers are subject to revision.

Similarly, we have for the equivalent shaft:

$$\delta = \frac{Ml_0}{C_0} \text{ and } C_0 = G\theta_0 \quad [3]$$

from which—

$$l_0 = \frac{C_0 l}{C} = \frac{\theta_0 l}{\theta} \quad [4]$$

As the foregoing shows, the calculation of the reduced lengths of the equivalent shaft has no difficulty for those portions of shaft in the actual engine which are straight. When the actual shaft is a crankshaft, however, the situation becomes very much more involved since it becomes necessary to determine the angular deformation δ brought about by a twisting moment M. Owing to the complex geometric shape of a crankshaft, these calculations can be accomplished approximately only. Various assumptions will have to be made, of which some are only roughly true. It is assumed that the throw is built up of component shapes whose deformations are totally independent of each other. Further, it is necessary to make certain assumptions about the nature and amount of constraint in the bearings. In the present paper only the single-throw crankshaft (Fig. 1) will be considered, and therefore the very considerable influence on it of the neighboring cranks will be neglected. Calculations will be made with three degrees of constraint.

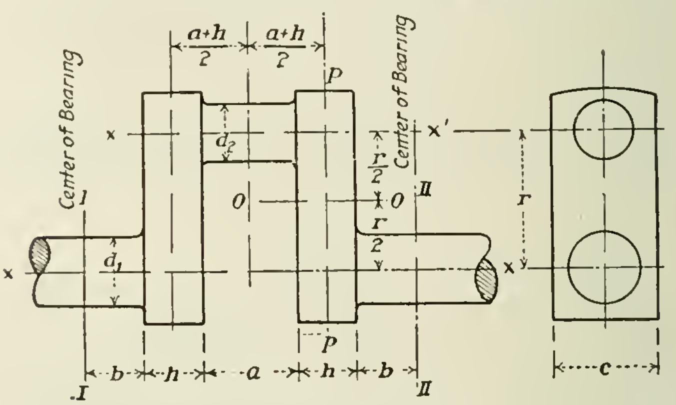

Fig. 1 Conventional Type of Single-Cylinder, Two-Bearing Crankshaft

Definitions and Symbols

Fig. 1 shows the conventional type of a single-cylinder, two-bearing crankshaft. In addition to the dimensions shown thereon, the following is a list of the definitions and principal symbols used in the paper:

Torsional rigidity, generally denoted by C, is the product of the modulus of shear G into the quantity corresponding to its resistance to twist. For a circular cross-section the latter is the polar moment of inertia of the cross-section in respect to the axis of twist. For a rectangular cross-section the quantity referred to is more complex. The formula usually used is only approximately true.

Flexural rigidity is similarly the product of Young's modulus into the quantity I corresponding to the resistance of the cross-section against bending. The latter is always the equatorial moment of inertia of the cross-section with respect to the axis of bending.

$C_0 = G\theta_0 = \frac{\pi}{32} d_0^4 G$ = torsional rigidity of equivalent shaft

$C_1 = G\theta_1 = \frac{\pi}{32} d_1^4 G$ = torsional rigidity of journal

$C_2 = G\theta_2 = \frac{\pi}{32} d_2^4 G$ = torsional rigidity of crankpin

$C_3 = G\theta_3$ = torsional rigidity of web in respect to twist around

O-O. Owing to the junction of journal and pin to the web, the latter's cross-section is not clearly defined, but in order to allow for local stresses at these junctions, at least in some measure, the assumption is made that the cross-section is a rectangle with sides r and c, whence—

$$\theta_3 = \frac{c^3 r^3}{3.6(c^2 + r^2)}$$

$C_3' = G\theta_3'$ = torsional rigidity of web with respect to twist around p-p. The cross-section is rectangular with sides h and c, whence—

$$\theta_3' = \frac{c^3 h^3}{3.6(c^2 + h^2)}$$

$B_1 = EI_1 = \frac{\pi}{64} d_1^4 E$ = flexural rigidity of journal

$B_2 = EI_2 = \frac{\pi}{64} d_2^4 E$ = flexural rigidity of crankpin

$B_3 = EI_3 = \frac{hc^3}{12} E$ = flexural rigidity of web against bending in the plane through p-p perpendicular to the plane of the drawing of Fig. 1.

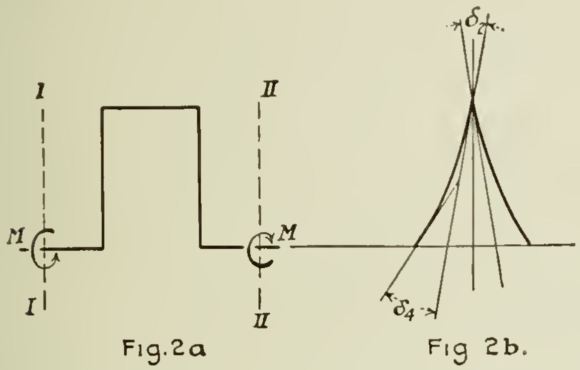

Fig. 2a Diagrammatic Representation of Single-Throw Crankshaft Before Deformation

Fig. 2b Diagrammatic Representation of Side View of Deformed Crankshaft

$F_1 = \frac{\pi d_1^2}{4}$ = area of cross-section of journal

$F_2 = \frac{\pi d_2^2}{4}$ = area of cross-section of pin

$F_3' = h \times c$ = area of cross-section of web taken on O-O

$F_3 = r \times c$ is taken to be the cross-section of the web on line p-p. This quantity is used in the calculation for the deformation due to shear in the plane through p-p perpendicular to the plane of Fig. 1. Similarly, as in the case of torsion, around O-O the cross-section is not clearly defined and $r \times c$ is used to allow for stresses at the junction of pin and journal to the web.

Case I—No Constraint, Corresponding to Ample Clearance in the Bearings

Fig. 2a is a diagrammatic representation of the throw before deformation with a twisting moment M applied at the middle cross-section of the journals. Fig. 2b is a side view of the deformed crankshaft. The total twist consists of the sum of the deformations of the portions b (see Fig. 1) of the journals, of the crankpin and of the two webs.

In the complete paper it is shown that—

$$l_0 = \frac{2bC_0}{C_1} + \frac{aC_0}{C_2} + \frac{2hC_0}{C_3} + \frac{2rC_0}{B_3} \quad \ldots\ldots\ldots\ldots [5]$$

Case II—Constraint at Bearings Complete, Corresponding to No Clearance

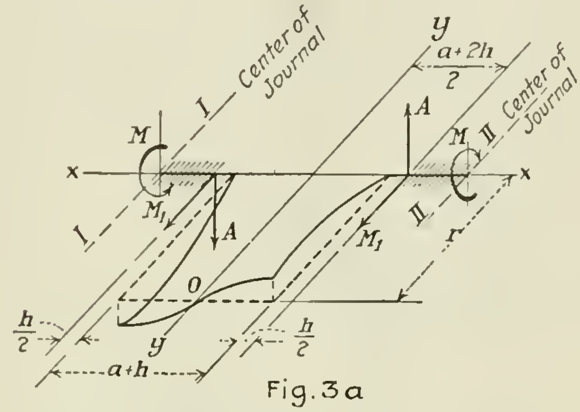
The deformed crank is shown diagrammatically in Figs. 3a and 3b. The constraint gives rise to a force A and a moment represented by the vector M_1 at each of the journals. The forces A and moments M_1 act in a plane through the axis of the journals perpendicular to the plane of the throw.

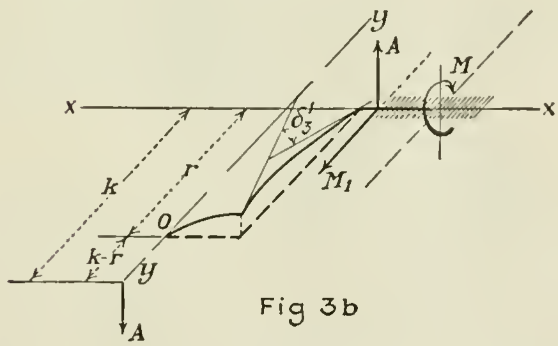
It is shown in the complete paper that—

$$l_0 = \left\{ \frac{2bC_0}{C_1} + a\left(1 - \frac{r}{k}\right)\frac{C_0}{C_2} + 2h\left(1 - \frac{r}{2k}\right)\frac{C_0}{C_3} + 2r\left(1 - \frac{r}{2k}\right)\frac{C_0}{B_3} \right\} \ldots\ldots\ldots [6]$$

from which it is seen that the reduced length of the throw is completely determined if we know the fraction r/k. For $A = 0$ or $k = \infty$ we must have the case of no constraint and, indeed, by placing $k = \infty$ in [6] we obtain [5]. The effect of the constraint is therefore measured by the quantity k. And in the special case where $2b = a$ and $C_1 = C_2$ we can immediately compare the case of a complete constraint with no restraint and find that the constraint decreases the reduced length in the ratio of 1 to $[1 - (r/2k)]$.

The author then proceeds to determine Equation [7], which makes it possible to calculate k, whence l_0 is obtained from [6]. γ is a coefficient having the value 1.2.





Figs. 3a and 3b Diagrammatic Representation of Deformed Crank—Case II

$$k = \frac{\frac{r(a+h)^2}{4C_3'} + \frac{ar^2}{2C_2} + \frac{a^3}{24B_2} + \frac{r^3}{3B_3} + \frac{hr^2}{4C_3} + \frac{\gamma a}{2F_2G} + \frac{\gamma r}{F_3'G} + \frac{\gamma h}{F_3G}}{\frac{ar}{2C_2} + \frac{r^2}{2B_3} + \frac{hr}{2C_3}} \quad [7]$$

This equation is at variance with the equation given by Geiger (Ueber Verdrehungsschwingungen von Wellen), for which reason, and as a check on the above results, the derivation of k and l by means of Castigliano's theorem is given in an appendix to the complete paper. This method is particularly useful in more complicated cases where the deformation of the throw is not as easily seen as in the preceding case.

Case III—Partial Constraint

It is here supposed that there is ample clearance in the halves of the bearings nearest the web, and no clearance in the other half. See Figs. 4a, 4b and 4c. In this manner we will now have bending, as well as torsion, in the halves of the journal next to the webs, a condition which no doubt prevails in practice. The author finds that—

$$k = \frac{\dfrac{r(a+h)^2}{4C_3'} + \dfrac{ar^2}{2C_2} + \dfrac{a^3}{24B_2} + \dfrac{r^3}{3B_3} + \dfrac{hr^2}{4C_3} + \dfrac{\gamma a}{2F_2G} + \dfrac{\gamma r}{F_3'G} + \dfrac{\gamma h}{F_3G}}{\dfrac{ar}{2C_2} + \dfrac{r^2}{2B_3} + \dfrac{hr}{2C_3}}$$

$$+ \frac{b^3}{3B_1} + \frac{b^2(a+2h)}{2B_1} + \frac{b(a+2h)^2}{4B_1} + \frac{\gamma b}{F_1G} \cdots \quad [8]$$

Numerical Example

Let $d_1 = d_2 = 10.25$ in.; $a = 13$ in.; $r = 11$ in.; $b = a/2 = 6.5$ in.; $h = 5.5$ in.; $c = 14$ in. Then—

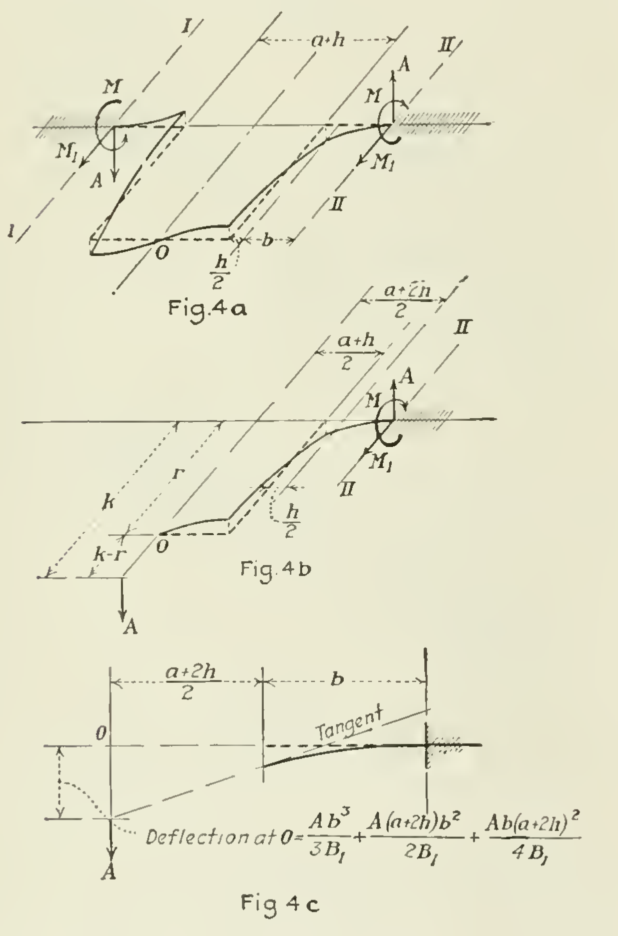
$$B_1 = B_2 = \frac{\pi \times 10.25^4 E}{64} = 54E;\ B_3 = \frac{5.5 \times 14^3 E}{12} = 1258E$$

$$C_1 = C_2 = \frac{\pi \times 10.25^4}{32} G = 1085G;$$

$$C_3' = \frac{14^3 \times 5.5^3}{3.6(14^2 + 5.5^2)} G = 562G$$

$$C_3 = \frac{14^3 \times 11^3}{3.6(14^2 + 11^2)} G = 3200\,G$$

Take $E/G = 2.6$ and the diameter of the equivalent shaft equal



Figs. 4a, 4b, 4c Diagrammatic Representation of Crankshaft—Case III

to the diameter of the journal, whence in this example $C_0 = C_1 = C_2$. Then, when there is no constraint (Case I), substitution in Equation [5] gives—

$$l_0 = 37 \text{ in.}$$

For the case of a complete constraint (Case II), Equation [7] gives—

$$k = 31.6 \text{ in.}$$

and since in the present case $2b = a$, the complete constraint reduces l_0 in the ratio—

$$1 : \left(1 - \frac{r}{2k}\right) = 1 : (1 - 0.174)$$

that is, the reduced length is reduced by 17.4 per cent.

In the case of a partial constraint (Case III), Equation [8] gives—

$$k = 44.2 \text{ in.}$$

and the reduced length, as compared with the case of no constraint, is reduced in the ratio of—

$$1 : \left(1 - \frac{11}{2 \times 44.2}\right)$$

that is, by 12.5 per cent.

These examples plainly show the effect of the constraint at the bearings. The more complete it is, the stiffer the shaft and the shorter the reduced length. The calculations further show that an increase in the diameters of journal and pin and an increase in the length of the pin cause an increase of k and thereby a reduction of the effect of the constraint and reduced bearing pressures A. On the other hand, an increase in the thickness of the web brings about a smaller length k and a corresponding augmentation of the bearing reactions.

Corrosion Problems

A paper on Corrosion as Affecting Metals Used in the Mechanical Arts was read on December 5, 1922, before the Sheffield Association of Metallurgists and Metallurgical Chemists, by Dr. W. H. Hatfield, Brown-Firth Research Laboratories, and past-president of the Association. The object of the paper was to give the particulars and results of an interesting set of experiments made at these laboratories to decide upon the resistance of typical industrial metals to various corroding agents. Dr. Hatfield referred to former work in the matter of various steel alloys, including that by Brearley in regard to stainless steel, and added that acid tests—the means generally employed—gave no direct indication, unfortunately, of the usefulness of an alloy for general corrosion-resisting purposes. A 30 per cent nickel steel was very resistant to sulphuric and hydrochloric acids, but was rapidly soluble in nitric acid of 1.20 specific gravity. The 14 per cent chromium steel was readily soluble in hydrochloric and sulphuric acids, but insoluble in nitric acid, while the 15 per cent silicon steel, although practically insoluble in all three acids, could not be considered completely rustless. These outstanding facts led largely to the carrying out of the experiments.

The materials dealt with numbered over twenty, and in addition to pure irons, carbon steels, alloy steels, cast-iron, they included nichrome and a good selection of non-ferrous metals.

He drew the two following conclusions: (1) There were now available steels and alloys which could effectively resist ordinary corroding influences. The different alloys, while at times each resisting the same media, did not give the same response to other media. It was essential in the application of corrosion- and acid-resisting alloys for actual practical experiments to be made in connection with the particular application intended, since not only composition, but also concentration, temperature, and extraneous influences had to be considered. (2) There was no obvious law, or set of laws, at present available, nor was any existing working theory sufficiently satisfactory to render effective aid to the investigator.

In regard to determining the relation which might exist between the electrode potential and solubility, it being understood that solubility was a function of electrode potential, the author said the main remarks to be put forward were: (1) When rapid solution took place the potential was highly negative; (2) when the potential had a high positive value very little corrosion or chemical action took place; and (3) otherwise the magnitude of the potential gave no indication of the solution properties of the metal. Another point worthy of note was the fact that in those cases in which rapid corrosion took place with evolution of gas, the potentials in hydrochloric and sulphuric acids were approximately the same, while in the case of the normal acids (acids containing 1 gram of available hydrogen per liter) the potential in nitric acid was about 0.2 volt less negative than in the other two acids. No satisfactory explanation of these observations could be put forward. The history of the metal would have some influence on the measured electrode potential, as shown by a table included in the paper. *Engineering*, Dec. 15, 1922, p. 747.

The Design of Cooling Towers

By C. S. Robinson,[1] Cambridge, Mass.

The author points out that engineers have designed cooling towers in the past on empirical information and in accordance with the experience of previous successful designs. Wide departure from standard designs is difficult because of the lack of scientific basis for the design. The author therefore establishes the general principle applicable to cooling-tower design and derives equations for the use of the designer. He presents a quantity of experimental data to substantiate the validity of his formulas and shows by an actual experiment how these formulas are applicable to the design of a counter-current cooling tower.

THE factors influencing the design of cooling towers have been studied by a number of investigators. There has been, however, no statement of the influence of these factors of such a nature that it has been possible to calculate easily the performance of a given tower under widely varying internal and external conditions. Engineers have found that towers of specified construction, when operated at specified air and water rates, may be expected to cool water to within a certain number of degrees of entering air tempeature and to discharge the air from the tower nearly saturated at some temperature approaching that of the entering water. In the absence of anything but empirical information, towers are therefore constructed along certain well-established and successful lines. However, this empirical knowledge will not enable the engineeer to predict what will happen when conditions depart widely from standard practice.

Investigations carried on by the Department of Chemical Engineering at the Massachusetts Institute of Technology under the direction of W. K. Lewis in connection with humidification and air drying, have led to the development of fundamental conceptions as to the mechanism involved in the transfer of heat between liquids and gases and in the vaporization and condensation of liquids and vapors. It is the purpose of this paper, which is based on the principles demonstrated in one written by Professor Lewis,[2] to show how these concepts can be applied to the particular case of cooling towers, and to devise by these means methods by which the engineer can simplify their design.

General Principles

There are two principles upon which all of the subsequent work will be based, (*a*) the conservation of matter and energy, and (*b*) the potential concept. The latter may be expressed briefly as the effect upon the rate of flow of matter or energy of the driving force applied.

The conservation of energy as applied to a cooling tower may best be shown by means of a heat balance. This can be written as—

$$s_w w(t_1 - t_0) = Ws'(T_1 - T_0) + Wr'(H_1 - H_0) \qquad [1]$$

where s_w = average specific heat of the water between the bottom and top of the tower

w = weight of water leaving tower

s' = humid heat[3] if the air entering the tower, that is, the heat required to raise one degree in temperature one pound of dry air plus the water vapor H that it contains

T = temperature of air

t = temperature of water

W = weight of air (moisture free) entering tower

r' = total heat of water vapor at the top of the tower at the temperature of the leaving air minus the heat of the liquid of water at the temperature of the entering water.

The subscripts 1 and 0 refer to the top and bottom of the tower, respectively.

Equation [1] is used universally by engineers at the present time in cooling-tower problems, usually in the approximate form—

$$w(t_1 - t) = Ws(T_1 - T_0) + Wr(H_1 - H_0) \qquad [2]$$

where s and r are the average humid heat and latent heat between the top and bottom of the tower, respectively.

The potential concept may be applied to both the rate of transfer of heat from the liquid to the gas and to the rate of diffusion of water vapor from the liquid to the gas, as shown in the following paragraphs.

The rate or flow of heat is proportional to the temperature difference between the liquid and the gas, and the rate of diffusion of water vapor is proportional to the difference between the vapor pressure of the liquid water and the partial pressure of the water vapor in the gas. The amount of heat flowing from the water to the gas per unit time would therefore be—

$$WsdT = haAdx(T - t) \qquad [3]$$

where h is the coefficient of heat transfer per unit area (sq. ft.), a the square feet of cooling surface per cubic foot of volume of the tower, A the cross-sectional area of the tower, and x the height of the tower.

In the same way the weight of the vapor vaporizing per unit time would be—

$$wdH = k'aAdx(P' - p) \qquad [4]$$

where k' is the diffusion coefficient in pounds per unit area of exposed surface, P' the vapor pressure of the water, and p the partial pressure of the water vapor in the air. Since for small partial pressures p is nearly proportional to the absolute humidity H, Equation [4] may be written as—

$$WdH = kaAdx(P - H) \qquad [5]$$

where P, the vapor pressure of the water, is expressed in terms of absolute humidity, that is, the absolute humidity of saturated air at the temperature of the water in question.

Dividing [5] by [3] gives—

$$\frac{dH}{sdT} = \frac{k(P - H)}{h(T - t)} \qquad [6]$$

The mechanism by which the heat passes from water to the air may be understood by considering that the heat flows first from the interior of the water to the surface, and then from the surface through a substantially stationary air film in contact with the surface to the moving air.

It has been shown[2] that $h/k = s$ when h refers to the coefficient of heat transfer through the air film only. If the total coefficient of heat transfer from the interior of the water to the moving air be used instead of h, the ratio h/k would not equal s, but would only approximate it to a greater or lesser degree according to whether the heat flow through the water took place easily or with difficulty as compared with the flow through the air film.

Unless otherwise noted h and k will henceforth refer to the overall coefficient of heat transfer and vapor diffusion, respectively.

Therefore, taking $h/k = s$, [6] becomes—

$$\frac{dH}{dT} = \frac{P - H}{T - t} \qquad [7]$$

Equation [7], stated in words, says that the *differential* increase in humidity of the air is to the *differential* increase in temperature of the air as the humidity difference between the air and the water is to the temperature difference between the air and the water.

Equation [7] when integrated between proper limits would give the change in humidity and temperature of the water in its passage through the cooling tower. However, while the humidity of the air and the vapor pressure of the water are related to each other and the temperatures of the air and water are also related, the relationships are nevertheless of such a nature that exact integration is impossible, and an approximation is obtained by the following assumption.

---

[2] W. K. Lewis, The Evaporation of a Liquid into a Gas, Mechanical Engineering, July, 1922, p. 445.

[3] Wm. S. Grosvenor, Trans. Am. Inst. Chem. Engrs., 1908.

Presented at the Annual Meeting, Dec. 4 to 7, 1922, of The American Society of Mechanical Engineers. Slightly abridged. All papers are subject to revision.

It will be noted that the temperature difference between the water and the air in a counter-current cooling tower does not change greatly between the top and bottom of the tower, nor does the difference in humidities between the water and air. It is therefore a justifiable assumption that the average temperature difference is approximately equal to the arithmetical mean temperature difference, and that the average humidity difference is approximately equal to the arithmetical mean humidity difference. It may therefore be said that for the whole tower the total increase in humidity of the air is to the total increase in temperature of the air as the arithmetical mean humidity difference between the air and the water is to the arithmetical mean temperature difference between the air and the water.

For the tower shown in Fig. 1 where the subscripts 0 and 1 represent conditions at the bottom and top, respectively, there may now be written—

$$\frac{H_1 - H_0}{T_1 - T_0} = \frac{H_1 - P_1 + H_0 - P_0}{T_1 - t_1 + T_0 - t_0} \qquad \text{[8]}$$

which is the integrated form of Equation [7].

Experimental Data

The author has collected and arranged in Table 1 the results of twenty-three tests made by himself and others on various types of cooling towers.

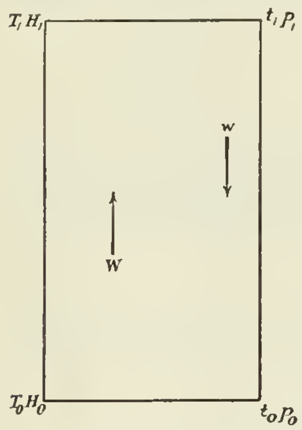

FIG. 1 DIAGRAMMATIC REPRESENTATION OF COUNTER-CURRENT COOLING TOWER

Tests 1 to 5 were on a slat type of forced-draft tower, 6 and 7 were on the same tower operating under natural draft, and Test 23 was on a Wheeler-Balke tower, all described in the Journal of the Ohio Society of Mechanical, Electrical and Steam Engineers, vol. 7. Tests 8 and 9 were on a forced-draft slat-type tower described in the Journal of the American Society of Refrigerating Engineers, vol. 3, 1916–17, p. 32. Test 10 was on a natural-draft tower described in the Transactions of The American Society of Mechanical Engineers, vol. 31, 1909, p. 75. Tests 11 to 22 were on an experimental Badger spray-type tower erected at the Massachusetts Institute of Technology, and the results have not been previously published.

The method of calculating the data may be explained by reference to Test 1.

T_0, (T_1) = temperature of inlet (outlet) air, deg. fahr.
t_1, (t_0) = temperature of inlet (outlet) water, deg. fahr.
Rel. Hum. = relative humidity in per cent
Q = heat given up by water in B.t.u. per min.
$= 651 \times 8.3 \times (105 - 84.7) = 110{,}500$
V = cubic feet of air per minute
H_0 = absolute humidity of inlet air in pounds of water per pound of dry air, as read from humidity chart[1]
P_0 = equivalent absolute humidity of outlet water, i.e., the absolute humidity of air saturated at the water temperature
H_1 = absolute humidity of outlet air, assuming saturation
P_1 = equivalent absolute humidity of inlet water
H = mean humidity difference between the air and water
$$= \frac{0.026 - 0.006 + 0.050 - 0.031}{2} = 0.0195$$
W = pounds of dry air per minute, as calculated from the volume of air V divided by the bumid volume (the cubic feet occupied by one pound of dry air plus the water vapor which it contains, as read from the humidity chart)
w = pounds of water evaporated per minute
$= W(H_1 - H_0) = 3700(0.031 - 0.006) = 93$
$ka \times$ vol. = pounds of water evaporated in the whole tower per minute per one pound mean humidity difference
$$= \frac{93}{0.0195} = 4800$$
Q_{sens} = sensible heat picked up by the air per minute
$= Ws(T_1 - T_0)$, where s is the humid heat as read from the humidity chart[3] ($s = 0.25$)
$= 3700 \times 0.25(90 - 71) = 18{,}000$ B.t.u.
t = mean temperature difference between air and water
$= (105 - 90 + 84.7 - 71)/2 = 14.4$
$ha \times$ vol. = B.t.u. picked up as sensible heat by air in the whole tower per degree temperature difference
$$= \frac{18{,}000}{14.4} = 1250$$
$$\frac{h}{k} = \frac{ha \times \text{vol.}}{ka \times \text{vol.}} = \frac{1250}{4800} = 0.26$$
$$ha = \frac{ha \times \text{vol.}}{\text{vol.}} \text{ where "vol." is the volume of the tower.}$$

The dimensions of the tower in Test 1 were not given in the article, but other information led to the assumption that the tower was 10 × 10 × 22 ft., a volume of 2200 cu. ft., whence—

$$ha = \frac{1250}{2200} = 0.57 \text{ and } ka = \frac{4800}{2200} = 2.18$$

[a] Assumed values. [c] Calculated values.

u = linear velocity of air through the total cross-section of the tower

$$= \frac{53{,}900}{10 \times 10} = 540 \text{ ft. per. min.}$$

$$\frac{ka}{u} = \frac{2.18}{540} = 0.0040$$

The most interesting tests are those numbered 1 to 7, which have been quoted several times in articles by different investigators. In these tests the first five were under forced draft, while the last two were under natural draft, with much reduced air velocity. A plot of ka versus air velocity for these seven tests gives a straight line passing through the origin.

It has been noticed by others[1] that the rate of cooling in towers is approximately proportional to the air velocity. Investigations at the Institute being carried on at the present time indicate that ka for humidifying apparatus in general is probably proportional to a power function of the air velocity something less than one, but for the present, at least, linear proportionality is a fairly close approximation. While k is the actual coefficient of diffusion per square foot of surface, since in many types of towers the active surface cannot be accurately measured the coefficient ka is used instead, where a represents the actual surface in square feet per cubic foot of tower. In most towers a is uniform throughout the volume of the tower.

It is therefore justifiable to call the value ka/u the "tower constant" and to use the value of this constant as a means for comparing the operation of towers of various sizes and types. Thus for tower No. 1 the average value of ka/u is 0.0037 and the average deviation from this value is 0.00021, or less than 6 per cent, while the maximum deviation is 0.0006, or 16 per cent. The important thing indicated by these tests is that ka/u was unaffected whether the tower was operated with forced or with natural draft.

Tower No. 4 has an average value of 0.00475 for ka/u, with an average deviation of 10 and a maximum deviation of 31 per cent.

Tower No. 2 has an average constant of 0.0080, which is high compared with the other towers tested. The drop in pressure through this tower was not published. It would be interesting to compare its drop in pressure with that in other towers which show smaller tower constants. It is of course obvious that a high tower constant can be obtained by obstructing the flow of air through the tower by cutting down the mean free area, but this again is at the expense of friction and back pressure. Wherever possible the drop in pressure through the tower should be measured and published.

The average value of the humid heat of air in a cooling tower is about 0.25. It will be noted that the column h/k in Table 1, which should be approximately equal[2] to s, has values of the same order of magnitude in general, but which are somewhat higher. The reason for this as predicted from the statements made in Par. 12 is shown by the fact that, while the surface of the water is at a lower temperature than the interior, making the true h for the air film greater, the value of k was calculated for the average water temperature instead of using the surface temperature. The latter is lower and would give a higher value for k. But since the vapor pressure of water rises more rapidly than the temperature, the ratio of h to k calculated on the average water temperature would be greater than that calculated on the lower surface temperature, which was the case in all but two cases in Table 1. The experimental data are therefore offered as proof of the validity of Equation [7].

Information regarding the size of tower in Test 23 was not available. It would be interesting to compare the values of ha and ka for this large tower with those of the smaller ones in the previous tests.

The results of the calculations of the test runs are felt to confirm in a remarkable manner the conceptions regarding humidification in general as developed by W. K. Lewis, furnishing as they do ample experimental proof of their validity.

Application of Equations Developed to Tower Design

The value of the foregoing equations with respect to cooling-tower design may best be shown by means of an example.

In any cooling tower the law of conservation of energy must apply. This law is represented by the heat balance of Equation [1]. Furthermore, in any cooling tower there is a necessary relationship between the amount of heat transferred by conduction and that eliminated by evaporation which is represented by Equation [8]. Finally, the capacity of any cooling tower is determined by the rate of transfer of heat and the rate of diffusion of vapor in it. These rates are dependent upon the design of the tower, and can only be determined on the basis of experimental data on the performance of towers of the type in question. The capacity factor is covered by Equation [3] or Equation [5] in the differential, but in actual design it is more satisfactory to use an integrated form of Equation [5] obtained by the use of arithmetical mean humidity differences and represented by Equation [9]. The combination of these three equations represents the conditions that must obtain in any tower and therefore serve as a proper basis for tower design.

The coefficient ka/u expresses the volumetric capacity of any particular type of tower. Experimental determination of this constant is necessary before design can be accomplished.

It is necessary for the engineer to select the type of tower most suitable for his purpose, and, from previous tests on towers of similar type, obtain values of ka which can be anticipated. In general certain specifications must be met. There may be:

Weight of water to be cooled, w (= 3000 gal. per min.)
Temperature of water to be cooled, t_1 (= 110 deg. fahr.)
Temperature to which water must be cooled, t_0 (= 80 deg. fahr.)
Average (or worst) outside air temperature, T_0 (= 80 deg. fahr.)
Average (or worst) outside air humidity, H_0 (= 0.0130, i.e., 60 per cent relative humidity)

for which the values in parentheses may be taken, those for T_0 and H_0 being the worst atmospheric conditions under which a tower must cool the water at 80 deg. fahr.

It will be noted that the condition of reducing the temperature of the water to that of the entering air is exceptionally severe and will call for a tower considerably larger than usual, since towers rarely have to meet such specifications.

There are in this case three unknown conditions, the temperature and humidity of the outgoing air, and either the volume of the tower or the ratio of the amount of air to the amount of water. The air-water ratio is usually determined by the type of tower selected and is therefore known, leaving the volume of the tower as the third unknown.

In order to calculate these unknown quantities three independent equations are needed. These may be taken as Equations [2], [8] and [9], and an integrated form of Equation [4] obtained by employing the same assumption as that used in integrating Equation [7], namely,

$$W(H_1 - H_0) = kaAx\,\frac{P_1 + P_0 - H_1 - H_0}{2} \quad\ldots\ldots\ldots[9]$$

Equations [2], [8], and [9] may be solved simultaneously for H_1, T_1, and Ax (which latter equals the volume of the tower). The author has seen fit to solve for W instead of Ax, but after H_1 and T_1 have been found it is easy to convert the solution for W into that for Ax.

$$W = -\frac{\dfrac{w(t_1 - t_0)}{s(2T_0 - t_1 - t_0) + r(2H_0 - P_1 - P_0)}}{1 + \dfrac{2w(t_1 - t_0)}{kaAxs(2T_0 - t_1 - t_0) + r(2H_0 - P_1 - P_0)}} \quad\ldots[10]$$

In the particular problem in question, suppose that a forced-draft slat-type tower such as was used in Tests 1 to 7, whose tower constant ka/u is 0.0037, be selected. Towers of this type are found to be economical when handling 6.5 gal. of water per min. per sq. ft. of ground area with an air velocity of about 500 ft. per min.

The area of the proposed tower will therefore be 3000/6.5 = 460 sq. ft., and the volume of air will be 500 × 460 = 230,000 cu. ft. per min. The humid volume of one pound of dry air as read from the humidity chart is 13.8 cu. ft. Therefore—

$$W = \frac{230{,}000}{13.8} = 16{,}700 \text{ lb. per min.}$$

also—

$w = 3000 \times 8.3 = 25{,}000$	$r = 1050$ (approx.)
$t_1 = 100$	$H_0 = 0.013$
$t_0 = 80$	$P_1 = 0.0585$
$s = 0.24$	$P_0 = 0.022$
$T_0 = 80$	$ka = 0.0037 \times 500 = 1.85$

[1] Jour. Am Soc. Refrig. Engrs., vol. 3. 1916–17, p. 32.
[2] W. K. Lewis, The Evaporation of a Liquid into a Gas, Mechanical Engineering, July, 1922, p. 445.

Substituting these values in Equation [10] and solving for Ax gives 41,500 cu. ft. for the volume of the tower, and since the ground area was determined to be 460 sq. ft., the tower height would be 41,500/460 = 90 ft. The severe conditions imposed account for the great height required.

If the tower be built as calculated, the performance under any other atmospheric conditions may be readily calculated by substitution in the proper equation.

The author realizes that the foregoing methods of calculating cooling-tower performance do not form the complete solution of the problem, and that the ultimate design of the best tower will depend upon the striking of an economic balance between the size of the tower and the cost of moving the water and the air. He feels, however, that this method of calculation is distinctly in advance of anything which has thus far appeared in print, that it furnishes a convenient and accurate tool for the designing engineer, and that it is the necessary basis for the economic balance referred to.

Finally, the author wishes to urge the inclusion of more complete and more accurate data in published accounts of tower performances. Of all the published tests studied, only those tabulated had sufficient data to enable them to be analyzed, and even then, in most cases, assumptions were necessary. Inaccurate data are often common. Test No. 10 is an example of this, the heat of vaporization alone being considerably greater than the total cooling of the water, which inaccuracy renders the test useless for purposes of analysis. A more complete knowledge of the effect of varying conditions on ha and ka can only come from studies of large numbers of accurate tests, and it is upon such increased knowledge that advance in tower design depends.

Discussion

B. H. Coffey[1] wrote that the members of the American Society of Refrigerating Engineers present at the session would remember that Mr. George Horn and he had devoted much time and study to this subject. They were therefore gratified to see the theory of cooling towers becoming of interest to the scientific men of college faculties as instanced by Mr. Robinson's paper. If the unequaled experimental facilities and mathematical ability of our great engineering schools became engaged upon this subject, they believed it could be shortly put upon a practical basis for the general profession.

All cooling towers, Mr. Coffey wrote, were more structural assemblages of cooling surface, the cost of which was by far the largest item in the installation. For this reason the designer and purchaser were peculiarly interested in the area of surface required to do the specified cooling. The discussion would therefore be confined to the points bearing on this part of the subject.

Equations [3] and [4] showed the dual heat currents that always existed between air and water when not in thermal equilibrium, both expressions containing a cooling surface term and transmission coefficient. In Equation [3] the potential or driving force was temperature difference and in Equation [4] pressure difference. For future reference they—Mr. Coffey and Mr. Horn—wished to point out that by simple transposition in each equation the surface increment would equal the heat increment multiplied by the reciprocal of the potential and consequently for zero potential the surface increment was infinite.

By ingenious use of the connecting constant s, Equation [7] was established showing the relation between the latent and sensible heat currents. The author failed to integrate this equation, however, and resorted to an approximation with which they took issue.

This approximation was based upon the assumption that the mean of the extreme differences was the true mean and the assumption was based upon the stated fact that in counter-current cooling towers the pressure and temperature differences did not change greatly between the top and bottom of the tower. No evidence was offered to support this statement, which they disputed. Referring to Table 1, tests 1 to 7, the temperature differences at the bottom of tower as a percentage of those at the top ranged from 91 to 366 per cent, and on the same basis the pressure differences varied from 83 to 148 per cent. These figures were sufficient to cast grave doubts upon the author's statement and basis of his approximation and that probably the mean potentials he obtained were not the true means.

[1] Elizabeth, N. J. Mem. Am.Soc.M.E.

If the mean potentials were incorrect the mean transmission coefficients h and k which were derived from them were incorrect and the ratio h/k would be incorrect. Referring to Table 1, col. h/k, they found this ratio varied from 0.20 to 0.38 when it should be approximately constant and about 0.25. The explanation of these wide discrepancies given by the author was not convincing to them.

The extraordinary height of tower, 90 ft., to meet the not particularly severe conditions as obtained from the simultaneous Equation [10], was they believed, due to incorrect mean potentials.

As a further test of Equation [10] they had used for final water temperature 69.7 deg. the wet-bulb temperature of the entering air. Under these conditions the total potential became zero and the cooling surface infinity, as pointed out above. The calculation resulted in a tower 230 ft. high instead of infinity, which they again would attribute to incorrect mean potentials.

In their opinion this line of attack upon the cooling-tower problem, while promising, had failed to produce working formulas that expressed the cooling process. They suggested as a basis using total potential equations. The relation $h/k = s$ gave a means of converting temperature potential into equivalent pressure potential or the reverse. The total potential could be thus expressed either in temperature or pressure alone and the problem much simplified.

They noted with regret the absence of any reference to the wet-bulb temperature in the paper, a physical quantity universally regarded of the greatest importance in this subject.

W. M. Grosvenor[1] wrote that it was a real satisfaction to find after fourteen years that a piece of one's own work stood the test of time and was still of use to other engineers, particularly in such a very admirable consideration of cooling towers as the author had given in his paper. The article on Calculations for Drier Design to which he referred had been published in the *Proceedings* of the American Institute of Chemical Engineers and the *Heating and Ventilating Magazine* for 1908, when the best available data on humidity were those of the U. S. Weather Bureau, and on these figures the calculations were based and the resulting curves plotted. The conception was there introduced of representing what might be called adiabatic evaporative cooling by lines intersecting the curves of relative humidity on a chart having temperatures as one ordinate and weight of moisture per lb. of air, volume per lb., B.t.u. per lb. of air when damp (humid heat), etc., on the other ordinate. This had proved to be a very useful and easy way of calculation. Some three years later at the annual meeting of The American Society of Mechanical Engineers for 1911, in a paper entitled Rational Psychrometric Formulae, Willis H. Carrier had used this method of presenting a newly calculated set of curves based, Mr. Grosvenor believed, on more accurate data than those of the Weather Bureau. It seemed to him that Mr. Carrier had done a very excellent and valuable piece of research work that was very thoroughly discussed at that meeting but had received too little attention since. This valuable paper contained no reference to any previous publication of humidity charts with adiabatic cooling lines, etc., but Mr. Grosvenor desired to call the author's attention to it and to ask for it the careful consideration he believed it deserved.

Now that we had in the author's work the foundation laid for a more logical and clear understanding of the data needed for perfecting the design of cooling towers, it became the obvious duty of engineers having cooling towers under operation to determine as well as they could the conditions of operation and communicate the information to him. He would then be in a position to suggest changes in operating conditions if not in design and on the basis of the results before and after could revise and perfect what should be a very valuable solution of a problem that was becoming increasingly important with municipal growth.

L. A. Phillips[2] asked if the author's formula for cooling towers which, in the example in the paper had resulted in a tower 90 ft. high, had been checked with a tower of commercial height, say, about 30 ft.

Size Selection of Dry-Vacuum Pumps

By EDWARD W. NOYES[1] and HAROLD V. STURTEVANT,[1] CLAREMONT, N. H.

In pumping from atmospheric pressure down to a given vacuum with a dry vacuum pump, as during the process of exhausting a closed tank, the volumetric efficiency of the pump varies from that at atmospheric pressure to that corresponding to the given vacuum and an average value has to be determined to use in the theoretical formulas which apply to this kind of service.

Two methods of determining the average volumetric efficiency were successively tried out by the authors and results plotted in the form of curves, but these results did not check satisfactorily with those obtained in actual tests of an installation. The process of calculation employed in the second (and somewhat more accurate) method was then reversed, and working with actual test data, values were obtained from which a "constant" curve was plotted, this curve giving closely accurate results from 80 per cent perfect vacuum up. With the aid of this "constant" curve two charts have been plotted, by means of which it is possible to determine rapidly and with sufficient accuracy (1) the size of pump required to exhaust a given volume to a specified degree of vacuum in a predetermined time; or (2), where a vacuum pump is already installed, the time required to exhaust a given volume to a specified degree of vacuum.

DRY-VACUUM PUMPS are subjected to two different kinds of service, one of which may be classified as continuous vacuum service, in which the intake and delivery pressures remain practically constant during the operation of the pump; and the other as variable vacuum service, in which the intake pressure varies from atmosphere down to some low vacuum during the operation of the pump, as would be the case in exhausting a closed tank.

The dry-vacuum pump is employed on the latter class of work in many of the industries, notably in (1) creosoting and impregnation of wood; (2) dehydrating of food products; (3) in textile and dye works to assist in the penetration of the fabrics with dyes; (4) in electrical establishments, to remove air from insulation; and (5) in the extraction of wax from waste wax paper.

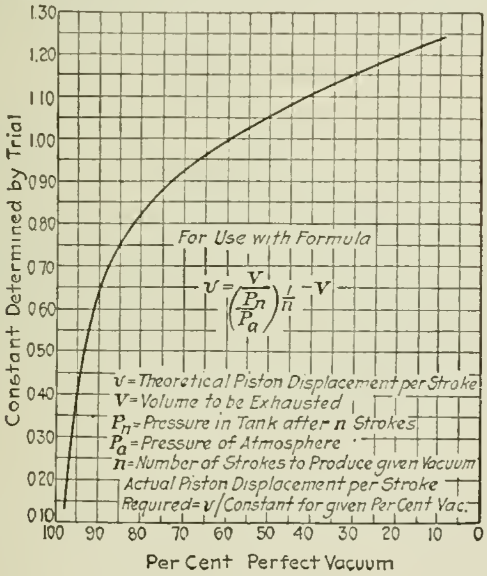

Fig. 1 Vacuum-Pump Constant for Use with General Formula for Piston Displacement

The problem of determining the size of vacuum pump required to evacuate a tank of given size to a certain degree of vacuum in a predetermined time seems to be a rather elusive one, and the purpose of this paper is to present a method for its solution which will apply to any set of conditions, and which may be quickly used to determine the correct size of pump, with accuracy sufficient for all practical purposes.

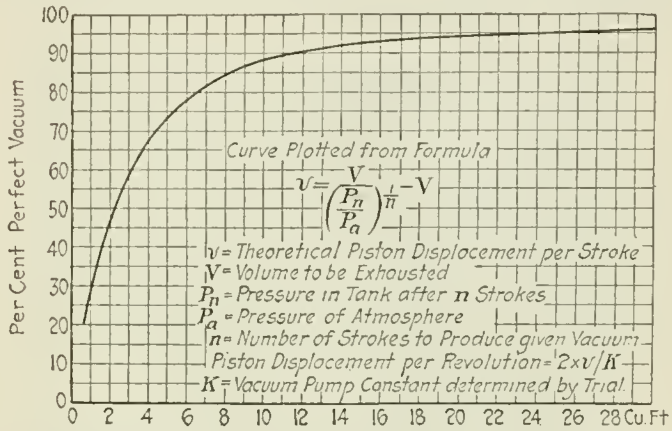
[1] Sales Engineer, Sullivan Machinery Company of Claremont, N. H., and Chicago, Ill.

Presented at the Annual Meeting, New York, December 4 to 7, 1922, of The American Society of Mechanical Engineers. Abridged. All papers are subject to revision.

The experimental work described was conducted at the Claremont N. H., plant of the Sullivan Machinery Company, and the machines used were the standard, straight-line, belt-driven vacuum pumps manufactured by that company.

Two methods of determining the average volumetric efficiency were successively tried out by the authors and the results plotted in the form of curves, but these results did not check satisfactorily with those obtained in actual tests of an installation. The process of calculation employed in the second (and somewhat more accurate) method was then reversed, and, working with actual test data, values were obtained form which a "constant" curve was plotted.

Fig. 1 shows this constant curve plotted against percentage of perfect vacuum. The individual constant curves of which it is an average show some divergence between zero and 80 per cent perfect vacuum, so that within this range the results obtained by using the chart are slightly inaccurate. From 80 per cent up, however, the values given are accurate for all practical purposes.



Piston Displacement per Revolution required to Exhaust a Volume of 1000 Cu. Ft. from Atmospheric Pressure to any Per Cent Vacuum with 300 Revolutions. (For a Different Volume or Number of Revolutions the Piston Displacement varies Directly as the Volumes and Inversely as the Revolutions.)

Fig. 2 Dry-Vacuum Pump Piston Displacement Required to Exhaust a Closed Space

It is evident that this curve is to be used in connection with the general formulas for solving any vacuum-pump problem rather than the average volumetric-efficiency curve, because the former has been determined from the results of tests on an actual installation.

In the general formulas given respectively in Figs. 2 and 3 there exist direct and inverse relationships between the variables which may be taken advantage of in plotting the curves. For example, in the formula of Fig. 2 v varies approximately inversely as n and directly as V, and in the formula of Fig. 3 n varies approximately directly as V and inversely as v.

This relationship makes it possible to plot the formula of Fig. 2 for some given values of V and n, such as $V = 1000$ and $n = 600$, and with v and the percentage of perfect vacuum as the variables. Then for any given case where the values of V and n are different from those in the plot, the value of v required would be directly proportional to V and inversely proportional to n. Likewise the formula of Fig. 3 can be plotted for some given values of V and v, such as $V = 100$ and $v = 0.5$, and with n and the percentage of perfect vacuum as the variables. Then for any given case the value of n required would be directly proportional to V and inversely proportional to v.

The value of v thus obtained was multiplied by 2 and divided by the constant determined by trial and plotted as piston displacement per revolution in Fig. 2. The value of n was divided by 2 and by the constant and plotted in Fig. 3 as total revolutions required.

Fig. 3 will apply to cases where the displacement of the pump is assumed or known and it is desired to find the total number of revo-

lutions required to exhaust a given volume to a predetermined vacuum. Knowing the time which may be used in the process, the r.p.m. of the pump may be obtained. A barometric pressure of 29.5 in. was used in the computations and the results plotted against percentage of perfect vacuum, so that the curve will apply with any barometric pressure. In using the curves, the average barometric pressure over a long period of time in any given locality should be used. Knowing the degree of vacuum desired, the percentage of perfect vacuum can be readily calculated. Following is a sample calculation used in the determination of this curve.

Barometer = 29.5 in.; vacuum in inches of mercury = 24; percentage of perfect vacuum = (24/29.5) × 100 = 81.3; V = 100 cu. ft.; v = 0.5 cu. ft. Then—

$P_n = (29.5 - 24) \times 0.4912 = 2.70$ lb. per sq. in.

$P_a = 29.5 \times 0.4912 = 14.49$ lb. per sq. in.

Also, from Fig. 1,

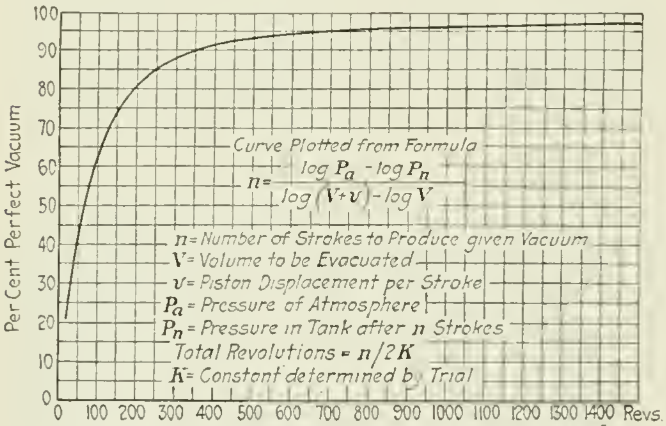
$K = 0.81$

Whence—

$$\text{Total revolutions} = \left(\frac{1}{2} \times \frac{\log 14.49 - \log 2.70}{\log (100 + 0.5) - \log 100}\right) \div 0.81 = 207.95.$$

Hence at 81.3 per cent perfect vacuum is plotted 207.95 revolutions. This same process was followed for about twenty different points and the curve thus obtained.

Fig. 2 will apply to problems in which the total revolutions or



Total Revolutions required to Exhaust a Space of 100 Cubic Feet from Atmospheric Pressure to any Per Cent Vacuum with a Pump of One Cubic Foot Piston Displacement per Revolution (For Different Volume or Piston Displacement the Total Revolutions vary Directly as the Volumes and Inversely as the Piston Displacement.)

Fig. 3 Dry-Vacuum Pump Revolutions Required to Exhaust a Closed Space

r.p.m. and time are known or assumed, and it is desired to calculate the piston displacement necessary to exhaust a given volume to a predetermined vacuum. A sample calculation used in the determination of this curve follows.

Barometer = 29.5 in.; vacuum in inches of mercury = 25; percentage of perfect vacuum = (25/29.5) × 100 = 84.7; V = 1000 cu. ft. Then—

$P_n = (29.5 - 25) = 4.5$ in. $\qquad P_a = 29.5$ in.

$n = 600$

$$v = \frac{V}{\left(\frac{P_n}{P_a}\right)^{1/n}} - V = \frac{1000}{\left(\frac{4.5}{29.50}\right)^{1/0.0016667}} - 1000 = 3.138$$

Actual piston displacement per revolution = 3.138 × 2/0.76 = 8.258 cu. ft., where 0.76 is the value of K from Fig. 1 for 84.7 per cent perfect vacuum.

Thus piston displacement of 8.258 cu. ft. per revolution was plotted against 84.7 per cent perfect vacuum. This process was repeated for many different percentages of vacuum and the curve obtained.

The problems which may be solved with the aid of the formulas of Figs. 2 and 3 will vary in nature, but a few typical cases will be worked out in order to illustrate the application of the curves.

First and most important is the case where it is desired to determine the size of pump required to exhaust a given volume to a certain degree of vacuum in a predetermined time.

I—Given a volume of 5000 cu. ft., including the piping between the pump and tank, it is desired to find the size of pump required to exhaust the tank to a vacuum of 26 in n. i30 min. Barometer, 29.5 in.

a Assume that the pump will run at 280 r.p.m. In this case the percentage of perfect vacuum = 26/29.5 = 88.1. Using chart of Fig. 2, follow line at 88.1 per cent horizontally until it intersects the curve, then vertically downward to the base line, when the piston displacement will be found to be 10.15 cu. ft. This is the piston displacement per revolution required to exhaust 1000 cu. ft. from atmospheric pressure to 26 in. with 300 revolutions of the pump. Hence—

$$\text{Displacement per revolution} = \frac{10.15 \times 5000}{1000} \times \frac{300}{280 \times 30} = 1.814 \text{ cu. ft.}$$

This is the actual piston displacement required with a pump running at 280 r.p.m. to exhaust 5000 cu. ft. to 26 in. in 30 min. Allowance has been made for leaks such as are always present in the average installation. For xcessive leakage, however, a small factor of safety may be added.

b Assume piston displacement per revolution = 2 cu. ft. Using chart of Fig. 3, follow line at 88.1 per cent horizontally until it intersects the curve; hen vertically downward to the base line, where the number of revolutions is found to be 305. This is the total number of revolutions required to exhaust a volume of 100 cu. ft. from atmospheric pressure to 26 in. with a pump of 1 cu. ft. displacement per revolution. Hence—

$$\text{Total revolutions} = \frac{5000}{100} \times \frac{305}{2} = 7625$$

$$\text{R.p.m.} = \frac{\text{Total revolutions}}{\text{Time in minutes}} = \frac{7625}{30} = 254$$

This is the actual r.p.m. required with a pump of 2 cu. ft. piston displacement per revolution to exhaust 5000 cu. ft. to 26 in. in 30 min.

The second type of problem, the solution of which may be obtained by use of the curves, is the one in which a vacuum pump is already installed and it is desired to determine the time required to exhaust a given volume to a certain degree of vacuum.

II—Given an 18-in. by 8-in. pump running at 300 r.p.m., how long will it take to exhaust a tank of 2500 cu. ft. capacity from atmospheric pressure to 26 in. vacuum? Barometer, 28.4 in. Piston displacement per rev. = 2.34 cu. ft.; percentage of perfect vacuum = 26/28.4 = 91.5.

Using chart of Fig. 3, follow line of 91.5 per cent horizontally until it intersects the curve, then vertically downward to the base line, when the revolutions are found to be 415. This is the total number of revolutions required to exhaust a volume of 100 cu. ft. from atmospheric pressure to 26 in., with a pump of 1 cu. ft. piston displacement per revolution. Hence—

$$\text{Total revolutions} = \frac{2500 \times 415}{100 \times 2.34} = 4433.8$$

$$\text{Time required} = \frac{\text{Total revolutions}}{\text{r.p.m.}} = \frac{4433.8}{300} = 14.8 \text{ min.}$$

This is the actual time required, allowance having been made for leaks such as are present in the average installation.

In presenting this method of solving problems concerning the evacuation of closed spaces, the authors do not claim to have produced an absolutely accurate rule which will answer in every case. They do hold, however, that the method proposed of using a constant determined by trial gives much more accurate results than can be obtained by the use of an average volumetric efficiency computed by either of the two methods mentioned.

It will be noticed that the question of the effect of varying amounts of leakage on the size of pumps required has not been considered. This is undoubtedly an important phase of the problem and in any accurate determination of the size of pump or time required for evacuation, as the case may be, the leakage area of the system should be previously determined.

Obviously, if the system under consideration has two or three times the leakage area that was present in the system from which the curves of this paper were obtained, then the size of pump determined from them will be too small, or the number of revolutions required to exhaust the system in the given time will be too small. Yet even had this leakage factor been included, it is doubtful whether in the majority of cases it could be made use of.

Take the case of a purchase of a vacuum pump for evacuating a closed system. The chances are that the buyer has no means at hand for determining the leakage area before the pump ordered arrives, and it is unlikely that he would first install the closed system and have a test made on it before determining the size of pump required. This of course applies to an average commercial installation where the buyer, if he specifies a ten-minute period that he wishes to allow for the evacuation, will not care much if the pump provided actually requires, say, eight or twelve minutes in which to do the work.

The method presented is intended for such cases and it is assumed that leakage conditions will be approximately the same in a commercial installation as those under which the experiment described was made.

Feed Heating for High Thermal Efficiency

Economies of 25,000-kw. Power Stations Using Single- and Multiple-Stage Condenser Heaters, with And Without Economizers, Determined for the Purpose of Demonstrating The Effect of Varying the Feedwater Temperature

By LINN HELANDER,[1] EAST PITTSBURGH, PA.

FOR power plants using single- or multiple-stage feedwater heaters of the condenser type, the temperature of the boiler feedwater as it leaves the heaters should not be less than 150 deg. fahr. when using economizers and probably not more than 260 deg. fahr. when not using economizers, although certain conditions permit improving thermal efficiencies up to a temperature of 300 deg. fahr., corresponding to a pressure of 72 lb. per sq. in. absolute in the heater. The maximum of this range was established by consideration of fuel charges only. The lower limit of 150 deg. fahr. was chosen to avoid mechanical difficulties met when sending colder water to economizers, although this temperature, as will be seen, is less than the lowest temperature justified by purely thermal analyses of the 25,000-kw. plant used as a basis for the present studies.

That there exists for any fixed set of conditions a definite feedwater temperature at which the efficiency of power generation is a maximum is most readily demonstrated by consideration of a theoretically perfect generating plant using perfect condenser heaters. Since the feedwater heaters are considered as being perfect condensers, the pressure within them, and for the purposes of the theoretical analyses, the back pressure on the auxiliary turbine or at the extraction point on the main unit supplying the heating steam will be that corresponding to the vapor tension of the feedwater, and so will increase as the temperature of the feedwater increases. This increase in pressure in turn will increase the water rates of the steam units exhausting to the heaters, or, from another viewpoint, will decrease the work capable of being done by a pound of steam used for heating the feedwater.

Consequent upon increasing feedwater temperatures, therefore, we have a reduction in the amount of work obtainable from each pound of steam used for heating the feedwater and an increase in the total amount of steam required for heating purposes. The relation between these offsetting effects is such that the work done by the steam used for heating the feedwater increases as the temperature is increased to a certain point, after which it decreases. This is also shown by curves of Fig. 1. Any increase in feedwater temperature beyond that for which maximum work obtains continues to augment the demand for exhaust steam, but the capacity of a given quantity of the steam to do work is so reduced that the result is diminution in the total power generated by it.

Effect of Multiple-Stage Heating

A conception of what happens may be had by reference to the temperature-entropy diagrams, Figs. 2 and 3, given for both single- and double-stage heating, assuming for simplicity that saturated instead of superheated steam is used.

As the number of stages of feedwater heating increases, the work derived from the steam used for heating the feedwater increases and the temperature of the feedwater, as established for maximum theoretical efficiency, approaches that of the initial steam. Using an infinite number of stages, the temperature of the feedwater for best efficiency is equal to that of the initial steam and the efficiency of the theoretical power-generating cycle is that of Carnot's cycle.

Description of Assumed Power Station

Illustrative of what is involved in the practical problem of determining the most efficient feedwater temperatures for power stations, the effect of varying this temperature was determined for several assumed stations of 25,000 kw. capacity, using various methods of heating the feedwater. To illustrate the influence of factors such as the water rate of the main unit and the slope of the Willans line of this unit, the internal Rankine-cycle efficiency of the bled steam and the Rankine-cycle efficiencies of the house turbine, two cases—designated Case 1 and Case 2, respectively—were worked out for each arrangement of feedwater heating. The Rankine-cycle efficiency used in Case 1 for the bled steam based on the steam pressure on the turbine side of the throttle was approximately 67 per cent, slope of the Willans line was 12 lb. per kw-hr., and the water rate of the main unit when carrying the total gross station load was 10.6 lb. per kw-hr. For Case 2 the corresponding values were 80 per cent for the Rankine-cycle efficiency of the bled steam, 9 lb. per kw-hr. for the slope of the Willans line, and 10.26 lb. per kw-hr. for the water rate of the main unit.

The following are the principal data used as bases for the heat-

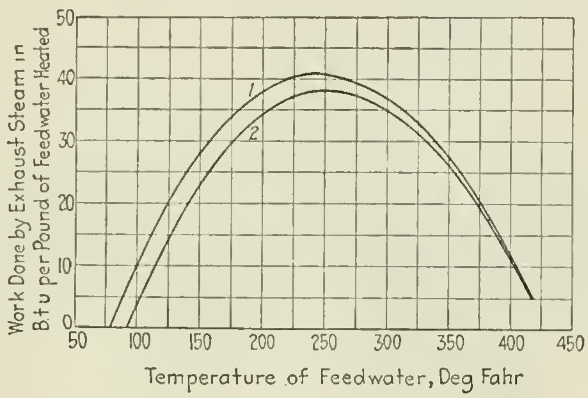


FIG. 1 WORK DONE BY EXHAUST STEAM

(Curve 1 shows for single-stage heating that the theoretical maximum work obtained from steam subsequently used for heating boiler feedwater is obtained with a final feedwater temperature of approximately 240 deg. fahr. when the initial temperature of the feedwater is 79 deg. fahr. Curve 2 is based on a condensate temperature of 92 deg. and shows that in this case the maximum work is obtained with the final feedwater temperature at 260 deg. Initial steam pressure, 325 lb.; superheat, 200 deg. fahr. The peaks of the curves establish the feedwater temperatures for maximum theoretical thermal efficiency. With two-stage heating and the same initial steam condition (condensate at 79 deg. fahr.) the maximum work is obtained at a feedwater temperature of approximately 300 deg., which theoretically, therefore, is the temperature for best thermal efficiency.)

balance study of the paper. The various formulas employed in making the study are given in an appendix to the complete paper.

Net station load....................25,000 kw.
Load on auxiliary bus....................1,300 kw.
Gross station load....................26,300 kw.
Steam consumption of the main unit when carrying the gross station load:
Case 1: 279,000 lb. per hr. Case 2: 270,000 lb. per hr.
High-pressure drips....................1000 lb. per hr.
Condensate losses....................1000 lb. per hr.
High-pressure steam losses....................3000 lb. per hr.
Radiation losses from low-pressure steam:
2 per cent of total heat in steam used for heating the feedwater
Pressure of steam at throttle....................330 lb. per sq. in. gage
Boiler pressure....................350 lb. per sq. in. gage
Superheat....................200 deg. fahr.
Heat content of boiler steam....................1326 B.t.u. per lb.
Heat content of steam at throttle....................1324 B.t.u. per lb.
Vacuum on main unit....................29 in. Hg.
Temperature of condensate....................75 deg. fahr.
Temperature of make-up water entering evaporator....................60 deg. fahr.
Slope of Willans line of main unit....................Case 1: 12 lb. per kw-hr.
Case 2: 9 lb. per kw-hr.
Heat content of the high-pressure drips recovered....................390 B.t.u. per lb.
Radiation, friction and generator losses of the house turbine in kw.:
650 kw. turbine, 65 kw. 1500-kw. turbine, 135 kw.
Radiation losses from bled steam on passing through the main unit:
1 per cent of load developed by the bled steam
Internal Rankine-cycle efficiency of bled steam based on steam pressure after throttle:
Case 1: 67 per cent. Case 2: 80 per cent
Boiler efficiency when not using economizers....................78 per cent
Boiler efficiency when using economizers but not including
the economizer efficiency....................75 per cent
Coefficient of heat transmission through economizers....................5 B.t.u. per sq. ft.
per deg. mean temperature difference between flue gases and water
Temperature of gases entering economizers....................580 deg. fahr.
Specific heat of flue gases....................0.2375
Percentage of recoverable heat recovered by economizers....................85 per cent
Flue gases per lb. of coal....................19 lb.
Heating value of coal....................13,500 B.t.u. per lb.
Ratio of the load developed by the boilers to the full-load rating of the boilers
when using economizers....................2.25

The Rankine-cycle efficiencies of the house turbines are given in

[1] General engineer, Westinghouse Elec. & Mfg. Co. Jun. Am.Soc.M.E.

Contributed by the Power Division and presented at the Annual Meeting, New York, December 4 to 7, 1922, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS. Abridged. All papers are subject to revision.

Figs. 4 and 5. An average value of 80 per cent was used for the Rankine-cycle efficiency of the bled steam on the main unit, though this will vary 2 or 3 per cent either way, depending on the conditions of bleeding and the design of the turbine.

All auxiliaries in these stations were considered as being motor-driven during normal operation. Surface condensers were used on the main units and the condensate before going to the feedwater heaters was passed as cooling water through the evaporator system supplying boiler-feed make-up water so long as this operated on exhaust steam. When the temperature of this exhaust steam was too low to evaporate the water efficiently and the use of live steam became necessary, the condensate was returned directly to the feedwater heater and the water used for the condenser of the evaporator was taken from the boiler feedwater previously heated in the economizers or in the feedwater heaters. With this arrangement the use of live steam on the evaporators did not materially affect the heat balance, and the pressure of the exhaust steam used for heating the feedwater was determined by the pressure within the feedwater heater rather than the requirements of the evaporator system. A schematic arrangement of these plants is shown in Fig. 6. Economizers are shown, but heat balances as well were worked out for plants not using economizers, in which case the boiler feedwater was delivered directly to the boiler.

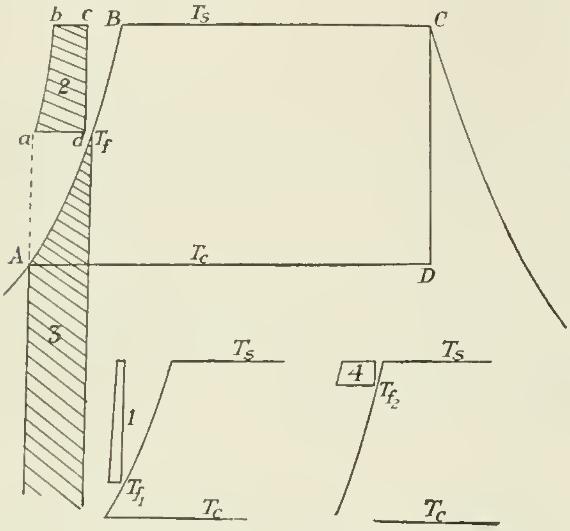

Fig. 2 Temperature-Entropy Diagram for Single-Stage Heating Using Dry Saturated Steam

(Large area $ABCD$ represents the work done by the steam passing through the main unit. The shaded area 2, above the water line, represents the work done, before entering the heater, by the steam used for heating the feedwater. The shaded area 3, below the water line, represents the heat added to the feedwater and is equivalent to the area under line ad. As indicated by areas 1 and 4 of the diagram at the bottom of the illustration, the area representing the work done by the steam used for heating the feedwater becomes rather small when the feedwater temperature deviates largely from that for best efficiency. The letters with subscripts f, f_1 and f_2 indicate the feedwater temperature for different positions of the area showing the work done by the steam usedfor heating the feedwater. The temperature of the initial steam is T_s; T_c is the temperature of the condensate.)

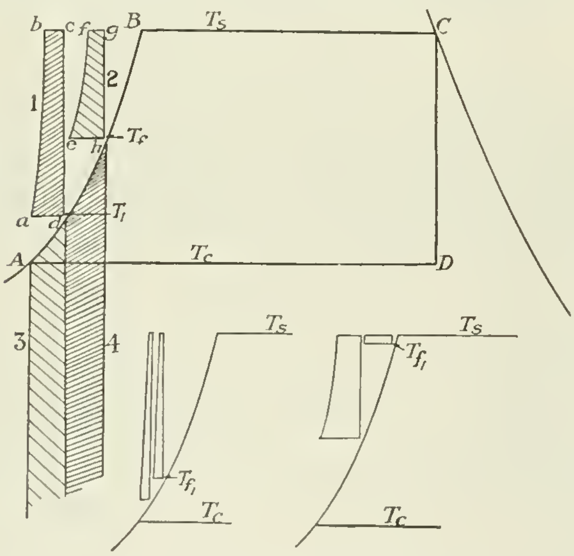

Fig. 3 Temperature-Entropy Diagram for Double-Stage Heating Using Dry Saturated Steam

(Large area $ABCD$ represents the work done by the steam passing through the main unit. Instead of a single area above the water line, as for single-stage heating, two areas, $abcd$ and $efgh$, represent the work done by the steam passing respectively to the first and second stages. For equivalent heating effects in each heater, areas 3 and 4, below the water line, are equal. The figures at the bottom of diagram show that when the feedwater temperature is rather close to either the condensate temperature or the temperature of the boiler steam, the sum of the areas representing the work done by the steam used for heating the feedwater is small. When the temperature of the feedwater equals that of the boiler steam the effect is simply that of a single-stage heater. Evidently at some temperature between that of the condensate and that of the boiler steam the sum of the areas representing the work done by the steam used for heating the feedwater is a maximum. The temperatures indicated as T_f, T_{f_1} and T_{f_2} are those of the feedwater.)

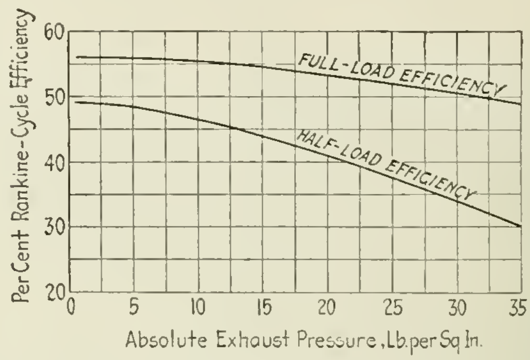

Fig. 4 Rankine-Cycle Efficiencies for Case 1

(Estimated Rankine-cycle efficiencies of 1500–1700 kw. house turbine generators as used for determining the heat balance for Case 1. The efficiencies used for the 650-kw. house turbine for Case 1 were approximately the same as those of Case 2, though the shape of its curve is similar to those given here. Steam pressure, 330 lb. gage; superheat, 200 deg. fahr.)

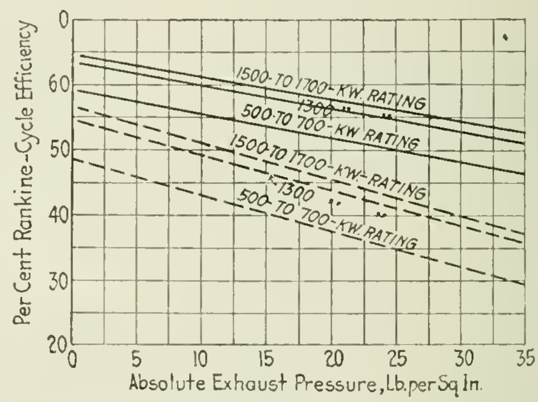

Fig. 5 Case 2. Estimated Rankine-Cycle Efficiencies of Turbine Generators Designed for Any of the Various Back Pressures and Operating against the Back Pressure for Which they Are Designed

(Steam pressure, 330 lb. gage; superheat, 200 deg. fahr. The efficiencies would deviate somewhat from those shown with back pressures below 2 lb. absolute.)

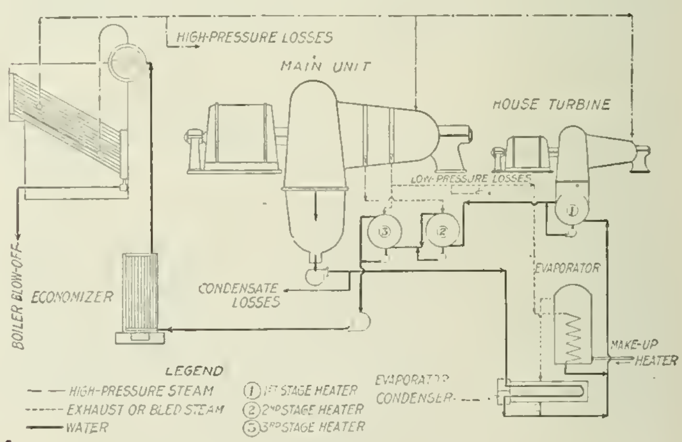

Fig. 6 Schematic Diagram of Station Layout for Three-Stage Feedwater Heating

(The condensate from the main unit is circulated through the condenser of the make-up water evaporator system before going to the feedwater heater.)

When bleeding the main unit the pressure drops in the bleeder piping varied with the amount of steam bled, and this was taken into consideration. The boilers were operated between 175 and 200 per cent of rating when economizers were not used, and under this condition had an efficiency of 78 per cent. When economizers were used the operating capacity was increased to 225 per cent of rating and the efficiency reduced to 75 per cent, not including the economizers. The power taken by the induced-draft fans was not included in the auxiliary load, and to obtain the true heat consumption for the stations using economizers the equivalent heat consumption of these fans will have to be added to the rates given.

Heat Balance for Single-Stage Heating

Heat balances for two arrangements using single-stage heating and no economizers were worked out. In one arrangement the auxiliary power was obtained from a house turbine of 650 kw. capacity, or one-half the total auxiliary load. The remainder of the auxiliary load was carried by the main unit. Steam, in addition to that supplied by the house turbine, in this case was bled from the main unit for heating the feedwater. The other arrangement used a house

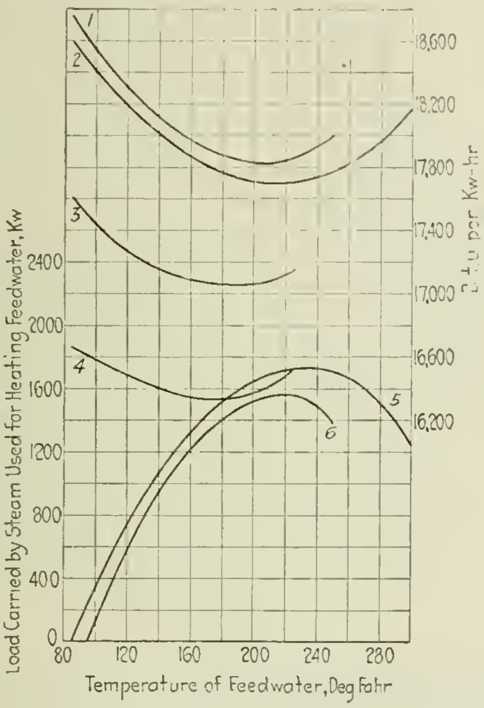

Fig. 7 Single-Stage Heating—Case 1

(Steam pressure, 330 lb. gage; superheat, 200 deg. fahr.; vacuum on the main unit, 29 in.)

Curve 1. B.t.u. per kw-hr. using a 1600-kw. house turbine and not bleeding the main unit. Economizers were not used. Feedwater temperature for best efficiency is approximately 210 deg. fahr.

Curve 2. B.t.u. per kw-hr. using a 650-kw. house turbine and bleeding the main unit. Economizers were not used.

Curve 3. B.t.u. per kw-hr. using a 650-kw. house turbine, economizer of 21,875 sq. ft. area and bleeding the main unit. Economizer surface approximately 50 per cent of the boiler area. The heat consumption of the induced draft fans, equivalent to the power consumed by them, not included.

Curve 4 B.t.u. per kw-hr. using a 650-kw. house turbine, economizer of 49,450 sq. ft. of surface and bleeding the main unit. Though the economizer area is double that for Curve 3, the feedwater temperature for best economy is reduced only 10 to 15 deg. Power taken by induced-draft fans not included with auxiliary power when determining heat-consumption curves.

Curve 5. Load developed by the steam used for heating the feedwater when using a 650-kw. house turbine and bleeding the main unit.

Curve 6. Load developed by the 1600-kw. house turbine supplying exhaust steam to the feedwater heater. A comparison of the temperature at which the peak of Curve 6 occurs with that of Curve 5 indicates the influence that decreasing Rankine-cycle efficiencies with increasing back pressures on the house turbine have on the feedwater temperature for best economy. By reference to Curves 1 and 2, showing the B.t.u. rates per kw hr., it is seen that the real influence of the decreasing Rankine-cycle efficiencies with increasing back pressures is small.

turbine with its point of best economy at 1600 kw. for Case 1 and 1700 kw. for Case 1, and was considered as being so designed that the house turbine could deliver power to the main bus. With this arrangement no means for bleeding the main unit were provided, all steam for heating feedwater being obtained from the house turbine. As indicated by the curves 1 and 2 of Figs. 7 and 8, the first arrangement is thermally the more economical and also requires for best efficiency a slightly higher feedwater temperature than the second arrangement. It is interesting to note that whereas the theoretical feed temperature for best efficiency was in the neighborhood of 250 deg. fahr., the actual temperature is closer to 200 deg. fahr. This is due to various factors, among them being the decreasing Rankine efficiency of house turbines when operating at successively higher back pressures.

Heat Balance for Double-Stage Heating

Similarly heat balances for two arrangements using double-stage heating and no economizers were worked out on the basis that the heating effect was divided equally between the two stages. In

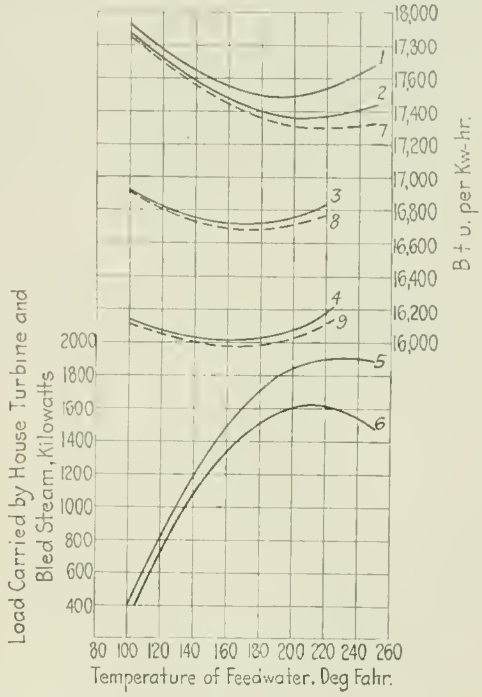

Fig. 8 Single-Stage Heating—Case 2

(Steam pressure, 330 lb. gage; superheat, 200 deg. fahr.; vacuum on the main unit, 29 in.)

Curve 1. B.t u. per kw-hr. using a 1700-kw. house turbine and not bleeding the main unit. Economizers not used. The feedwater temperature for best economy is approximately 190 deg. fahr. This is 20 deg. lower than the best feedwater temperature for the corresponding conditions of Case 1, though due to the flatness of the curves over this range, the proper temperature for either case may be considered as approximately the same. The difference in temperature indicated is due to the difference in the slopes of the Rankine-cycle efficiency curves for the house turbine.

Curve 2. B.t.u per kw-hr. using a 650-kw. house turbine and bleeding the main unit not using economizers.

Curve 3 B.t.u. per kw-hr. using a 650-kw. house turbine, economizer of 21,875 sq. ft. area, and bleeding the main unit. The feedwater temperature for best economy is lower than the corresponding temperature for Case 1, due largely to the difference between the slopes of the Willans lines of the main units. Power consumed by induced-draft fans not included in auxiliary power.

Curve 4. B.t.u. per kw-hr. using a 650-kw. house turbine, economizer of 49,450 sq. ft. of surface, and bleeding the main unit. Power consumed by induced-draft fan was not included in auxiliary power.

Curve 5. Load developed by the steam used for heating the feedwater using a 650-kw. house turbine and bleeding the main unit.

Curve 6. Load developed by the 1700-kw. house turbine supplying exhaust steam to the feedwater heater.

Curve 7. Same as Curve 2 except that low-pressure steam losses are neglected.

Curve 8. Same as Curve 3.

Curve 9 Same as Curve 4 except that low-pressure steam losses are not included.

one of these arrangements the first-stage heaters derived the steam for heating the feedwater from a house turbine with its point of best economy at 1400 kw. for Case 1 and 1500 kw. for Case 2, only the second-stage heater deriving steam by bleeding the main unit. The other arrangement used a house turbine with its point of best economy at 650 kw., additional steam required by the first-stage heater being obtained by bleeding the main unit. The feedwater temperatures for best efficiency as indicated by curves 1 and 2 of Figs. 9 and 10 are seen to be approximately the same in either case, and about 25 deg. below that indicated by theoretical considerations alone. Both curves are rather flat over a range of 50 deg. in the vicinity of the point of best efficiency. The more efficient of the two arrangements, as with single-stage heating, is that one using the smaller house turbine, or the one bleeding the largest amount of steam from the main unit. This latter arrangement, with feedwater temperature of 275 deg. fahr., showed a possible saving of approximately 320 B.t.u. per kw-hr. as compared with single-stage heating. The maximum efficiency using single-stage heating, however, was obtained with a feedwater temperature of approximately

200 deg. fahr. Comparing single-stage with double-stage heating on the basis that this temperature of 210 deg. fahr. was not to be exceeded, the difference between double-stage and single-stage heating is about 225 B.t.u. per kw-hr.

Effect of Economizers

Economizers in connection with single- and double-stage heating were applied to those stations which used a 650-kw. house turbine and bled the main unit this arrangement being the more economical. The economizers were assumed as having a heat-recovery factor of 85 per cent and a heat-transfer rate of 5 B.t.u. per hour per deg. mean temperature difference between the flue gases and the water. Two sizes of economizers were applied to each station to illustrate the effect of varying the size of the economizers. The boilers, as previously stated, were assumed to operate at approximately 225 per cent of their rated capacity, and their efficiency in this case was taken as 75 per cent, or 3 per cent less than that used when the stations had no economizers. The temperature of the flue gases entering the economizers in all cases was taken as 580 deg. fahr., which meant that for the type of boilers selected the percentage of rated capacity developed did not vary with the temperature of the feedwater. This, of course, required that the total operating capacity be slightly decreased as the temperature of the feedwater entering the boiler was increased. The weight of the flue gases per pound of coal burned was taken as 19 lb. and independently of the feedwater temperature, but, inasmuch as the weight of coal burned per pound of steam generated varied with the feedwater temperature, the weight of gas per pound of steam generated likewise varied.

Analyses of heat balances as affected by feedwater temperatures did not involve considerations of boiler-room efficiency for those stations not using economizers. When economizers were used, however, the temperature of the flue gases leaving the economizer, for given equipment and operating conditions, was determined by the temperature of the water entering the economizer. Increasing the temperature of the water entering the economizer simultaneously increased the temperature of the flue gases so that the combined efficiency of the economizers and boilers was decreased. However, as the temperature of the feedwater leaving the heaters was increased above that of the condensate, the efficiency of converting steam to power, as previously demonstrated, increased, thereby opposing the consequent decrease in efficiency of steam generation. The relative rates at which the efficiency of steam generation decreased and that of power generation increased determined the temperature of the feedwater for best efficiency, these rates being equal for the condition of best efficiency. The rate at which the efficiency of steam generation decreases with increase in feedwater temperatures depends on the relative area of the economizers and the boilers. The larger the economizer relative to the boiler, the more rapid is the rate at which this efficiency falls off. In consequence of this, the feedwater temperatures for best efficiency were found to be lower for the larger economizers than for the smaller ones, though the differences were not of great moment.

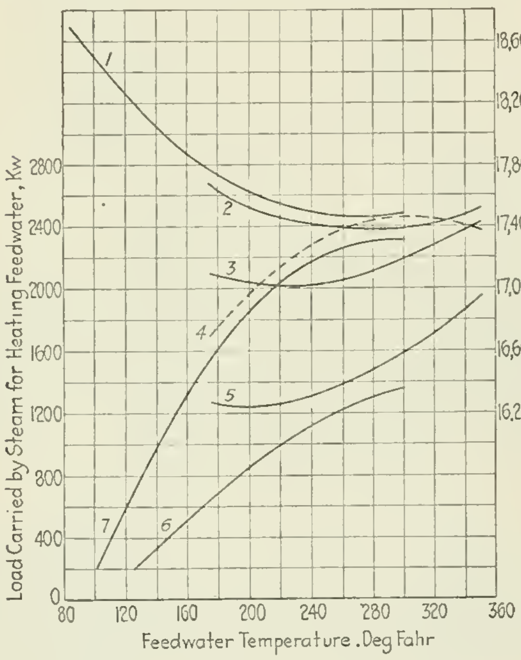

Fig. 9 Double-Stage Heating—Case 1

(Steam pressure, 330 lb. gage; superheat, 200 deg. fahr.; vacuum on the main unit, 29 in.)

Curve 1. B.t.u. per kw-hr. using a 1400-kw. house turbine and bleeding the main unit to obtain steam for the second stage, not using economizers. The feedwater temperature for best economy is approximately 280 deg. fahr.

Curve 2. B.t.u. per kw-hr. using a 650-kw. house turbine and bleeding the main unit at two points, not using economizers. It is noticeable that as the number of stages used for heating the feedwater increases, the curve of heat consumption per kw-hr. flattens out.

Curve 3. B.t.u. per kw-hr. using a 650-kw. house turbine, economizer of 18,180 sq. ft. area and bleeding the main unit at two points. Economizer surface approximately equivalent to 45 per cent of boiler area. Power taken by induced-draft fans not included in the auxiliary load.

Curve 4 (dotted). Load developed by steam used for heating feedwater when using a 650-kw. house turbine and bleeding the main unit at two points.

Curve 5. B.t.u. per kw-hr. using a 650-kw. house turbine, economizer of 47,000 sq. ft. area and bleeding the main unit at two points.

Curve 7. Load developed by the steam used for heating the feedwater when using a 1400-kw. house turbine and bleeding the main unit only for the second-stage heating. Curve 6 shows the load carried by the house turbine for this arrangement of heating the feedwater.

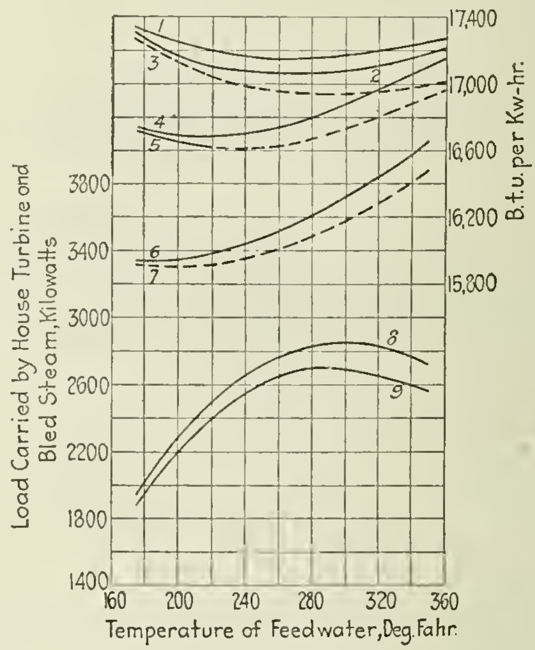

Fig. 10 Double-Stage Heating—Case 2

(Steam pressure, 330 lb. gage; superheat, 200 deg. fahr.; vacuum on the main unit, 29 in.)

Curve 1. B.t.u per kw-hr. using a 1500-kw. house turbine and bleeding the main unit to obtain steam for the second stage, not using economizers. The feedwater temperature for best economy is approximately the same as for the same conditions of Case 1.

Curve 2. B.t.u. per kw-hr. using a 650-kw. house turbine and bleeding the main unit at two points, not using economizers. Curve 3 is the same except that losses due to leakage from the low-pressure steam piping are not included.

Curve 4. B.t.u. per kw-hr. using a 650-kw. house turbine, economizer of 18,180 sq. ft. area and bleeding the main unit at two points. The feedwater temperature for best economy is slightly lower than for Case 1. The power taken by the induced-draft fans was not included in the auxiliary power load. Curve 5 is the same but does not include the low-pressure steam losses.

Curve 6. B.t.u. per kw-hr. using a 650-kw. house turbine, economizer of 47,000 sq. ft. area and bleeding the main unit. The feedwater temperature for best economy is lower than for Case 1, due to difference in the slope of the Willans lines of the main units. Curve 7 is the same but does not include the low-pressure steam losses.

Curve 8. Load developed by the steam used for heating the feedwater when using a 650-kw. house turbine and bleeding the main unit at two points.

Curve 9. Load developed by the 1500-kw. house turbine when used to supply steam for feed heating in conjunction with bleeding the main unit.

The temperature for best economy when economizers are used, as given by the heat-consumption curves 3 and 4 of Figs. 7 and 8 for single-stage heating, lies between 175 and 190 deg. fahr. for Case 1 and 165 and 175 deg. fahr. for Case 2. With double-stage heatings, Figs. 9 and 10, the corresponding temperatures are 225 and 175 deg. fahr. for the smaller and larger economizer surfaces, respectively, for Case 2, and 230 and 200 deg. fahr. for Case 1. The temperatures for Case 1 are lower than those for Case 2, due to the difference in the slopes of the Willans lines used. For each kilowatt-hour developed by the steam used for heating the feedwater in Case 1, the steam condensed in the main unit's condenser was reduced

12 lb., while for Case 2 this figure was 9 lb. The benefit derived from carrying load on steam used for heating the feedwater was therefore relatively less for Case 2 than for Case 1, while the economizer and boiler efficiency remained the same. The differences in temperature are small, however, and indicate that with fair accuracy the desirable feedwater temperature may be considered as a range which is largely independent of the characteristics of the steam equipment used. The economizers used for double-stage heating were slightly smaller than those used for single-stage heating, commercial considerations indicating that this was justified. The difference in the sizes of the economizers did not, however, materially affect the feedwater temperature for best efficiency. The rate-of-heat-consumption curves are rather flat over a considerable range in proximity to the temperature for best economy, and increasing the area of the economizers even to the extent of doubling them need not require large changes in the temperature of the feedwater. The various data used in connection with the economizers are given in curves in the complete paper.

Comparison of Results With and Without Economizers

A comparison of feedwater temperatures for best economy as indicated by Case 1 and Case 2, respectively, shows that when economizers are not used ordinary variations in the Rankine-cycle efficiency of the bled steam, the efficiency curve for the house turbine, and the slope of the Willans line of the main unit have no considerable effect. When economizers are used, the temperatures are reduced by decreasing the slope of the Willans line of the main unit, but, as previously stated, the influence is not large. It is evident that for the purpose of establishing the proper feedwater temperature for best economy minute accuracy in the determination of the various turbine efficiencies is not required. The overall efficiency of the entire station is influenced, of course, by these efficiencies, but the best feedwater temperature changes only slightly with them. For this study a constant efficiency for bled steam was used. However, the house-turbine efficiencies were considered as being a function of the feedwater temperature, and a comparison of the temperatures for best economy obtained when using a house turbine alone with those obtained when using a smaller house turbine together with bleeding the main unit illustrates the influence of the variation in the Rankine-cycle efficiency. The difference in the temperatures that were obtained is between 10 and 15 deg. fahr., but inasmuch as the curves are flat this is of no great consequence.

Multiple-Stage Heating

By similar methods of computation, heat balances for four-stage heaters with and without the use of economizers were determined. The average Rankine-cycle efficiency for the bled steam in this case was taken at 79 per cent instead of 80 per cent, as the average efficiency over four stages would probably be somewhat less than that for one stage. Fig. 11 shows the heat consumption per kilowatt-hour for the various methods of heating the feedwater worked out for Case 2, using the 650-kw. house turbine. As the number of heating effects increase, the value of the last effect decreases, which is to be expected. It is interesting to observe also that as the number of effects increase, the heat-consumption curves for the various stations flatten out in proximity to the temperature for best economy and that it would therefore seem undesirable to go beyond a certain feedwater temperature regardless of the number of stages. When economizers of 21,850 sq. ft. are used the gains in efficiency referred to a basis of no heating for single-, double-, triple-, and quadruple-stage heating are 1.86, 2.88, 3.35, and 3.64 per cent, respectively. When the number of heating effects is increased the value of the last heating decreases, and in determining the proper number of stages consideration must be given to the investment and also to the operating problems encountered.

Air Economizers

If air for the boilers is preheated by means of air economizers and no feedwater economizers are used, such preheating does not affect the feedwater temperature for best economy. However, the air may be preheated by exhaust steam similarly to heating feedwater. Also air economizers and exhaust-steam air heating may be used with or without the coincident use of water economizers, and with single- or multiple-stage feedwater heating. If air is heated by exhaust steam alone, the problem of determining its temperature for maximum efficiency is not different from that for determining the temperature of feedwater heated only by exhaust steam. This, however, is not the case if both air and water economizers are used simultaneously.

Air and water economizers, if used simultaneously, may be placed either in parallel or in series. If placed in parallel the effect of the air economizer is to reduce the amount of gases available for heating the feedwater, and so alter the operating characteristics of the water economizers so far as these are determined by the ratio of the waste gases to the water heated. If the air heater is placed in series with the water economizer and in the coldest part of the flue gases, the leaving temperature of these gases is no longer determined by the temperature of the boiler feedwater. For such an arrangement it would appear desirable to heat the boiler feedwater to that feedwater temperature giving the maximum efficiency for the conversion of steam energy to electrical power. The feedwater would then be further heated in a water economizer while the temperature of the flue gases leaving the water economizer could be reduced to a desirable point, justified, of course, by the efficiency of the air economizers and their cost. On this basis the temperature of the feedwater entering the economizers would correspond to that previously determined when no economizers were used. The air

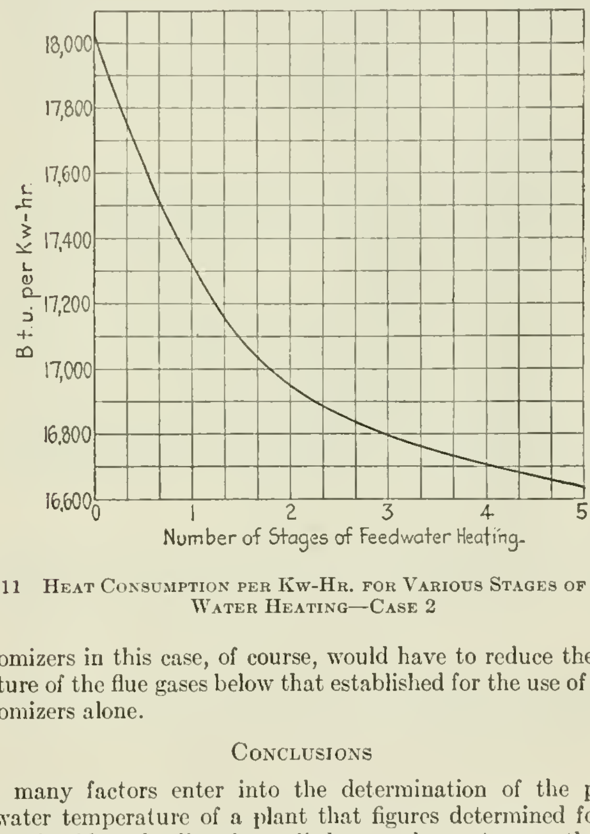

Fig. 11 Heat Consumption per Kw-Hr. for Various Stages of Feed-Water Heating—Case 2

economizers in this case, of course, would have to reduce the temperature of the flue gases below that established for the use of water economizers alone.

Conclusions

So many factors enter into the determination of the proper feedwater temperature of a plant that figures determined for one station should not be directly applied to another. As seen, the temperature should be lower for plants using single-stage heating than for those using multiple-stage heating, and also should be lower for plants using economizers than for plants not using economizers. Efficiencies of auxiliary apparatus as well as of the main generating units have their influence. If the feedwater temperature be raised much above 212 deg. fahr., factors incident to the use of pressures well above atmosphere in the auxiliary exhaust piping come into play. The proper feedwater temperature is dependent somewhat upon the initial steam pressure and temperature and on the temperature of the condensate, increasing as these increase. It is quite impossible, therefore, to determine, except within wide limits, feedwater temperatures applicable to all plants, and the present purpose has been rather to indicate in a broad way the effect of feedwater temperatures on power-plant efficiency, leaving out the matter of costs, and to give some basis for estimating the sacrifice in fuel made to assure practicable operation of the feedwater-heating system as laid out for a particular station.

Lumber Dry Kilns

By THOMAS D. PERRY,[1] GRAND RAPIDS, MICH.

The three main divisions into which lumber dry kilns may be grouped are blower, condenser, and ventilated kilns. The author, who believes that scientific kiln drying offers engineers a splendid field for research work, describes these types and discusses the possibilities of each, with particular reference to the ventilated kiln, of which there are several classes. The questions of moisture deficit and equilibrium, air interchanges, and drying cycles are adequately treated, and data showing the relation between relative and absolute humidity during the drying period are included.

THE PROBLEM presented to the manufacturer who would utilize woods intelligently is a diversified one owing to the fact that the score or more of major varieties of commercial timbers are grown in climates and seasons differing widely in temperature and moisture, and on soils ranging from the rocky hills of the Appalachians to the rich alluvial lowlands of the Mississippi delta. The origin of the lumber, has a noticeable effect on its water content. Lumber or veneer (thin lumber produced usually by rotary cutting or flat slicing, sometimes by sawing), when produced from the log, contains a large proportion of water, ranging from 25 to 75 per cent of the total weight. One square foot (board measure, one inch thick) of gum lumber, weighing approximately five pounds when sawed, will be reduced to about three pounds when its water content of approximately one quart has been evaporated. Oak grown on a hillside may contain only a pint (approximately 1 lb.) and swamp gum may have from 2 to 4 pints of water per sq. ft. B. M.

This water content of wood exists in two forms, free moisture and cell moisture, the former being readily evaporable in ordinary air drying, and the latter demanding excessive air drying (several years) or artificial treatment in kilns. The usual border line between the two forms of moisture is in the vicinity of 30 per cent moisture content (the percentage of the weight of water removed being computed on the dry fiber weight as a base). It is possible to use artificial means to remove this free moisture, but a simple air exposure is usually more economical.

By far the largest volume of lumber products are dried in the form of lumber or veneer. The drying of unusual forms and shapes, such as staves, handles, shingles, laths, etc., is decidedly specialized and outside the range of this discussion.

Types of Kilns

The original artificial drier was a smoke kiln, now practically obsolete. This was followed by the furnace kiln and the steam-coil kiln. Some woodworkers still persist in using home-made equipment, but kiln design and building has become a special branch of manufacturing that has its own recognized field.

The three main divisions into which lumber kilns may be grouped, as illustrated in Fig. 1, are:

1 Blower: Mechanically forced ventilation, or recirculation, whether suction or plenum method; moisture-laden air usually discharged out of doors

2 Condenser: Generally of the gravity recirculating type, in which the air passes over moisture-removal or condensing units, once in each interchange

3 Ventilated: Fresh air taken in and used air discharged direct from kiln to atmosphere, utilizing the fundamental laws of physics to obtain internal circulation.

To understand the particular range of each of the foregoing types it is necessary to outline the moisture-removal problem in some detail from the standpoint of the lumber to be dried. Air drying removes more moisture from the surface than from the center, and owing to the length and width of a board, drying takes place chiefly through the flat faces, rather than through the ends or edges. The inevitable result is a surface drier than the interior, and air-dried stock is therefore subject to an internal strain that often manifests itself in the form of warp, twist, or other surface irregularities. The problem is to draw the center moisture out and have surface and interior equally dry.

The skill of an engineer is not required to discover that, if the drying of wood afforded no organic difficulties, the blower would dry rapidly, utilizing considerable power, and the condenser would function slowly but at low cost.

The ventilated kiln is the least understood, even though most generally used, and offers an unusual opportunity for speed and efficiency when its underlying principles are grasped.

The nature of wood is the phase of the problem that engineers least appreciate. It is almost axiomatic that wood should not be subject to external or internal strain during drying, but it is practically impossible to obtain such a "strainless" condition. The reduction of this drying strain to a minimum point is necessary to drying without damage to the lumber, the usual manifestations of which are checking, warping, honeycombing, "hollowhorning," etc. The chance of internal strain greatly increases with the thickness of the wood to be dried: e.g., $^1/_{16}$-in. veneer is practically all surface and can develop little internal strain in any kind of drying, while 4-in. green oak presents a decidedly stubborn drying problem, and taxes the skill of the best operator in an efficiently controlled kiln.

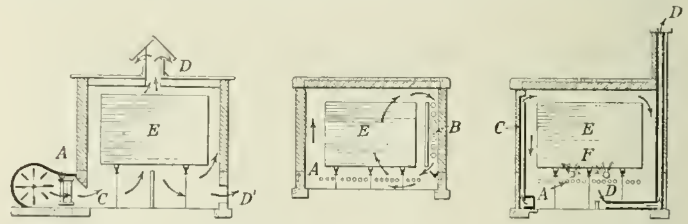

Fig. 1 Showing (from Left to Right) Blower, Condenser and Ventilated Kilns

(*A*, Heating unit; *B*, condensing unit; *C*, fresh-air inlet; *D* and *D'*, used-air outlets; *E*, lumber charge; and *F*, humidifying unit.)

Blowers and Condensers

These facts lead to the logical conclusion that where thickness is nominal, as in the case of veneer, applied shellac, stain, filler, varnish, and glue, the speed of the air movement in a blower kiln will remove moisture rapidly and cause no serious damage; but where thickness becomes appreciable ($^1/_2$ in. and up) the rapidly moving atmosphere of a blower kiln will produce uneven drying and unnecessary interstrain that will inevitably damage the lumber. Even with attempted maintenance of high humidities (difficult in blower kilns[1]) the hazard is serious. On the other hand, the slowness of the condensing kiln will make for accurate control, but the lack of speed may force the initial cost of installation to an excessive amount. As a matter of fact, Government experts have frequently recommended the condensing kilns without comprehending in most cases the economic aspect. It has been the author's experience during the last five years that kilns of the condensing type used for war work did no better drying than the best of the ventilated types, and required for an equivalent output practically twice as many units, at approximately double the initial cost per unit, or a quadruple investment, with no appreciable gain in quality or safety.

As a conclusion it may be noted that blower kilns are most suitable where thickness is not a factor, and that condenser kilns are especially serviceable in the drying of thick green woods where internal strain is a decided danger.

Typical Drying Cycle

Before considering the individual characteristics of the various types of ventilated kilns, it may be well to outline briefly a drying cycle. Take an actual operation schedule, tested by practice,

[1] Vice-president and manager, Grand Rapids Veneer Works. Assoc-Mem. Am.Soc.M.E.

Contributed by the Forest Products Division for presentation at the Annual Meeting, New York, December 4 to 7, 1922, of The American Society of Mechanical Engineers. All papers are subject to revision.

[1] Kent's Mechanical Engineers' Pocket Book, 1916 edition, p. 573.

of reducing 1-in. oak from 35 to 5 per cent moisture content in 16 days of 24 hours steam. Plotting this schedule, curves showing the variations in temperature and the relative humidity during the period of drying are obtained as shown in Fig. 2. The drying cycle divides itself into three phases: initial "steaming" or high-humidity period in which lumber is heated through and enough moisture added to make the surface as wet as the center; intermediate "stewing" or cooking,[1] a transition period; and the final "drying," when humidity may be dropped and temperature raised within limits demanded by the kind and condition of lumber.

The temperature should gradually rise from 125 to 170 deg. fahr. and care should be exercised that it does not go up too fast during the initial steaming, which would tend to crust the outside of the boards. The relative-humidity line reaches 100 per cent as rapidly as possible without producing an excess of temperature. The reason for the high initial humidity is that partly dried lumber, as placed in the kiln for drying, normally has a surface drier than the interior, and unless the surface is thoroughly moistened the internal moisture will be sealed in by the dry and shrunken surface layers; in other words, the degree of internal strain will be intensified rather than

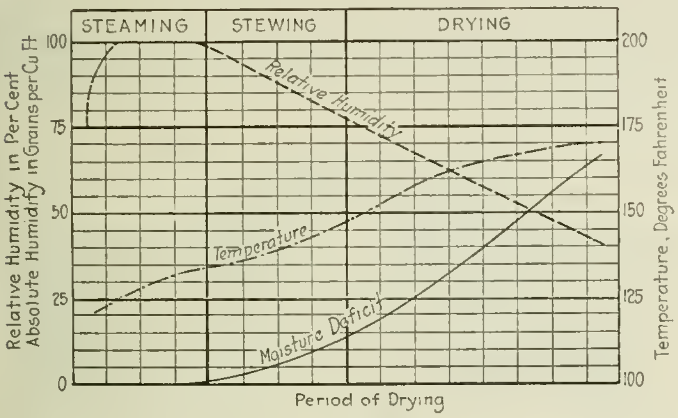

Fig. 2 Temperature and Relative Humidity During Drying Cycle and Curve Showing Moisture Deficit

reduced. If the surface of the board is steamed or exposed to an atmosphere of high humidity it will absorb moisture and expand, making it possible for the cellular structure to conduct additional moisture to the surface, and reducing the internal strain. Heating the lumber through is also accomplished quickly and safely by this steaming.

Moisture will pass out more rapidly from the surface of a board the center and surface of which are approximately equal in moisture content, and the final result of the drying cycle will be a reasonably uniform moisture content from face to face of the board and an absence of internal strain, with consequent damage. It is a rather significant fact that lumber dried by the so-called "wet" process explained in the preceding paragraph is more plump than when treated by the old-fashioned method of "giving it all the heat it will stand" without preliminary steaming or due regard to the humidity. Experiments have proved that the endeavor to dry without steaming takes longer because moisture transfuses more slowly through a dry than a wet surface, and the resulting damage is usually serious.

Relative vs. Absolute Humidity—Moisture Deficit

Another way of expressing the function of humidity is to express the cycle of drying from the standpoint of absolute humidity, or the grains of water vapor per cubic foot of atmospheric kiln content. Table 1 shows the relation of absolute (grains of water per cubic foot) and relative humidity (percentage of saturation) within the usual ranges of kiln temperature.

If we could isolate and examine a cubic foot of space (containing air and water vapor) in a kiln at a temperature of 150 deg. fahr. and a relative humidity of 50 per cent, we would find that it contains 36.76 grains of water in the form of vapor and possesses the capacity, before reaching saturation, of absorbing an equal additional amount of water vapor. It is this difference between actual grainage and the grainage of saturated water-vapor content that expresses the drying power of the kiln.[2] Stated in another way, this means that a cubic foot partly saturated has a tendency to become entirely saturated if free moisture is accessible, i.e., from the lumber.

This moisture deficit may be termed the measure of drying power in a kiln (when considered in connection with the temperature and circulation) and the greater the deficit the greater will be the pull exerted on the moisture contained in the lumber. At the beginning of the drying operation, when reducing the lumber to a uniform wetness, the moisture deficit is nil; and toward the end of the operation, at a temperature of 170 deg. fahr. and a relative humidity of 40 per cent, each cubic foot is eagerly seeking for 67 grains of water vapor or such part of it as can be extracted from the lumber. Fig. 2 contains a curve showing the moisture deficit expressed in grains per cubic foot. It will be noted that this line curves up more rapidly than the temperature line. This moisture deficit may be termed the measure of potential drying power. It is easy to remove moisture from the lumber at first, but the last few stages of drying require a decidedly strong pull.

While it would be possible to reduce the relative humidity to below 40 per cent (carrying the moisture deficit above 67 grains), it would result in too rapid a rate of surface drying and leave an unevenly dried product. The secret of controlling temperature and humidity in efficient drying is to avoid any sudden changes during the progress of the operation and to finish without carrying the temperature to an extreme that will damage the wood; and to avoid reducing the relative humidity at any point where it will dry the surface faster than the center.

Air Interchanges

The number of air interchanges per hour should not be too great. If an anemometer test shows three or four complete air changes per hour, it is enough. The process of the withdrawal of water

[1] "Stewing" used in the sense of a vapor bath, rather than as cooking (212 deg. fahr). Some authorities merge this into the "drying period."
[2] It is obvious that the higher the temperature, with a given moisture deficit, the more rapid the evaporation.
Adapted from tables compiled by Dr. William M. Grosvenor, with intermediate readings interpolated and decimals discarded.

vapor from the interstices of the lumber cannot be very rapid. Too rapid air movement in a gravity kiln subjects it to the same criticism as a blower kiln, i.e., too rapid surface drying.

High humidity and large circulation of air are antithetical to one another. To obtain high humidity, the circulation must be either stopped altogether or greatly reduced, and to reduce the humidity a greater circulation must be induced by increasing the draft.

The following example, based on three interchanges per hour, illustrates this point:

Size of kiln inside	15 ft. high by 19 ft. wide by 26 ft. long
Cubic contents, gross	7410 cu. ft.
Lumber allowance	1083 cu. ft. (13,000 ft. B. M.)
Equipment allowance	50 cu. ft.
Cubic contents, net	6277 cu. ft.

Allowing a moisture-lifting capacity averaging 25 grains of water vapor per cu. ft. of each discharge from the kiln:

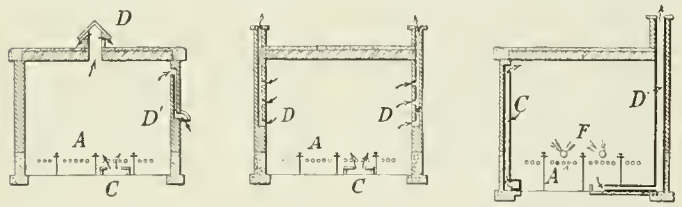

Fig. 3 Classes of Ventilated Kilns
(From left to right, ventilated at top, side and bottom. *A*, heating unit; *C*, fresh-air inlet; *D* and *D'*, used-air outlets; and *F*, humidifying unit.)

Discharge per cu. ft.	25 grains or 0.00357 lb. avoirdupois
Total single discharge	0.00357 × 6277 = 22.42 lb.
Hourly discharge (3)	67.26 lb.
Daily discharge (72)	1614.25 lb.

Estimating the average water content of saturated oak lumber at 1 lb. per ft. B. M.:

Lumber allowance	13,000 ft. B. M.
Moisture to be removed	13,000 lb.
Time required	13,000 ÷ 1614 = 8.05 days

This would indicate that the actual drying period (Fig. 2) will require practically eight days if the texture of the lumber permits of an average removal of 25 grains. An additional time allowance should be made for steaming.

The removal of 2 lb. moisture per ft. from green gum, for instance, would necessitate either increasing the drying time proportionately, or operating at a higher temperature.

Moisture Equilibrium

Theoretically it may be possible to reduce lumber to absolute dryness, but it cannot be kept so except in sealed receptacles. Under ordinary factory-workroom conditions, it will reabsorb to 6 or 8 per cent moisture. It is necessary, therefore, only to dry down below normal and allow for reabsorption. In ordinary lumber yards the lumber will rarely air-dry below 15 per cent, and kiln-dried stock left out of doors will absorb to about the same point. For structural purposes, exposed to weather the moisture content of timbers should be around 15 per cent to prevent shrinkage or expansion. For more accurate work the equilibrium point should be ascertained for each plant and will be found for interior trim to be about 8 to 10 per cent and for furniture, pianos, etc., from 4 to 7 per cent.

Ventilated Kilns

Ventilated kilns are readily grouped into three classes as indicated in Fig. 3.

Kilns of the first class are ventilated at the *top*, either through the ceiling and a cupola on the roof, or through openings in the side walls near the ceiling. Fresh air is usually admitted near the floor and the air movement must be distinctly upward. The real problem is to obtain an efficient utilization of this air movement to lift moisture out and up from the lumber.

No difficulty will be encountered in securing ample air discharge, as hot air will always rise and seek an exit. It is obvious that the hot air escaping will not be heavily charged with moisture. Only to a limited extent is it possible to use this upward-moving air as a moisture vehicle, because the increased water-absorption capacity accompanying higher temperatures will carry only a small amount of water vapor without a net increase in weight.

As an example, suppose the temperature of the air in the lower part of the kiln is 140 deg. fahr. and at the top 160 deg. fahr.; dry-air weights, 463.09 and 448.11 grains per cu. ft., respectively, a difference of 14.98 grains (less than 20 per cent relative humidity at 160 deg.). Air, therefore, cannot move upward and carry as much as 15 grains (neglecting expansion which is less than 4 per cent). Compare this with the fact that in a down-draft kiln the air at 140 deg. can carry 56 grains per cu. ft. before reaching saturation.

Any steam spray in this type tends to monopolize the limited moisture deficit of the kiln air and to greatly decrease the drying power as the air circulates upward through the lumber.

The second class have air exits at the *sides* and air inlets usually at the bottom. There is less of a scientific basis for this type than for either the first or the third type. There is great danger of "short-circuiting" the air across a corner of the kiln, thus causing pockets in places where a lack of air movement prevents drying. When this type is applied to the primary drying (to reduce shipping weight) at sawmills, with high temperatures, it may give fair results in regard to the removal of free moisture, and perhaps will reduce the moisture content to 15 per cent, but below this point it is undependable.

The use of steam spray or the handling of relatively moisture-laden atmosphere is no more possible than in the first

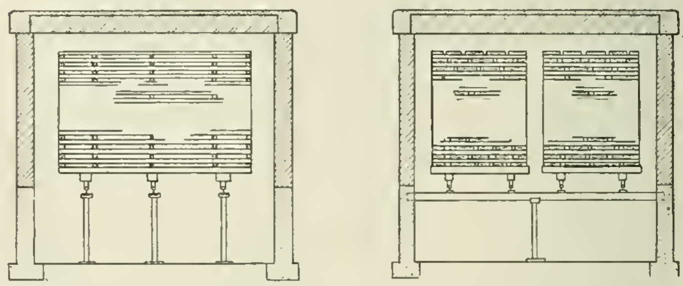

Fig. 4 Transverse Section of a Kiln, Showing Cross-Pile (at Left) and End-Pile (at Right)
(Notice somewhat better air circulation opportunity in end-pile.)

type. Neither of these types are adapted to what might be termed final drying for musical instruments, furniture, high-grade cabinet work, interior trim, or any object where permanence of dimension and a high degree of finish are required.

The third type, which is often called "reversed" ventilation, has a downward circulation with outlets at the *bottom*. The fresh-air inlets are at or near the ceiling line and the damp-air exits are in the pit below the lumber. This method adapts itself most effectively to the handling of heavy moisture-laden air shown to be necessary to dry the lumber uniformly. Whenever any portion of the atmosphere of the kiln acquires a substantial amount of moisture, it will lose temperature, increase in weight, and settle. It is therefore necessary to provide an adequate damp-air accumulation pit below the lumber, and to supply chimneys or stacks with sufficient draft to carry this moisture-laden air up and out. Heavy air that has settled into a pit will not readily be drawn up a stack. Steam-heated pipes in the stacks will accomplish this and at the same time keep the water vapor from condensing on the interior of stacks or at their top outlets. This type gives opportunity for excellent control, as any humidity can be handled and the air discharge be under positive control under various climatic conditions. For high-grade work it affords reliable regulation of the three essentials: temperature, humidity, and circulation.

It has been the purpose of this paper to outline some of the fundamental principles in lumber drying and to indicate their most important applications. Many of the combinations of mechanical apparatus are adequately covered by United States and foreign patents, although the fundamental elements have been in use too long to have further protection.

(*Continued on page 120*)

Diesel-Engine Clutch Used in the German Submarine "U-117"

By W. H. Nicholson,[1] Camden, N. J.

The purpose of this paper is to give to American builders of Diesel engines the benefit of the author's knowledge of German Diesel-engine clutches obtained at the time of the dismantling of ex-German submarines in the United States. The U-117's clutch is described in detail and other types of German Diesel-engine clutches are covered generally.

The submarine *U-117* was commissioned by the Germans in 1917 and operated off our North Atlantic coast in that summer and in the summer of 1918. It is known that this submarine took part in the sinking of coal barges and fishing boats in the vicinity of Nantucket and it is supposed that she is responsible for the planting of mines off the Long Island Shore, one of which sank the U. S. Cruiser *San Diego*.[2]

The *U-117* is a large mine-laying and -operating submarine. Her overall dimensions are: length, 275 ft.; beam, 17 ft.; and draft, 10 ft. She has a carrying capacity of 20 torpedoes and 45 mines. The armament consists of a 6-in. rapid-fire gun forward

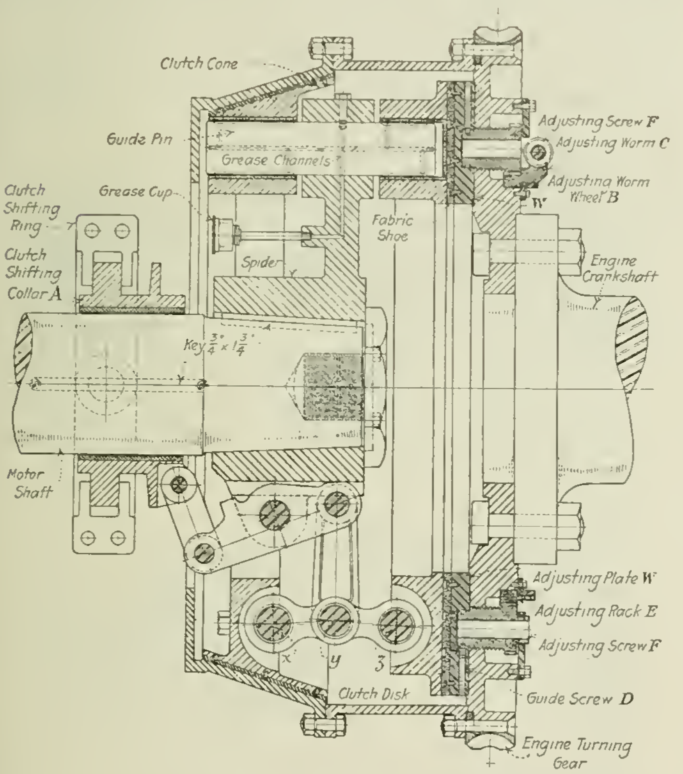

Fig. 1 Sectional View of Diesel-Engine Clutch Used in the German Submarine *U-117*

and a 5-in. gun aft, both on the main deck. There are four torpedo tubes in the compartment forward, and two mine tubes in the compartment aft.

The engine equipment consists of a port and a starboard Diesel oil engine, four-cycle, six-cylinder with two air-compressor cylinders of 1200 i.hp. at 450 r.p.m. for surface cruising and battery charging. The bore of the working cylinder is 17.73 in. and the stroke 16.5 in. The complete engines weigh 57,000 lb. each.

There are also the port and starboard main motors, each rated at 600 hp. at 332 r.p.m., for submerged operation. In general, the design of the motor comprises two compound interpole assemblies in one frame with the armatures in tandem on the same shaft motor-generator fashion. The motors receive their power from two 124-cell 248-volt storage batteries. When the boat is under way on the surface, each motor unit is driven as a generator by the Diesel oil engines, using the excess power of the engine to recharge the batteries and carry the auxiliary power load.

The log of the *U-117*, her general description, and the description of her propelling machinery give some idea of the work performed by her clutches.

Details of the *U-117* Main Engine Clutch

The clutch is located between the Diesel oil engine and the main

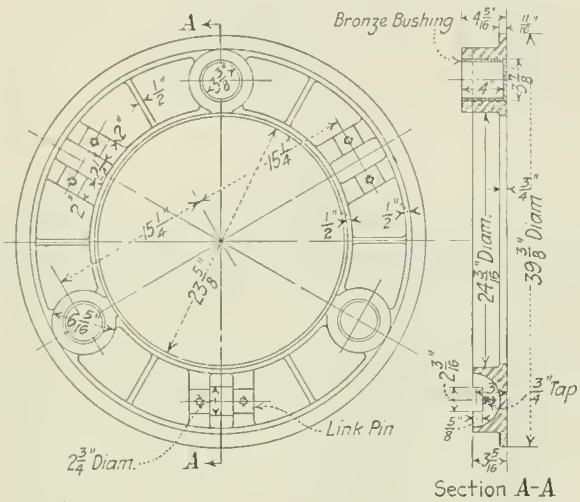

Fig. 2 Clutch Disk

motor, both port and starboard. It is of the single cone and disk friction dry type, constructed of semi-steel and cast iron, and operated by compressed air. The clutch was built to metric measure. All dimensions given in this paper, however, are in nearest inches or fractions of an inch.

The outer casing, adjusting plate, worm wheel, and adjusting screws, which serve as a flywheel, are carried on the engine crankshaft. The casing as shown in Fig. 1 is made of two parts bolted together. The inner surface of the after casing is machined to a cone surface; the forward casing is a straight sleeve or spacer for power transmission only. The extreme outside diameter of the casing is 45 in.

The inner clutch cone or male cone and clutch disk are carried on the guide pins of the spider, on which they are a sliding fit. They are of semi-steel and the outer surface of the male cone is finished to conform to the conical surface of the female or flywheel part. The forward surface of the clutch disk is finished for contact on the fabric shoe of the adjusting plate. Figs. 2 and 3 are detail sketches of the male cone and the clutch disk carried by the spider. The taper of the cone surfaces is about 14 deg. The cone and disk are bronze-bushed for the guide pins.

To the outer surface or periphery of the male cone there is attached, by means of countersunk machine screws, a fiber shoe as shown in Figs. 1 and 3. The shoe is $^1/_4$ in. thick and is made up in four sections, the divisions being in the direction of the axis of the guide pins or shaft. It is the surface of the fiber shoe that contacts with the metal surface of the female or outer casing when the clutch is thrown in.

The spider, attached to the motor shaft by a single key and a retaining screw has three guide pins parallel to the axis of the engine and motor shafts and extending through the spider on either side

[1] Designer, Engr. Dept., Westinghouse Elec. & Mfg. Co.

[2] The *U-117* was recently used as a target and sunk off the Virginia Capes in the U. S. Army airplane bombing experiments.

Contributed by the Gas Power Division for presentation at the Annual Meeting, New York, December 4 to 7, 1922, of The American Society of Mechanical Engineers. All papers are subject to revision.

as shown in Figs. 1 and 4. The guide pins are steel forgings and are shrunk in the spider.

The clutch is thrown in by forcing the male cone and the disk apart until the male and female cone surfaces engage and the disk surface engages the fabric shoe of the adjusting plate; and by drawing the male cone and the disk together and thus releasing the surfaces the clutch is thrown out. The male cone and the

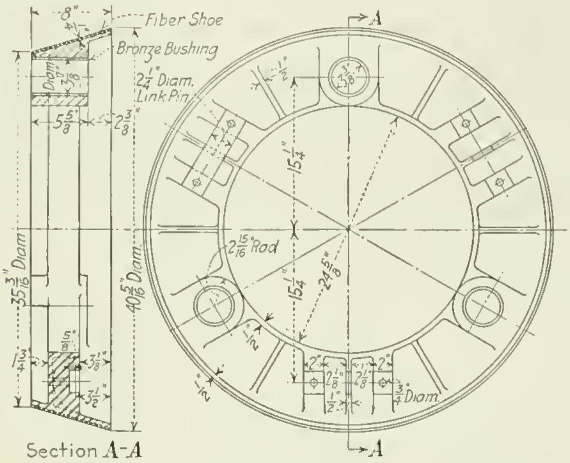

Fig. 3 Clutch Cone

disk are drawn together or forced apart by a series of links and toggles actuated by a sleeve or collar (A in Fig. 1) sliding on the motor shaft. The shifting collar is shown in detail in Fig. 5. It is babbitted for a sliding fit on the motor shaft and is single-keyed thereto.

Referring to the lower half of Fig. 1, the center x is shown fixed to the male cone and center z to the disk. The clutch is engaged by separating centers x and z and by forcing center y up to a line adjoining centers x and z. There are three sets of operating links and toggles equally spaced between guide pins of the spider as shown in Fig. 4.

To the after side of the worm wheel there is attached by means of six adjusting screws a steel disk or adjusting plate faced with fabric. The fabric is $^{7}/_{16}$ in. thick and serves the same purpose as the fiber shoe of the male cone. The fabric is also in four sections and is secured by means of countersunk machine screws. The sectional divisions of the fabric are radial. When the clutch is engaged, the forward surface or finished surface of the clutch disk has contact with the fabric shoe.

The fore-and-aft movement of the male cone and disk is $^{3}/_{8}$ in., or a total of $^{3}/_{4}$ in. The fiber and fabric shoes have some flexibility and it is these surfaces that absorb the load shocks and transmit the power of the engine. The design of this clutch differs in this respect from the clutch used with the 3000- and 1750-hp. engines, in that those clutches have, when engaged, a metal-to-metal contact on lubricated surfaces. The fabric and fiber shoes may be renewed when worn.

The adjusting worm wheel is carried on the engine turning gear (see B in Fig. 1) and is rotated by the adjusting worm (C) which is hand-operated from either end of the worm shaft by means of a wrench. The adjusting worm is bracketed to the engine turning-gear cover plate. Any movement of the adjusting worm is transmitted through the rack (E) and rotates the adjusting screws (F) which are threaded through the worm wheel. There are six adjusting screws equally spaced, three of which are secured to the adjusting plate by means of the guide screws (D). The other three adjusting screws have contact only on the forward surface of the adjusting plate; their ends are flat and do not penetrate the plate. The sketches do not show the short adjusting screws. By means of the adjusting mechanism there is a movement of $^{9}/_{16}$ in. between the disk and the fabric shoe, the adjusting plate moving aft from the turning gear that distance at the surfaces marked W in Fig. 1.

The guide pins of the spider are lubricated by means of three grease cups attached to its arms by a length of pipe. The guide pins and spider arms are drilled for the passage of grease and the former are grooved for its distribution. Plugs are inserted in the blind ends of drilled holes. The circumferential force of centrifugal force of the clutch should carry sufficient grease to the pins without attention to the grease cups except for occasional filling.

The clutch shifting cylinder shown in Fig. 6 is of semi-steel. The bore is 7 in. and the stroke is from $7^{1}/_{2}$ to 8 in., depending on the setting of the pistons. The pistons may be set for long or short stroke by means of the piston adjusting nuts. To prevent pistons from striking cylinder heads when operating, adjustable stops are provided on the guide rods and spring stops are secured to the cylinder heads. The springs at either end of the cylinder absorb the shocks when throwing the clutch in or out.

The general arrangement of the clutch is shown in Fig. 7. The clutch operating cylinder is placed alongside the engine with its center line parallel with the axis of the crankshaft.

The clutch cylinder is operated by air pressure and transmits its power through the crosshead, yoke, and fulcrum to the clutch.

The fulcrum bracket is of semi-steel and is carried on a foundation from the ship's floor. It is estimated that the load at the fulcrum is about 16,000 lb.

The clutch shifting ring is held in its position by the yoke pins and is lubricated for contact with the clutch shifting collar by means of a wick in the oil reservoir.

The engine-turning gear carried with the clutch consists of a worm wheel carried on the engine crankshaft flange and a hand-operated worm which is locked out of position when not in use. The diameter of the turning gear is $46^{3}/_{8}$ in., which is the extreme outside dimension of the assembled clutch.

Fig. 8 shows diagrammatically the arrangement of the clutch-shifting piping. Compressed air for the operation of the clutch

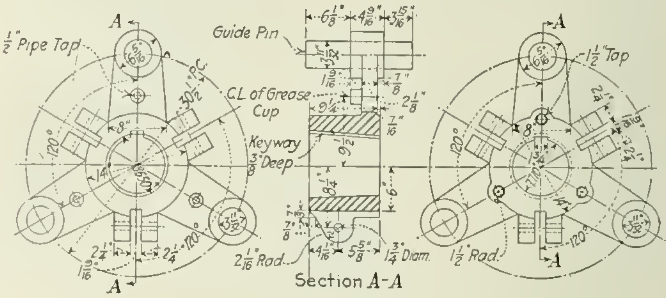

Fig. 4 Clutch Spider

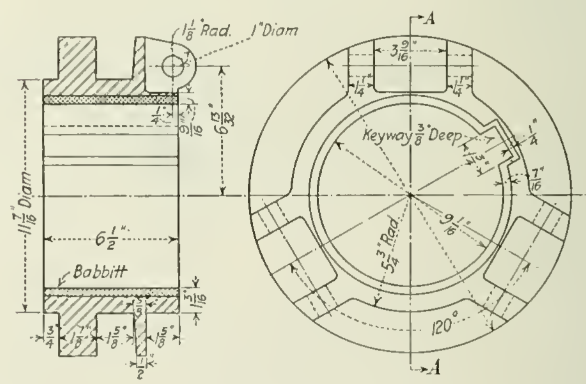

Fig. 5 Clutch Shifting Collar

is supplied from the main engine air-starting flasks at 160 atmospheres (metric measure) or about 2275 lb. per sq. in. It is noted that the air is drawn from the top of the flasks by means of an internal pipe to prevent water that may be collected in the flasks from passing through to the shifting cylinder and damaging it.

There is a pressure-regulating and relief valve in the pipe from the air-starting flasks, with stop valves on either side and at the flasks. The air passes through the clutch operating valve to the receivers and then to the clutch operating cylinder.

The clutch operating valve is so designed that its ports take care of the exhaust air from the opposite end of the clutch operating cylinder by a single movement of the handle, exhausting the air and entrained water to the ship's bilges.

When the clutch is thrown in, it is self-locking, as shown by position of links and toggles in lower half of Fig. 1. It is to be noted that this locking is accomplished by forcing center y slightly above centers x and z. Air may then be shut off from the clutch-shifting cylinder until it is necessary to throw the clutch out. The centrifugal force of the clutch will not throw it out. The advantage of the self-locking feature lies in the assurance that the holding power of the clutch does not depend on a constant pressure of air in the cylinder. Where air pressure would be used for holding the clutch in, there would be the possibility of leaks or fluctuations and the release of the clutch.

All air piping is $^1/_2$ in. in inside diameter and of seamless drawn steel with steel rings brazed to the ends for making up the joints. The pipes are secured in forged-steel fittings by means of a male nut placed on the pipe back of the brazed ring, the nuts then being screwed into the female joint of the fittings. Gaskets are either fiber or copper, placed within the fitting. All pipes and fittings tested to 3000 lb. hydrostatic pressure per sq. in.

For emergency there is a hand pump for the operation of the clutch.

Classification of German Diesel Engines and Clutches

The German Diesel oil engines were generally classified as follows:

- 10-cylinder, 4-cycle, 3000 i.hp., for large cruisers (submarine)
- 6-cylinder, 4-cycle, 1750 i.hp., for large operating submarines
- 6-cylinder, 4-cycle, 1200 i.hp., for large mine-laying and operating submarines
- 6-cylinder, 4-cycle, 550 i.hp., for mine-laying and coastal submarines.

Clutches for the 3000- and 1750-i.hp. engines were of the double-

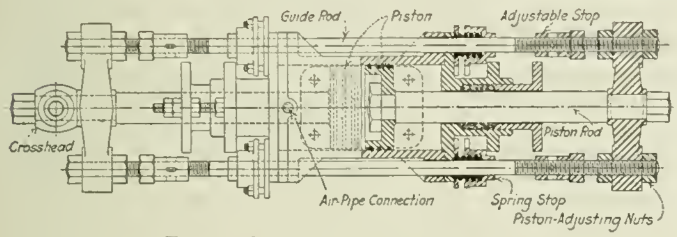

Fig. 6 Clutch Shifting Cylinder

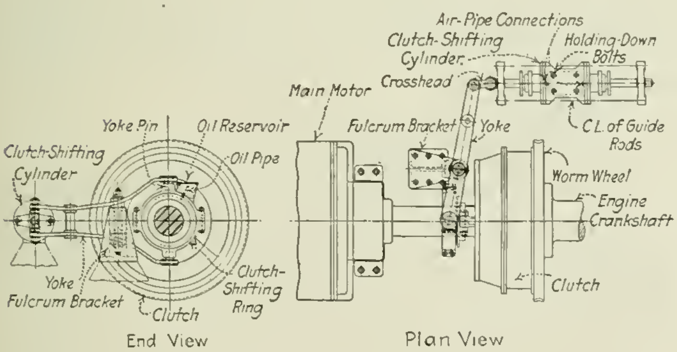

Fig. 7 General Arrangement of Clutch

cone, friction, lubricated type, operated by compressed air or electric motor.

Clutches for the 1200- and 550-i.hp. engines were of the single-cone and disk, friction, dry type. The 1200-i.hp. engine clutches were operated by air and are described in detail in this paper. The 550-i.hp. engine clutches were operated by hand through worm and gear.

The details of design of the German Diesel-engine clutches were practically unknown in this country prior to the surrender of the German submarines, and considerable difficulty was experienced in dismantling them.

At the time of the arrival of the submarine freighter *Deutschland* at New London, when an appointed board of naval officers and civilians inspected her to establish her status, it is known that much interest was shown in her clutches, the construction of which was considered remarkable in so far as so small a diameter of clutch was capable of transmitting such large horsepower. No information of value was then obtainable, but later, when the surrendered German submarines arrived in this country, the clutches were one of the first mechanisms to be investigated.

It is believed that many improvements can be made in the design of American clutches by adopting some of the principles of the German clutches. The author has had some experience with American clutches and has found them to be of the tooth or positive-drive type, or of the friction-jack type. These clutches have been

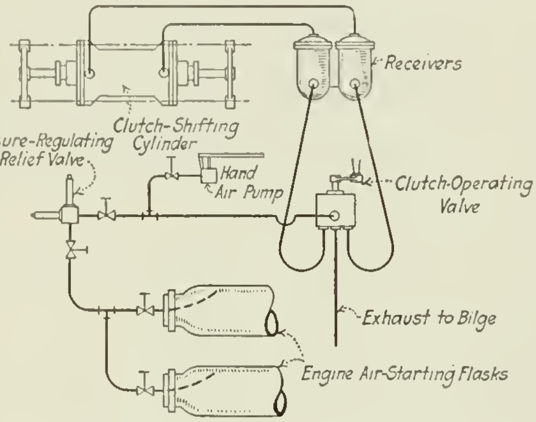

Fig. 8 Diagram Showing Arrangement of Clutch Shifting Piping

the source of trouble and are constantly in need of repair. The tooth type does not allow the flexibility of shaft speeds required in maneuvering a ship that a friction type allows, and from experience it has been found that the friction types are not of sufficient strength and rigidity to transmit heavy loads. During the war one of our American submarines went below her depth by accident and it was necessary to insert emery paper in the clutch before the jaws would take hold and allow her motors to operate the shaft-driven bilge pump. Such delays may cause the loss of a ship and many lives.

The friction-jack types are usually thrown in by hand through a series of levers and therefore lack the holding power of an air-operated clutch.

With the friction-jack type of clutch there is nearly always a misalignment of shafts when the clutch is in, due to improper setting of the jack screws or adjusting screws. The screws are placed radially and must be adjusted from time to time to take up wear. It requires a skilled operator to properly adjust such a clutch.

In the German clutches the adjustment is fore and aft along the axis of the shaft, and with a proper alignment of shafts when machinery is first installed there is little possibility of misalignment when the clutch is in.

The author will be glad to give any further information desired by clutch manufacturers or engineers that will help to improve our American clutches.

During the past year there has been a marked drift toward larger units of Diesel engines. Only a few years ago the Diesel engine was confined to sizes under 500 hp. It was considered that 150 hp. per cylinder was the maximum to be obtained save at the sacrifice of reliability. This impression has been obliberated, and a number of manufacturers are building units of 300 to 400 hp. per cylinder. Two years ago an investigation by *Power* on the Diesel engine industry revealed that the average horsepower per engine was close to 300. In 1922 the average horsepower per engine sold was over 500 and the total horsepower approximately 70,000. This is evidence of the greater faith of the builder as well as the increased confidence of the power user in the internal-combustion engine. A marked activity has been shown in the development of solid-ignition, gas-injection, and other oil engines not using air compressors. These units have been of such sizes as to be competitors of the semi-Diesel rather than of the Diesel engine. It would seem that these types will find their logical place between the capacities that are naturally Diesel and those adaptable to the semi-Diesel. *Power*, January 2, 1923, p. 17.

Test Code on Instruments and Apparatus

Preliminary Draft of Chapters 1 and 2, Dealing Respectively with General Considerations and with the Accuracy of Measuring Instruments, and Being the First Installment of this A.S.M.E. Power Test Code to be Published

As STATED a number of times before, the A.S.M.E. Committee on Power Test Codes is now engaged in the revision of the Society's Power Test Codes of 1915. Mr. Fred R. Low is Chairman of the Main Committee of twenty-five which guides the work of the nineteen Individual Committees. Below are reproduced the first two chapters of the Code on Instruments and Apparatus which is to cover the descriptions of instruments, apparatus, and processes common to the sixteen Power Test Codes. The individual Committee which is developing this Code is headed by Mr. C. F. Hirshfeld as Chairman and consists of Messrs. C. M. Allen, E. G. Bailey, L. J. Briggs, W. A. Carter, R. E. Dillon, S. B. Flagg, S. A. Moss, R. J. S. Pigott, G. B. Upton, E. B. Ricketts, J. J. Flather, F. M. Farmer and J. B. Grumbein.

The Committee and the Society will welcome suggestions for corrections or additions to these two chapters from those who are particularly interested in this part of the subject. These comments should be addressed to the Chairman of the Committee in care of The American Society of Mechanical Engineers.

CHAPTER I

General Considerations

1 The instruments and apparatus here considered are those used for measuring physical and chemical quantities in connection with tests of power equipment of various sorts, as required by other parts of the Code.

2 Measurement of a physical quantity never gives a result which is correct in an absolute sense. The numerical value determined always differs by some amount from the real value being measured, and the extent of the deviation depends upon the type of instrument and the method of its application. This fact imposes upon testing engineers the duty of studying measuring instruments and methods to such an extent that they can show in any given case that they have made all measurements to the degree of accuracy demanded by the purpose of the test.

3 The *accuracy* attainable in any given measurement is dependent upon four things:

- (*a*) The method of applying the instrument
- (*b*) The accuracy of the instrument itself
- (*c*) The accuracy of the observer, and
- (*d*) The characteristics of the quantity being measured.

4 As examples of the first effect the following may be cited:

(*a*) Even if a steam calorimeter were capable of indicating the quality of steam flowing through it without error of any sort and if the observer handled it perfectly, the value determined in any given case would not be the quality of steam in the pipe unless the sample flowing through the calorimeter correctly represented the steam flowing through the pipe from which the sample was drawn.

(*b*) If an absolutely accurate thermometer and a perfect observer could be obtained, such thermometer and observer would not necessarily give correct results in the measurement of, say, the temperature of superheated steam, unless the thermometer was properly immersed in the superheated steam or in a body having the same temperature as that steam and all necessary precautions were taken with regard to the thermal condition of the part of the thermometer not immersed.

(*c*) If a steam-engine indicator was a perfect instrument and perfect observers were obtainable, the card given by the indicator would still be in error if the pressure connections were not such as to apply instantaneously to the indicator piston the pressure acting on the engine piston, or if the motion of the indicator drum did not perfectly follow the motion of the engine piston.

5 In connection with the accuracy of the instrument, it should be noted that no instrument is accurate in an absolute sense. All instruments give only a more or less close approximation to the value of the quantity being measured. It is necessary to use that type which will measure to the required degree of accuracy and to know that it is in condition to do so. The accuracy of instruments will be considered at length in later paragraphs.

6 Accuracy of observers is not commonly given the attention it deserves. An observer should always be familiar with the theory and the mechanism of the instrument which he is using and should understand the degree of accuracy required on his part in its use. However, even after all such precautions have been taken there are still two forms of observational error to be guarded against. These are:

- (*a*) Accidental errors, due to misreading the graduations, incorrect entry on the log of a value correctly read, failure to perform some necessary manipulation, etc.; and—
- (*b*) Personal errors which are dependent upon the personal equation of the observer, such as carelessness in interpolation, tendency to consistently read high or low, inability to read rapidly, thus introducing a time lag, etc.

7 The characteristics of the measurement being made are of particular significance in engineering testing because conditions must usually be accepted as found. In the laboratory, on the other hand, conditions are ordinarily altered to facilitate measurement. Thus a quantity the magnitude of which is continuously changing is more difficult to measure at any moment than when it is not changing. The more rapid the variation the greater the difficulty, and, in general, the lower the accuracy attainable. Again, some quantities are measured so often under similar conditions that the methods have been developed in great detail, while others are measured so seldom or are ordinarily measured under such different conditions that little is known with respect to details, best methods, sources of error, etc.

8 At best, there will always be required in engineering tests certain measurements which are of such character that the degree of accuracy obtainable will be questionable. As examples of measurements which fall into this class at the present time the following may be cited:

- (*a*) Determination of steam quality
- (*b*) Determination of the temperature of superheated steam
- (*c*) Determination of the calorific value of fuels
- (*d*) Determination of combustible in boiler refuse, etc.

Since it is the purpose of the Code to provide methods upon which all can agree and upon the basis of which business can be done and guarantees can be made, rather than to produce a set of directions for scientific investigations, such cases are hereafter handled in a purely arbitrary manner. That is, attention is called to the known sources of error and to those precautions which can be taken to minimize their effects, and an arbitrary standard method of measurement is then prescribed. It is anticipated that as research develops, more accurate methods than these will be prescribed in subsequent revisions of the Code.

CHAPTER II

Accuracy of Measuring Instruments

1 Attention has been called to the fact that instrumental accuracy is purely a relative matter; there is no such thing as absolute accuracy in connection with the measurement of physical quantities. Accuracy in this connection has to do with two radically different considerations which may be designated as—

- (*a*) The *intrinsic accuracy* of the instrument, and
- (*b*) The *accuracy* resulting under the *conditions of use.*

The former is treated generally in the paragraphs which follow and more specifically in later sections dealing with individual instruments. The effects of conditions of use are considered in the sections dealing with the individual instruments.

2 *Accuracy* is used to designate the extent to which the indications of an instrument approach true values of the quantity being measured. The accuracy of an instrument can be determined by calibration, but it is important to note that this often determines the accuracy only for conditions of use similar to those maintained during calibration. For this reason it is often advisable to calibrate by methods which will subject the instrument to as nearly as possible the same conditions as those existing during use in a given test. It is also important to note that moving an instrument to or from the place of use or that dismantling during installation or removal may seriously affect its accuracy. For this reason calibration in place may be necessary under some conditions or with some types of equipment.

3 The methods used for expressing accuracy vary. One common method is to state that the instrument is accurate to within plus or minus a certain specific amount or a certain percentage at a certain point on the scale or between certain points on the scale. Thus a thermometer may be described as having an error not in excess of -0.5 deg. fahr. between 100 deg. fahr. and 300 deg. fahr. It is convenient to state the accuracy of instruments in this way when speaking in a general sense, but other methods are preferable for more specific applications. For such purposes the form of expression should indicate the correction to be added to the indication of the instrument to obtain the real value of the measured quantity. Thus, a thermometer might be said to have a correction of $+0.5$ deg., indicating that at this point of the scale it reads 0.5 too low. A correction of -0.5 would mean that it reads 0.5 too high.

4 For comparison of various instruments of similar character among themselves the specific inaccuracy at normal indications is a most useful value. The specific inaccuracy is the ratio of error to true value. The numerical value may be the same or different for various points within the range of the instrument. As an example of the meaning of this term, assume a pressure gage which reads 48 lb. when a pressure of 50 lb. is applied and 98 lb. when 100 lb. is applied. The specific inaccuracy at the lower point is $2/50 = 0.04$ or 4 per cent, and at the higher point $2/100 = 0.02$ or 2 per cent. If the inaccuracy is specified as a certain percentage of the full scale reading, then the maximum inaccuracy at any other reading is inversely proportional to that reading. This sort of thing is characteristic of nearly all measuring instruments which carry a uniform scale, that is, a scale divided uniformly from end to end. An error of given magnitude at a high scale reading represents a much smaller percentage error or specific inaccuracy than does an error of the same magnitude at a low scale reading. When instruments are so arranged that the length on the scale representing one unit of the measured quantity is long at the center of the scale and short at each end, the specific inaccuracy must obviously vary throughout the entire range in a more complicated way. Smaller inaccuracy in observation will be obtained with an instrument having two or more ranges than with one having only one range, as the deflection of the pointer or index to a point of maximum amplitude will reduce to a minimum errors due to parallax in observation or to any other cause.

5 *Inaccuracy* of an instrument in the sense in which it is here used is caused by features or factors in the instrument itself and has nothing to do with the effect of external conditions other than the value of the quantity being measured. Inaccuracy may be due to great number of different causes acting singly or in combination. The principal causes are:

(*a*) *Imperfect material,* as variation in bore of a glass tube, variation in the molecular structure of the material of springs, etc.

(*b*) *Unavoidable physical phenomena* such as capillary attraction, imperfect refraction of light, friction of rest and motion, etc.

(*c*) *Imperfect construction* which *cannot be improved,* such as lost motion in gear trains resulting from necessary clearance in bearings or between teeth, changing lengths of levers due to necessary clearance in bearings or to the finite width of knife edges or points, etc.

(*d*) *Imperfect construction* which *can be improved,* such as excessive friction, excessive lost motion, incorrectly cut cams, etc.

(*e*) Unavoidable or partly unavoidable *properties of materials* such as the aging of glass, the gradual yielding of materials to physical stress, the aging of permanent magnets, etc.

6 Inaccuracies arising from such causes as are included under Par. 5 (*a*) are ordinarily of irregular character, causing more or less erratic errors throughout the range of the instrument. They are usually permanent in character or change but slowly and are easily taken into account during calibration.

7 Inaccuracies arising from such causes as are included under Par. 5 (*b*), (*c*) and (*d*) are more or less regular in character and are responsible for what has been called the hysteresis loop of an instrument. This is the loop which is obtained by plotting instrument readings against true values, using the instrument first in an ascending sense and then in a descending sense. A similar but different loop can be obtained by plotting errors against true values or corrections against indicated values. This is considered later in greater detail.

8 Inaccuracies arising from causes included under Par. 5 (*c*) are responsible for what is known as aging or drift in instruments. Within certain limits such aging or drift is not detrimental, although it does necessitate frequent calibration to guard against its effects. In certain cases it must be taken into account if erratic results are to be avoided. Thus a glass thermometer which is to be subjected to high temperatures must be artificially aged before calibration and use.

9 *Sluggishness* is a term used to indicate the amount of displacing or actuating effect required to cause motion of the indicating part of an instrument. It is determined by noting the smallest alteration in the quantity being measured that will produce a perceptible change in the indication of the instrument. Thus a thermometer which at 400 deg. fahr. requires a change of ± 5 deg. fahr. to cause it to move up or down will have a sluggishness index of $5/400 = 0.0125$. This factor is most useful when expressed as a percentage, giving 1.25 per cent in the example cited. In comparing the sluggishness-index factors of instruments calibrated in different units it is necessary to refer them to the same base. Thus a thermometer calibrated in degrees centigrade would have the same factor as the one just considered if it required a change of ± 2.78 deg. cent. ($= 5/1.8$) to cause it to move up or down, since the temperature of 400 deg. fahr. corresponds with 204.4 deg. cent. or 222.2 deg. cent. above 0 deg. fahr. (-17.8 deg. cent.) which is the base of the fahrenheit scale. The sluggishness factor in this case would be $2.78/222.2 = 0.0125$ or 1.25 per cent. The value of the factor may and probably will be different for all points within the range of the instrument. "Passiveness" is often used as synonymous with sluggishness.

10 Sluggishness is often thought of as the opposite of sensitiveness or sensibility. Thus it is common to speak of a thermometer as "sensitive to 0.1 deg. fahr." meaning that it will respond to changes of that magnitude. This is technically an incorrect usage. Sensitivity is defined as the rate of displacement of the indicating element of the instrument per unit change of the measured quantity. That one of a group of comparable instruments which gives the greatest displacement for a given change in the measured quantity is the most sensitive.

11 *Sensitivity* of instruments is a most important property, as with other things equal it is the thing which determines the degree of refinement possible in their use. Unfortunately instruments are not always designed and constructed in such a way that the total available sensitivity is useful. Thus an instrument may be so constructed that it is possible to read on its indicator the movement corresponding to a variation of one unit in the value of the quantity being measured, but it may be so built that it will indicate values varying by as much as five units in successive trials with no change in the actual value being measured. The sensitivity of such an instrument is partly useless and is really misleading. A correctly designed instrument should have such sensitivity that the minimum readable movement of its indicator is not less than the amount by which the instrument may be expected to vary in successive indications of the same value of the measured quantity. To be exact these requirements should be stated in terms of the mean for both indication and variation as both may vary from point to point throughout the range of the instrument.

12 Sensitivity in excess of requirements, as set by the accuracy

desired in a given set of measurements, is generally a detriment because it involves delicacy, slowness of operation, or some other undesirable quality.

13 *Variance* is a term used to represent the amount by which the readings of an instrument vary in successive indications of the same value of the measured quantity. Variance is due principally to—

(*a*) *Lost motion*, which also affects the sluggishness or passiveness;
(*b*) *Friction*, which also affects the sluggishness or passiveness;
(*c*) Changes due to the stress-strain relation of springs *in the force-resisting or restoring element* of the instrument;
(*d*) *Changes in the distribution of parts*, as variation of position of pins in bearings or variation in the amount of liquid retained on wetted surfaces
(*e*) The *immediately preceding history* with respect to extent and speed of displacement; and—
(*f*) A great number of other more or less obscure phenomena.

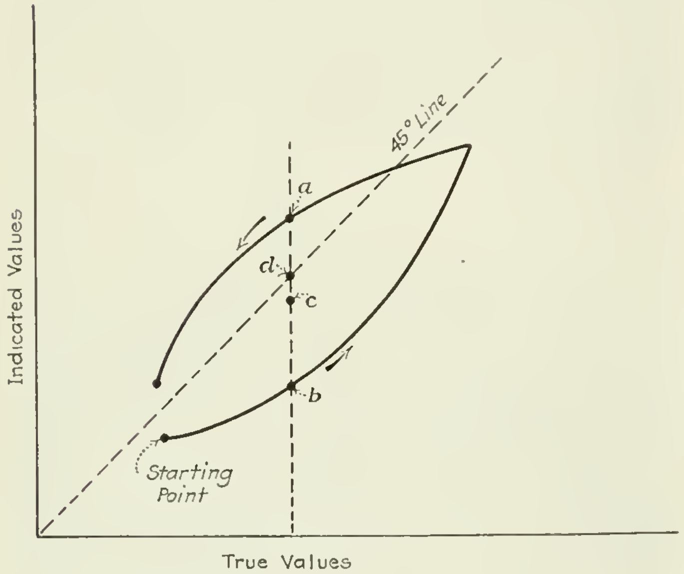

Fig. 1

14 Variance due to lost motion is commonly associated with the direction of motion of the parts in the instrument and it could be almost entirely eliminated if a given value could always be approached from the same side. Under conditions of use this is commonly impossible, although it can be done during calibration if desired.

15 Variance due to friction can be partly eliminated by tapping the instrument just before taking a reading. This is common practice in the use of instruments containing mechanical movements and is recommended if not carried to excess.

16 Variance due to the other causes enumerated above is not under control except in so far as it can be kept at a minimum value by proper maintenance and proper handling.

17 Instruments which are used in tests made according to the A.S.M.E. Power Test Codes must be tested to such an extent as may be necessary to determine their condition and their accuracy. Such testing is commonly known as *calibration of the instrument*.

18 The exact procedure to be followed in calibrating instruments varies not only with the instrument but also with the use to which it is to be put, the accuracy desired and other considerations. In general the calibration should include determination of the following throughout the range which is to be used:

(*a*) Sluggishness and its relation to the sensitivity of the instrument
(*b*) Variance and its relation to the sensitivity of the instrument
(*c*) Accuracy, or error of indication at different points within the useful range.

19 The principal methods available for the calibration of instruments and apparatus of different sorts are treated in detail in later paragraphs when the individual instruments are considered. Certain general features more or less applicable to all instruments are, however, discussed in the following paragraphs.

20 Calibration for the determination of error of indication may be conducted with one of two different objects in view: It may be desired to determine the errors of indication with respect to absolute accuracy; or it may be desired to determine only the extent to which the instrument is constant within itself with no reference to absolute values. As an example of the latter case, consider a speed-measuring device used in connection with a test to determine governor regulation with change of load. Under such conditions it is essential that the instrument shall give properly comparable values, but a correct indication of any one speed is not essential. In most cases, however, calibration on an absolute basis is required.

21 Most *calibrations* for error of indication are made by direct *comparison* of the readings of the instrument under calibration with the readings of some other instrument which is used as a standard, or by subjecting the instrument to the action of effects of known magnitude. Thus a thermometer may be calibrated by comparing its indications with those of another thermometer previously calibrated, with the two immersed in a liquid under such conditions that they should indicate the same temperature. Or, a thermometer may be calibrated by immersing it in pure materials undergoing changes of physical state known to occur at certain definite temperatures.

22 When it can be done, it is best to calibrate by some method which will make it possible to determine the errors of the instrument at successive points on its scale while the quantity being measured is varied by steps in an ascending and in a descending sense, successively.

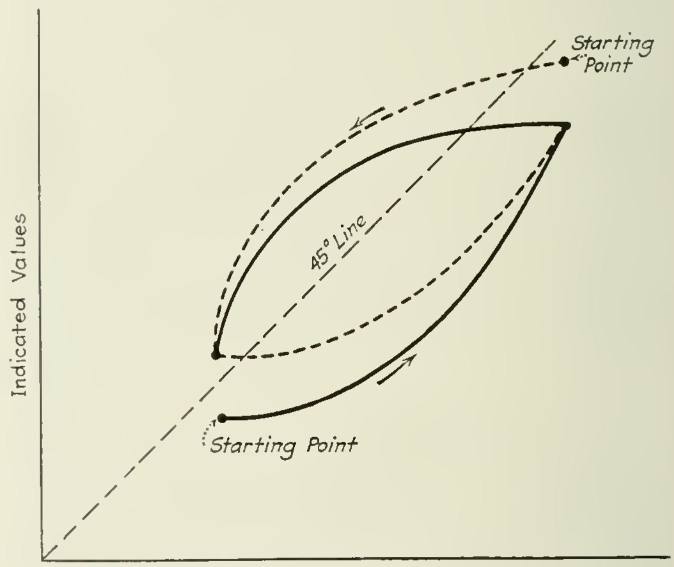

Fig. 2

23 When indications obtained in this way are plotted against true values a *hysteresis loop* will generally result if the work is done with sufficient care and skill. Such a loop is shown in Fig. 1 for a case in which ascending values are determined first and in which the instrument was reading a lower value than that at the starting point before calibration started. In such a case the lower end of the loop will not commonly close. If the procedure is reversed so that calibration starts at the higher values the resultant curve will be reversed in shape and the upper end will not close in most cases.

24 An ideally perfect instrument absolutely accurate throughout the range under test will give results plotting on the 45-deg. line indicated in Fig. 1 if true values and indicated values are plotted to the same scale.

25 In Fig. 2 are shown two hysteresis loops which might be obtained when calibrating the same instrument. The loop shown in full lines would be obtained with ascending values determined

first and that shown in dotted lines with descending values determined first. Obviously there is no simple correction for such an instrument. The departure from the true value varies with the past history of its moving parts or elements. It is also important to note that successive trials may not give values which will plot on the same hysteresis loops, particularly if the steps used in successive trials are of radically different magnitudes, or the rates of variation are radically different or the amount of vibration to which the instrument is subjected differs.

26 For convenience in engineering tests it is customary to draw some single line or curve as a sort of average of the hysteresis loop and to use this as the "calibration curve" of the instrument. This line or curve is usually drawn by plotting a series of points, each one of which is the mean of figures obtained for corresponding true values when ascending and descending. This procedure is shown in Fig. 3 for the case in which only one hysteresis loop is determined. It is obvious that the exact shape and location of such a curve will vary with the way in which the loop is obtained. It follows that the "calibration curve" is not a true representation of the behavior of the instrument during its calibration, and, further, that it is not an exact means for correction of indications obtained under the constantly varying conditions of use. The approximate nature of the calibration curve should be kept in mind in all considerations dealing with the accuracy of observations and hence with the accuracy of test results.

27 It is obvious that, with other things equal, the most accurate results are to be expected with instruments giving the narrowest

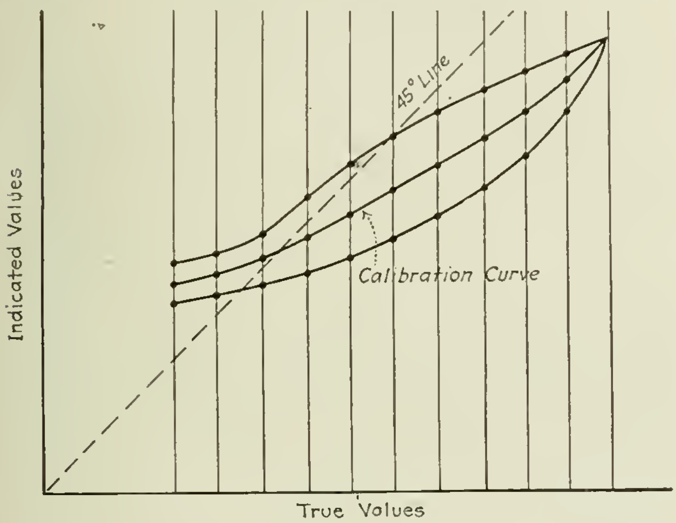

Fig. 3

hysteresis loops, and such instruments should be used when obtainable and when their use is justified by the degree of accuracy desired in the test.

28 The calibration curve as shown in Fig. 3 is not in the most convenient form for use under ordinary conditions. It is better to put it in the form shown in Fig. 4. Drawn in this way it is easily used and there is little possibility for error in its use. It has the further advantage that for ordinary conditions the entire plot occupies very little space, so that a number of curves can be drawn on one sheet without danger of causing confusion. Such an arrangement is shown in Fig. 5.

29 It will be observed that the calibration curve obtained in the way indicated shows only the average amounts by which the indications of the instrument may be expected to vary from the true values of the measured quantity. Such a curve tells nothing about sluggishness, sensitivity, or variance. These characteristics are, however, of importance in most cases and should be investigated during the calibration for the purpose of determining the adaptability of the instrument to the use intended, its condition, and the accuracy which can be obtained in its use.

30 *Sluggishness* is best investigated by determining the amount of displacing effect required to start useful motion of the indicating element after the instrument has been at rest. Such determinations should be made throughout the range which it is intended to use. In most cases such tests can be made conveniently while obtaining data for the hysteresis loop, so that a separate calibration for determining sluggishness is not commonly necessary. The observations made in determining sluggishness should be recorded with the other calibration data. They are best converted to a sluggishness index for successive points in the scale and tabulated as such.

31 The *sluggishness index* is not an exact numerical value in an absolute sense. The amount of vibration to which an instrument is subjected during calibration or use has a marked influence on its performance in this respect. Vibration has a tendency to decrease

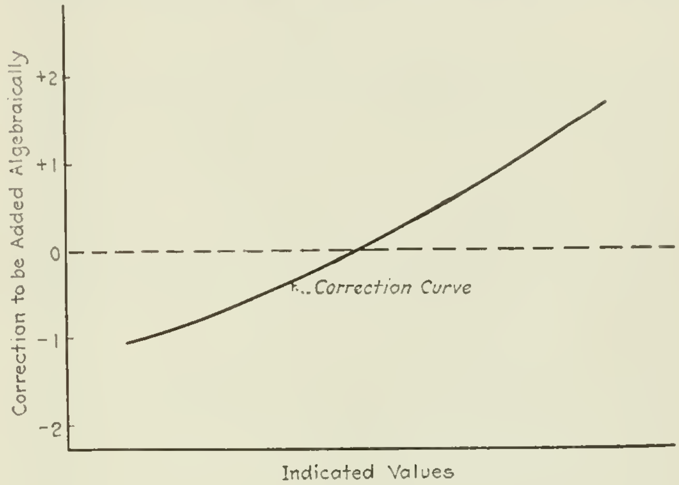

Fig. 4

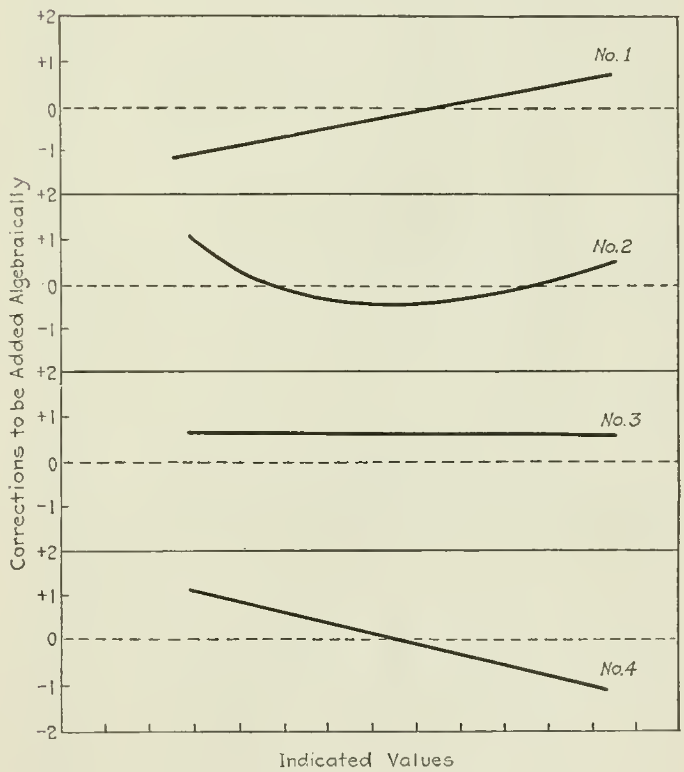

Fig. 5

sluggishness in all instruments containing kinematic trains of any sort, pivots, bearings, and the like. For this reason it is customary to tap such instruments to induce vibration before reading. This should be taken into account during calibration, both in determining the error of the instrument and in determining the sluggishness factor. If an instrument is going to be used under such conditions that it will be subjected to vibration or can be tapped before reading, it should be calibrated under analogous conditions. Again, the rate of variation of the measured quantity has a marked effect on sluggishness. The sluggishness factor determined when the variation of the measured quantity is very slow and very steady will be, ordinarily, quite different from that determined when the variation

is rapid but steady and, further, quite different from that determined with rapid variations of opposite sign. All these factors should be taken into account when calibrating, an effort being made to approximate as nearly as possible the conditions to which the instrument will be subjected when in use.

32 *Variance* can be determined directly from a hysteresis loop or, better, from a number of hysteresis loops obtained by starting at different points and by subjecting the instrument to variations of different directions, intensities, etc. The points marked *a* and *b* in Fig. 1 show two radically different indications which might be obtained for the same value of the measured quantity. It is quite common to assume that a point *c* midway between points *a* and *b* indicates the reading that would be obtained were there no variance. This is consistent with Par. 26. With this assumption the distance between *a* and *c* is a measure of the variance of the instrument at this particular point in the scale. There is obviously no certainty that the instrument will ever read closer to *c* than is indicated by the points *a* and *b*, respectively, and the possibility of variance of such extent must always be assumed in testing. Naturally, the value of variance will vary from point to point, so that it should be determined throughout the range that is to be used. When variance is determined in this way it should be tabulated or plotted and the record preserved with other calibration records of the instrument.

33 *Variance*, like sluggishness, varies in value with the conditions existing during test or use. The character of the variation of the value of the quantity being measured the amount of vibration and other factors all have their influence. As an example, consider an instrument subjected to a sudden increase of actuating force or effect of sufficient magnitude to cause its indicating parts to move so rapidly that inertia carries them beyond the position they would normally assume, for the final value of the quantity being measured. It may be that the amount of overtravel is so great that the unbalanced forces resulting are more than sufficient to overcome sluggishness without any vibration of the instrument. It may be that the overtravel is not so great and that sluggishness prevents restoration to the proper position even with vibration. It may be that the lost motion in the mechanical train is so great that even though the essential moving part of the mechanism comes back to a correct position the indicator or pointer remains in the position of overtravel. There are so many possibilities that it is practically impossible to correct for variance in the actual use of many instruments. The best that can be done is to recognize the fact that the calibration curve of the instrument is in reality not a line but a band of finite width (or height) and to interpret its readings and test results depending on those readings in the light of such knowledge.

34 *Sensitivity* is a property determined by the design of the instrument; it does not change with the condition of the instrument. In case of mechanically operated instruments if a certain moving element has been chosen and a certain multiplying device has been designed, the pointer or other indicator must theoretically move a certain distance for a given change in the value of the quantity being measured. In the case of a device like a mercury thermometer, if a given amount of mercury is subjected to a given change in temperature a certain volume change must occur and, in a capillary tube of a given bore, this must cause a movement of a given amount. The numerical value of the sensitivity is thus a characteristic determined by the design of the instrument. It is significant primarily in making a choice of instruments. These must have such sensitivity that the values of the quantities being measured can be read upon the instrument to at least as small a subdivision as is required by the conditions of the test.

35 The value of the sensitivity can be determined readily from the results of the calibration by noting the amount of displacement occurring for given variations in the values of the quantity being measured. It then becomes possible to state the displacement per unit of value and the minimum readable variation which follows from the design of the instrument.

36 It is always necessary to compare the values of sensitivity thus determined with the value determined for sluggishness and variance. Sensitivity within the limits set by sluggishness and variance is useless, and an attempt to use it results only in wasted effort and, possibly, mistaken accuracy.

LUMBER DRY KILNS

(*Continued from page 112*)

A few standards of construction, design, and operating methods are given below for the purpose of assisting in general layouts and development sketches.

Kilns may be *end-pile* or *cross-pile*, i.e., boards may be parallel or at right angles to the rails (Fig. 4), depending largely on the factory and yard arrangements. End-pile gives slightly better internal circulation, although this is rarely determinative.

A kiln car of lumber is usually 6 ft. wide, 9 ft. high (above rails including trucks), and from 12 to 16 ft. long (rarely longer). Higher loads not only upset easily but greater heights introduce uneven drying, or wet pockets, because of unavoidable temperature differences between the bottom and top of an enclosed space. The writer knows of a battery of kilns 20 ft. high in which the top half of the load always dried first and there was a temptation to discharge the kiln before the bottom half dried.

Kilns may be of the *progressive* (open at both ends) or *single charge* (usually open one end) type as shown in Fig. 5. The former

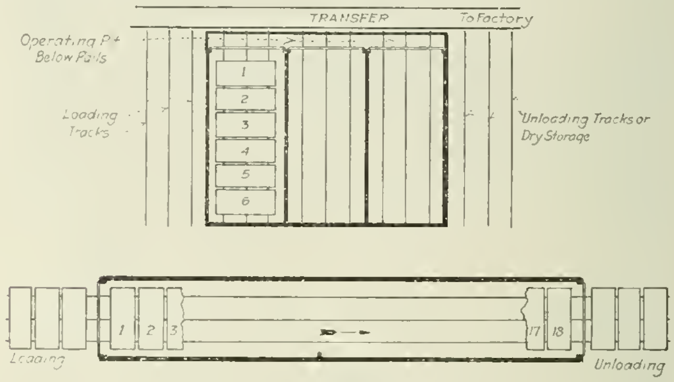

Fig. 5 Progressive Kiln (Below) and Single Charge (Above)
(Each has equal holding capacity and output, together with minimum necessary trackage for loading and unloading.)

involves a daily opening to remove and enter lumber, a daily moving forward of every car, with a consequent loss of from 5 to 10 per cent of the drying period from the opening of kiln, during the time required to cool sufficiently to move the cars, to the time when temperature and humidity are restored to operative conditions. The progressive kiln, to be efficient, requires that the charging end be maintained at a low temperature and a high humidity and the discharging end at a high temperature and low humidity with graduated intermediated conditions. Air circulation, chiefly transverse, prevents dependable graduated conditions and the operator copes with irregular conditions. The subdivision of the heat and humidity sources may be of slight help, but in any case the progressive kiln is more complicated than the single-charge type.

The latter type (sometimes called box, compartment, pocket, or cell) requires the operator to vary his entire kiln regulation from day to day according to a predetermined schedule. The room is small enough so that control of uniform conditions throughout is simple. Various kinds and thicknesses of lumber can be separated in different rooms and given individual treatment. Valves and dampers can be located in an accessible outside pit. When built in batteries with adequate transfer and yard trackage the single-charge type will produce as great a turnover from the investment as the progressive, and dry the lumber better.

Hollow tile, with an exterior brick veneer, makes the best walls, and a tile and reinforced-concrete roof with insulated wooden doors will complete an economical heat-retaining building. Solid concrete is not only a poor insulator but adsorbs too much moisture and checks badly under high temperatures. Frame buildings, under the varying conditions of temperature and humidity, rot and rack rapidly.

Scientific kiln drying is only at its beginning and wood users have but commenced to visualize the efficiency and economy that is possible. Engineers can do much toward the solution of the problem by giving it the same degree of study and research that has resulted in substantial progress in other fields.

SURVEY OF ENGINEERING PROGRESS

A Review of Attainment in Mechanical Engineering and Related Fields

AERONAUTICS (See also Internal-Combustion Engineering)

British Air Ministry and Rateau Scheme for High Flying. It is stated that the Directorate of Research of the Air Ministry (British) has rejected the Rateau scheme for flight at high altitudes for the following reasons quoted from the letter of the Directorate.

"Considering the conditions under which both turbine and blower have to work, it is not considered possible to obtain overall efficiencies of the order of 30 per cent. A more likely value would be 20 per cent, with 25 per cent as a practical limit. Taking 22.5 per cent as a value for an average plant, back pressures of the order of 3 lb. per sq. in. will have to be allowed in order to restore ground-level inlet pressures at 15,000 ft. The utility of the device will then depend largely on the effect this back pressure has on the running of an engine. In this connection both loss in power and possible overheating will have to be considered. In any case, the strictly limited range of 'full compensation' shows that the scheme proposed by Professor Rateau is not a complete solution of the problem, and that at greater altitudes, especially, other schemes will have to be considered." (*The Practical Engineer*, vol. 66, no. 1867, Dec. 7, 1922, pp. 353–354, *g*.—The mathematical foundations for the high-altitude flight scheme of Professor Rateau, Mem. Am.Soc.M.E., were presented in his paper before the Society and published in Mechanical Engineering, May, 1920.)

Paragon Adjustable and Reversible Propeller. Description of a propeller recently tested at Bolling Field. For this purpose it was installed on an automobile truck trailer equipped with a 150-hp. Wright-Hispano engine.

The two wooden or steel blades are fastened into steel sleeves, which, in turn, are held in a steel hub, the centrifugal force being taken on ball thrusts and torsional and axial forces on plain bearings. In the method of fixing the wooden blades into the steel sleeves as illustrated in the original article, the butt end of each blade is tapered outwardly at a small angle and the surrounding collar is split so that it may be first sprung over the butt and then compressed into the taper.

The pitch-changing mechanism is operated through the application of a braking force to either one of a pair of small brake drums surrounding the engine crankshaft and normally rotating with it. The brake drums are connected through a gear train to the individual blades of the propeller.

In the tests the engine was turning at 1500 r.p.m. No data are given as to the strength of the blade where it is held by the split collar and as to its ability to resist the centrifugal stresses, which is the main problem in the design of a variable-pitch propeller. (*Aerial Age*, vol. 15, no. 21, Dec., 1922, pp. 587–589, *d*)

Four-Engine All-Metal Airplane Built by the Schneider Co. Description of a airplane of the Henri-Paul type built by the great Schneider Works, the largest steel plant in France. There are several reasons why this airplane becomes of considerable interest.

The machine is of very considerable dimensions, weighing with full flying kit 10,020 kg. (22,050 lb.). It is equipped with four Lorraine-Diétrich motors of 370 to 400 hp. each.

The wings are made with chrome-nickel steel frame members with stiffening ribs of a light alloy. The fuselage is made up of high-resistance light alloy and steel tubing.

The original article gives considerable attention to the aerodynamic properties of the machine and some data on design. It is also stated that the Schneider works have under construction two four-engine airplanes which are each equipped with a 75-mm. gun. (*Le Génie Civil*, vol. 81, no. 23, Dec. 2, 1922, pp. 505–510, 18 figs., *dA*)

ELECTRICAL ENGINEERING (See Power-Plant Engineering)

ENGINEERING MATERIALS

Lead-Coated Pipe in the A. T. & S. F. Railway Enginehouses. Considerable trouble has been experienced from rapid deterioration of water pipe in enginehouses on the A. T. & S. F. Railway, and in an effort to remedy the situation a process of lead plating of pipe has been developed.

This is done in the following way: The material to be plated is first cleaned by immersion in a lye vat which serves to remove the grease and oil. The surfaces are next washed with a jet of water and then placed in another vat filled with a 17 per cent solution of sulphuric acid, which is followed by scouring produced by adding about 15 lb. of Chile saltpeter for each 600 sq. ft. of treated surface. The saltpeter is added after the steel has been placed in the sulphuric acid solution and its addition is followed by a violent eruptive action on all metal surfaces within the vat, which, by the way, is constructed of redwood timber. After this action has subsided the steel is removed from the cleaning solution and again washed with a jet of water preparatory to the plating operation. Lead plating is effected by dipping the steel in a vat filled with lead acetate solution ranging from 20 to 50 per cent for a period of about 20 min. About 0.1 oz. of lead is deposited per square foot of steel and the weight of this lead plating can then be built up electrochemically if desired.

It is stated that the resultant material retains all the physical strength of the steel superstructure and is as impervious to corrosive action as pure lead.

The article describes also the new method of making pipe joints by means of forged steel flanges welded to the tube ends. (*Railway Review*, vol. 71, no. 24, Dec. 9, 1922, pp. 818–820, 3 figs., *d*)

Carbonized Clay—A New Refractory Material, Walter Smith. General discussion of the carbonization of clays with special reference to the osmose process and material produced thereby.

In general carbonization of clays is based on the fact that clay reaches maximum porosity in the earlier period of firing at a point when the clay is in the biscuit state. The material is then extremely absorbent. This opportunity is seized for charging the clay with volatilized hydrocarbon. As the heating is continued the clay powerfully contracts and entraps the particles of atomic carbon which are then compressed from the easy position adopted by themselves by volatilization to a great density. The product thus made is carbonized clay.

Black carbonized clay consists of clay grains reinforced with countless infinitesimal particles of carbon diffused throughout the pores. This material is remarkably dense, and so long as it remains in a reducing atmosphere is capable of withstanding the destructive action of heat beyond the highest commercially workable temperature and is unaffected by acids.

White carbonized clay results from the action of an oxidizing flame on black carbonized clay. When such a flame plays on the black material myriads of particles of enclosed carbon are gradually consumed, a corresponding number of minute pores being created.

Thus, instead of having the porosity which occurred naturally in the biscuit state of the clay (uncontracted), there exists an artificial (and almost equivalent) porosity in the fully contracted material, and, since the contractive force of the clay has been expended, the artificially created pores remain constant. In other words, when further heating is applied to the mass, the limit of contraction having been reached, difficulty is encountered by the heat in bringing about a state of fusion; the fusing point is therefore transferred several hundred degrees higher than that of the same clay in its natural state.

The black state provides a material adapted for heat resistance in reducing atmospheres, for the manufacture of acid-resisting ware, and for abrasive powders. In the white condition the clay should be used for the manufacture of refractory materials to be employed in the open flame, and in furnaces where air is freely admitted.

It is stated that the material is very little affected by hot acid fumes, both hydrochloric and sulphuric acid. The hardness of carbonized clay is just short of carborundum; indeed, it might replace the softer grades of carborundum and the material is amorphous instead of crystalline. Its heat conductivity is twice that of standard firebrick. A specimen was shown which was intact after resisting a temperature of 1730 deg. cent.

A remarkable phenomenon which occurs as a result of carbonizing clay is the fact that by carbonization iron oxide may be liberated from clay as a by-product. Alkalis are similarly liberated. (*Journal of the West of Scotland Iron and Steel Institute,* vol. 30, no. 1, Oct., 1922, pp. 8–13, *dA*)

Marine Borers Attack Piling Along Atlantic Coast. In the report of the San Francisco Bay Marine Piling Committee (compare Mechanical Engineering, Dec., 1922, p. 834) it was mentioned that the marine borer had appeared on the Atlantic coast. It is stated now that the National Research Council has undertaken an investigation to determine methods of protection. The first appearance on the East coast was established in Barnegat Bay, New Jersey, in 1921. In order to secure definite information regarding the distribution of the various species and their rate of growth, a test board was designed carrying 24 blocks, one of which was to be removed on the first and sixteenth day of the month and sent to Harvard University or the University of California for proper investigation. The blocks are 2 in. by 4 in. by 5 in. in size, of whitering sappy yellow pine, surfaced on four sides. The first boards were placed in June, 1922, and altogether 235 of these boards have been put in place between the eastern boundary of Maine and Kodiak, Alaska. As a result it was found that the various types of borers are present practically along the entire coast.

In an effort to develop a system of protection, test blocks impregnated with various chemicals, in particular fractions of creosote, are being tested by immersion in Gulf and Pacific harbors, several tropical woods being also included in the test. A report on this work has not been published as yet. Reinforced concrete as a substitute for timber has not a record of useful success; in fact, the Committee has found very many more cases of failure than of success, and in most cases the causes of failure are very obscure.

This investigation is being conducted by the Committee on Marine Piling Investigations of the National Research Council, New York City. (*Railway Age,* vol. 73, no. 24, Dec. 9, 1922, pp. 1083–1085, 5 figs., *g*)

FOUNDRY

Casting of Aluminum Bronze, Chas. Vickers. Aluminum bronze requires some special methods of casting as compared with the practice of a brass foundry. It drosses and shrinks excessively and is also subject to gas cavities and internal shrinkage holes. Furthermore, machining is apt to disclose little nests of a white non-metallic substance (alumina). In the case of castings massive in size the alloy changes as it cools slowly in sand molds and suffers thereby a drop in tensile strength and particularly in elongation. (This change, known as "self-annealing," has to be counteracted either by some device for the quick chilling of the casting or by the use of special compositions of aluminum bronze immune to the effect of slow cooling.)

The article describes in detail how to counteract these undesirable tendencies in castings, in particular the method of gating used. Among other things it is recommended to use horn gates with the large end toward the casting and heavy risers to feed the shrinkage. Spiraling of the down gate is also suggested, and it is stated that a spiral runner of small cross-section is an important means of securing dross-free castings of aluminum bronze, because it eliminates vertical sprues of large size down which it is impossible to drop the liquid bronze and not create an excessive amount of dross.

The term "aluminum bronze" can be taken as meaning any alloy of copper and aluminum, with or without additions of other elements which have a base of copper. An alloy commonly used for small castings is copper, 89 per cent; aluminum, 10 per cent; and iron, 1 per cent. This has some advantages over the alloy of 90 per cent copper and 10 per cent aluminum. Where great strength is required, as in the case of large valve stems, shafting, etc., an alloy of copper, 86 per cent; aluminum, 10 per cent; iron, 4 per cent, is extensively used. Since this alloy was devised by the author in 1916 it has been extensively used under a variety of names, a proof of its remarkable qualities. In 1918, patent No. 1,264,459 was granted from the application filed Sept. 27, 1916. Its physical properties will vary according to the skill with which it is made. In tensile strength the cast metal should reach considerably over 80,000 lb. per sq. in. and its elongation should not be under 17 per cent, sometimes running as high as 30 per cent. (*The Foundry,* vol. 50, no. 23, Dec. 1, 1922, pp. 958–960, 4 figs., *d.*—In this connection it may be of interest to note that the first comprehensive account of the properties of aluminum bronze published in this country was printed in the Transactions of The American Society of Mechanical Engineers, vol. 15, p. 631, discussion by Mr. Leonard Waldo, Mem. Am.Soc.M.E.)

FUELS AND FIRING

Factors Affecting the Use of Air in Oil Burning, with Comparison of Cost, W. C. Buell, Jr. Discussion of the influence of air pressure in burning liquid fuels. The author classifies all oil-burning systems offered for industrial heating practice into three general types on a basis of air pressure at the source of supply from which they operate, these three classes being: (1) Burners employing so-called "volume" air which is moved by high-speed fan blowers and delivered to the burners at pressures of from 4 to 10 or 12 oz.; (2) burners operating on so-called "positive" air which is delivered to the burners by displacement or turbine-type machines and occasionally by high-speed centrifugal fans, at pressures of from 12 oz. to 2 lb.; (3) burners utilizing "high-pressure" air which is delivered to the burners from compressor lines in which pressures ordinarily run from 50 to 60 or 100 lb. gage.

The author discusses the factors affecting the use of air in oil burning under the above classifications, but with reference to the equipment included under class 1, it should be understood that burners operating on the low pressures of this class cannot depend on the air to atomize the oil but must of necessity use a mechanical system in which the oil fuel is atomized by the static oil pressure forcing the oil fuel through very small orifices in the form of a fine spray which the low-velocity air can easily pick up. The use of this system is therefore limited to oil which is very fluid and very clean. This confines it to a comparatively small field, as in this day and age only residual and heavy fuel oils should be considered as fuels.

The investigation of the author covers the subject of air velocity, quantity of air required for burning oil, inductive properties of primary air as applied to oil-burning practice, comparison of blowers, and, finally, comparative costs of air.

The author comes to the conclusion that consideration of the subject-matter and figures of this paper clearly show that the proper method of burning oil is with air pressure under classification 2, or under some conditions with 15-lb. air under classification 3.

Further, all fuels are high priced whether they are coal, natural gas, manufactured gas or the liquid hydrocarbons, and in the years to come the tendency will probably be for fuel prices to continue on an upward trend; therefore, to cut down fuel costs to the lowest possible figure it is necessary that all of the economic factors entering into combustion reactions be given the most careful consideration and sound engineering principles applied to the installation, application, and operation of all fuel-burning equipment.

The conclusion drawn throughout the paper can be applied with only slight modifications to the combustion of pulverized fuel. Naturally the requirements for atomizing as with oil are present only to a small degree, but undoubtedly the practice is similar with both types of fuel.

No attempt has been made to cover oil-burning equipment as used in the firing of steam boilers and open-hearth, glass, or other regenerative or recuperative furnaces. Conditions of combustion

set up with the latter type of equipment vary so radically from those found in industrial-furnace application that the results given in this paper can in no way be applied. (*Proceedings of the Engineers' Society of Western Pennsylvania*, vol. 38, no. 6, July, 1922, pp. 201–221, 11 figs., *cpA*)

HANDLING AND CONVEYING (See Special Machinery)

HEATING (See Thermodynamics)

HEATING AND VENTILATION (See Power-Plant Engineering)

INTERNAL-COMBUSTION ENGINEERING (See also Motor-Car Engineering)

Research on Small Drilled Orifices, W. S. von Bernuth. Data of tests carried out at Purdue University with special reference to the extremely small holes needed in carburetors and vaporizing devices, including a description of the special apparatus designed for the testing.

It is stated that insufficient data are available on the performance of small orifices. When applied to carburetors it is found that the same-bore orifice would change the metering characteristics, depending on temperature of the fuel, design of the orifice with respect to its length of bore, area of approach, discharge, and various other factors.

The article is devoted mainly to a description of the experimental equipment and states that at the present time data are available on 56.5 Be. gasoline, 41.2 Be. kerosene, and distilled water. It also gives a chart showing actual discharge and effect of temperature on orifice discharge with gasoline, the orifice diameter being 0.030 in. and the thickness of orifice plate 0.5 in., with the discharge plotted against fuel temperature and head on orifice. (*The Automotive Manufacturer*, vol. 64, no. 8, Nov., 1922, pp. 7–8, 3 figs., *e*)

Farman Aviation Motor, 600-Hp. 18-Cylinder W-Type. In this motor the cylinders are 130 mm. (6.1 in.) bore by 180 mm. (7.1 in.) stroke, located in three rows 40 deg. apart. This angle of 40 deg. was determined with a view to having a steady torque, the motor giving 18 impulses in each two revolutions or 720 deg., which gives one power stroke for each 40 deg.

The crankshaft has six throws. The use of a W-type motor was considered to be of advantage as it reduces the size of the crankcase. The increase in the number of cylinders leading to a reduction of the unit cylinder volume permits of a higher compression without fear of self-ignition owing to heating of the center of the piston. The weight of the motor with its full equipment of ignition carburation pumps, etc., is only about 780 kg. (1716 lb.) for an effective horsepower of about 800 at 2200 r.p.m. (The nominal rating of the motor is 600 hp. at 715 r.p.m.)

The motor drives the propeller through a reducing gear weighing 45 kg. (99 lb.). In addition to this there is a 1200-watt generator with a wireless-telegraph alternator weighing 34 kg. (86 lb.), and the total weight of the motor with all accessories including propeller hub is 920 kg. (2025 lb.). The cylinders are grouped in pairs and the compression ratio is one to six.

The cylinders are made from forgings and welded together in pairs. Each pair has a common water jacket made of sheet steel and welded over the group. There are four valves per cylinder, these valves being made of high-nickel steel. Each valve has two concentric springs wound in opposite directions and each cylinder carries three spark-plug bosses, two side by side and the third 180 deg. therefrom; this third boss is intended for the insertion of starting devices, be they explosive cartridges or compressed-air plugs. The article describes in some detail the design of such parts as crankshaft, pistons, valve gear, ignition and lubrication. In connection with this latter it is of interest to note that the oil filters are so arranged that they can be inspected while the engine is running. A safety valve is provided on the oil circulation pump to open when the oil pressure becomes excessive. The purpose of this is to prevent the breaking of the oil radiator at starting in cold weather when the oil is very viscous. Four Zenith carburetors are provided, two with single outlets and two double ones, each outlet feeding three cylinders. The carburetors are fed by two A M fuel pumps connected in parallel to each pump, being, however, of sufficient capacity to supply fuel to all the four carburetors. There is a device for setting these pumps in operation automatically as soon as the electrical starter begins running, in addition to which the pumps may be also started by hand. As it would be impracticable to start a motor of this size by hand, an electric starter has been provided. (*L'Aéronautique*, vol. 4, no. 42, Nov., 1922, pp. 343–347, 8 figs., *dA*)

Small British Two-Stroke Cycle Marine Engine

Bruntons Two-Stroke Marine Engine. Description of an engine built by Bruntons, of Sudbury, England, in which some novel features are embodied. The cylinder diameters are $2\,^5/_8$ in. bore and the stroke is 3 in. On brake test 6 hp. was obtained when running at 1000 r.p.m. which was raised to 8 hp. at 1400 r.p.m. The engine is illustrated in Fig. 1. The pistons are of aluminum alloy and are provided with two cast-iron piston rings at the top and a third one at the bottom. The connecting rods are made of nickel-chrome steel and are fitted with phosphor-bronze bushes to receive the gudgeon pins, and with roller bearings at the big ends.

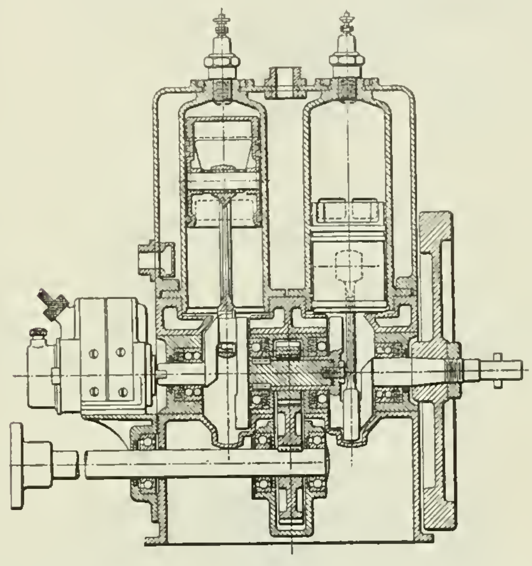

Fig. 1 Bruntons Two-Stroke-Cycle Small Marine Engine

A double-helical toothed wheel on the crankshaft, at about the center of its length, engages with another wheel on the lower shaft, for which a speed one-half of that of the crankshaft is obtained. The crankshaft runs in ball bearings. To prevent the air leakage that would otherwise take place an effective oil packing is arranged with the use of a phosphor-bronze casting with concentric grooves cut in it. The speed reduction gearing is kept completely isolated from the two separate crank chambers. A positive gear pump which is driven by a chain from the propeller shaft, is used to circulate the water required for cylinder cooling. Magneto ignition complete the equipment of what constitutes a complete power unit. The endeavor to produce a small two-stroke unit under conditions suitable for obtaining high efficiency and at the same time with a speed for the driving shaft which is suitable for the use of a reversible propeller, has engaged the attention of engineers for a considerable time, and this installation is not lacking in interest to all who have been faced by this problem. Among other engines described, particular attention is called to the Kelvin engine with single-sleeve valves built under the Burt-McCullum patents. The single sleeve has a motion which is a combination of a reciprocating vertical movement and a turning action upon the sleeve. Double inlet and exhaust ports register with ports leading through the cylinder walls, permitting entry and exhaust of the gases. (The Marine and Small Craft Exhibition. *Engineering*, vol. 114, no. 2969, Nov. 24, 1922, p. 645, 3 figs. Complete article p. 644–647, 10 figs. *d*)

MACHINE PARTS

Reversing Gear for Marine Turbine

Epicyclic Reversing Gear for Ljungström Marine Turbines. The interest in this transmission—which is not new in itself—lies in the fact that it is applied on a turbine-driven steamer of 2150 aggregate effective horsepower. The boat in question, the *Pacific*, which is owned in Denmark, is of 7400 tons dead weight, and is driven by a Ljungström steam turbine running at 3000 r.p.m. and designed to operate with steam supplied at a stop-valve pressure of 185 lb. per sq. in. and a temperature of 662 deg. fahr. The Ljungström turbine has two intermeshed rotors turning in opposite directions and it is always mounted on top of its condenser.

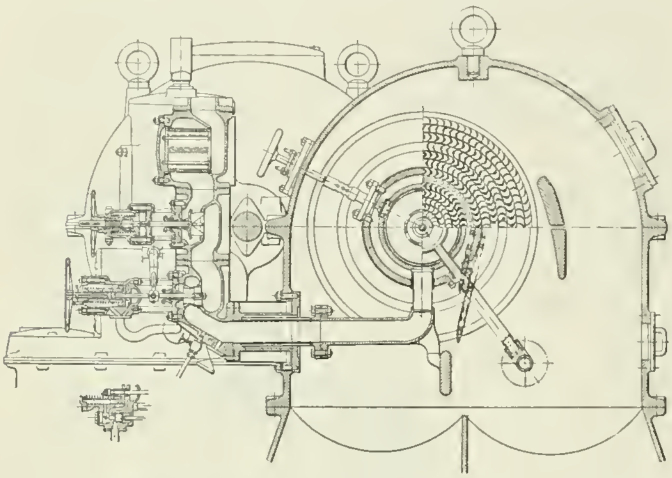

Fig. 2 General Arrangement of the Ljungström Epicyclic Reversing Gear for Marine Turbines

The general arrangement of the gearing is shown in Fig. 2, which represents diagrammatically a plan (partly in section) of the turbine first transmission shaft, reverse gear, the second reduction gear, and the thrust bearing. Each rotor shaft carries a pinion which drives a double-helical gear wheel on the first transmission shaft. As the two rotors turn in opposite direction an idler (not shown) is interposed between the rotor pinion and the gear wheel. In this first stage the speed is reduced from 3000 r.p.m. to 540 r.p.m., which is further reduced to 70 r.p.m. in the second reduction stage shown to the right of the reverse gear.

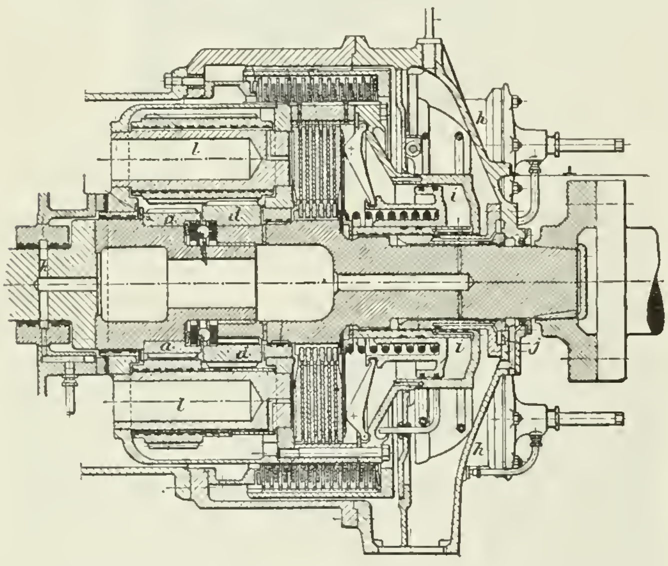

Fig. 3 Detailed View of Thrust Bearings and Lubrication in Ljungström Epicyclic Reversing Gear for Marine Turbines

The details of this reverse gear are illustrated in the original article, which also contains several diagrams together with a detailed description of the operation of the gear.

The oil for lubrication purposes enters at the port k, shown on the left, and as it escapes is collected in the fixed housing and conveyed away for filtration, after which it is again circulated through the system. The wheels a and d are clearly shown to the left of Fig. 3, and as will be seen, a ball thrust bearing is interposed between the opposing ends of the two shafts. This bearing has, it will be seen, an elastic seating on the left-hand side, which consists of a slightly dished steel ring similar to a component of a Belleville spring. Similar elastic cushions, it will be noted, are provided at each end of the outer multiple plate clutch. The planet pinions are mounted on hollow steel studs as shown at l, Fig. 3. They are themselves lined with white metal, and the bearing is supplied with oil under pressure through the ports shown to the right. Of each pair of pinions, one has teeth covering half its length only, as is best seen near the bottom of Fig. 3. This toothed portion gears with the wheel a and with its fellow-pinion which, as shown at the top of Fig. 3, has teeth extending over its full length and gears with the wheel d.

It will be seen that with this arrangement for reversing there is no necessity for stopping the turbine when maneuvring, and the gears are so well lubricated that even continuous slipping of the clutches causes little rise of temperature. Nevertheless provision is made by which in maneuvering the turbine speed is automatically reduced to 50 per cent of its normal value; the maneuvering wheel is fitted near the stop valve and is coupled up to the steam regulating valves so that during a change over the steam is partially shut off. A diagram showing the alterations in the turbine and propeller speeds during a change over shows that the maximum temperature rise did not exceed 20 deg. cent.

The T. S. *Pacific* has been twice to Australia, and has since returned to Denmark from a voyage to Honolulu. The reports from the owners are highly satisfactory. The total consumption of coal per day has been on an average 23 tons for all purposes with the turbines developing about 2300 i.hp., or 0.92 lb. of coal per i.hp. per hour. Average bunker coals were used, and the percentage of ash was on an average $16^1/_2$ per cent. When burning oil the consumption has been 16 tons per day.

A second vessel, the *T. S. Stal*, has also been fitted with a turbine of the same type developing 1350 i.hp. In this case the reverse gear is placed abaft the main-gear casing in order to increase its accessibility. (*Engineering*, vol. 114, no. 2971, Dec. 8, 1922, pp. 699–703, 24 figs., *dA*)

MACHINE SHOP

Hob Making and Special Cutter-Grinding Machinery

Simmons Method of Hob Making, Charles O. Herb. In the Simmons method a standard worm thread is first milled on the

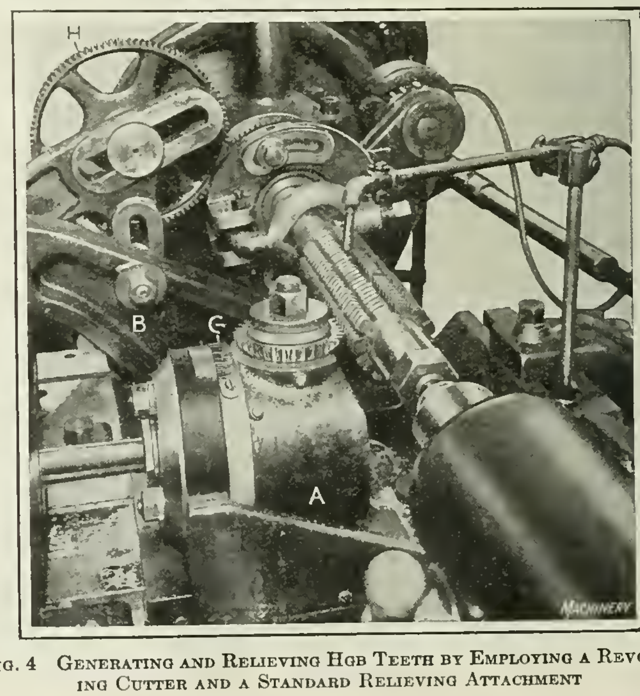

Fig. 4 Generating and Relieving Hob Teeth by Employing a Revolving Cutter and a Standard Relieving Attachment

hob in a thread-milling machine by means of a straight-sided formed milling cutter. After heat treating this preliminary thread is "generated" to the true tooth form in the relieving lathe by the action of a rotating cutter somewhat similar to that employed on the Fellows gear shaper. Because of the action of the cutter the teeth are of the true involute form and mesh with standard gears of the same diametral pitch. The front face of the cutter teeth has a rake of about five degrees.

The two operations of particular interest in this process are the relieving operation which is performed in a lathe which, in addition to the standard relieving attachment, is equipped with a special attachment mounted on the carriage, and the grinding of the cutter teeth done in a machine designed for this purpose. The special attachment used in performing the relieving operation (Fig. 4) consists essentially of a cutter head A mounted on a special cross-slide of the lathe and a unit attachment to the front of the carriage for transmitting the rotary motion to the cutter. Power is delivered to this unit by means of a gear on the headstock spindle directly in back of the faceplate which meshes with idler gear H on bracket B. This idler gear, in turn, drives a gear K on the forward end of the large screw C, which is also designated by the letter C in Fig. 5.

From this screw power is transmitted through worm wheel D and sliding shaft E. At the cutter-head end of the sliding shaft is an integral bevel gear which meshes with a second bevel gear on the lower end of cutter shaft F. By designing shaft E to slide through worm wheel D the cutter may be moved toward the work at the same time that the carriage is operated along the ways of the

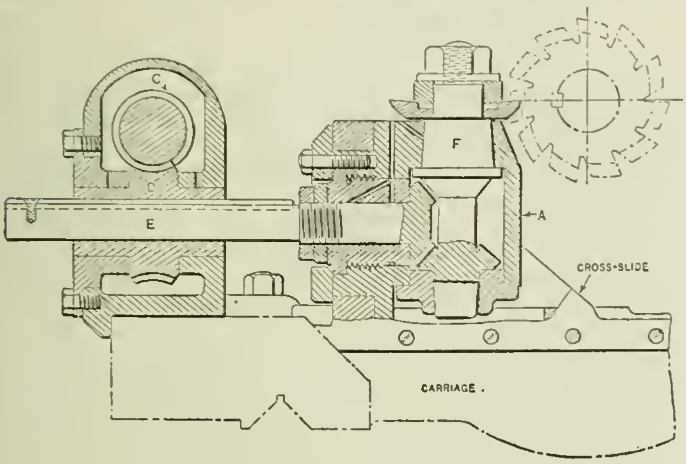

Fig. 5 Cross-Sectional View Through the Cutter Head and Driving Unit of the Special Generating Attachment

bed, either by hand or by means of the feeding mechanism. The gear at the end of screw C is chosen to suit the cutter and has two and one-half times as many teeth as are in the cutter.

After the cutter has been set properly relative to the hob teeth and gashes, and the dog on one end of the work arbor has been clamped to the faceplate to eliminate lost motion, if the cutter is moved away from the work, along the bed, and then forward toward the work again, its teeth will always properly engage the spaces between the hob teeth. This is certain, because the rotation of the cutter and the rotation of the hob are always correlated. When the carriage is moved along the bed, the cutter rotates faster than when the carriage is stationary, due to the rolling of worm wheel D on screw C.

The cutter for producing gear hobs is inclined so that as each tooth engages the work, the face is in a plane at right angles to the helix of the hob thread. The hob teeth are therefore "generated" rather than "formed." The cutters are made from forged disks. These disks are rough-drilled, rough-faced on both sides and rough-turned in a lathe, given an annealing and then permitted to season. The next step consists of finish-boring, finish-facing both sides, and finish-turning the peripheral surfaces to the required angles.

The cutter disks then undergo several machining and grinding operations, of which the most interesting is that of grinding the tooth profiles. For this purpose a special machine described in the original article is used. (*Machinery*, vol. 29, no. 4, Dec., 1922, pp. 255–260, 11 figs. *d*)

MARINE ENGINEERING (See also Machine Parts)

Discarding Geared Turbines. It is stated that several ship owners are removing geared turbines and replacing them by reciprocating engines. Two American-built steamers, the *Wildomina* and *Sylvia Victoria*, which were fitted with geared-turbine machinery are in the hands of a Clyde firm which is substituting for it ordinary triple-expansion reciprocating engines. Other ship owners are said to be showing a disposition to revert to reciprocating engines for their new vessels. The 11,300-ton steamer *Port Hardy*, for the Commonwealth and Dominion Line, recently launched, is to be fitted with twin-screw triple-expansion machinery developing 4500 i.hp. It is said that the *Port Hardy* had really been designed for geared turbines, but there had been a great deal of trouble with the double-reduction-geared turbines and as the line already had seven vessels with turbines they preferred not to continue with that type of engine until they had gained a little more experience. Quite possibly they would return to that type at a later date. The last ship, the *Port Hunter*, had run trials on turbine engines which had proved to be among the smoothest they had giving great hopes for the future. (*Practical Engineer*, vol. 66, no. 1866, Nov. 30, 1922, p. 344, *g*)

METALLURGY

New Type of Open-Hearth Furnace. Description of the Loftus furnace, a producer-gas furnace wherein the producer gas is discharged from a restricted nozzle into a mixing chamber serving to induce the necessary air for combustion. A booster supply of regenerated air is withdrawn from the regenerative chamber, passed through a special chamber driven by a variable-speed motor and introduced into the center of the stream of gas in the direction of its flow through the furnace. The pressure and volume of this booster supply of regenerated air may be governed by the control of the variable-speed motor, in this way giving the operator control over the flame. With such a furnace construction more efficient combustion is obtained, as shown by the actual operation through the mixing of the air with the gas in the hot mixing chamber. The air and gas enter an extremely hot mixing chamber in the form of an outer envelope of air completely surrounding an annular ring of gas containing an inner core of air which is calculated to produce an extremely intimate mixture. This mixture is discharged from the mixing chamber in the form of a flame having practically no stratification and with the utmost compactness and continuity of construction. The operator can control the flame by regulating the pressure and flame of the booster supply of regenerated air. If he wishes he may melt down a charge with a short hot flame and refine with a long mellow flame which completely covers the bath without extending through the outgoing channels.

The original article describes and illustrates the furnace in some detail. Such a furnace has been operating on producer gas at the Ohio Works of the Sharon Steel Hook Co., Lowellville, Ohio, since June 8, 1922. While the charging conditions were not ideal the furnace is said to have produced an average of approximately 30 per cent more steel than the other furnaces in the plant on approximately 30 per cent less coal per ton of ingots. The furnace, up to December, 1922, has given more than 300 heats and from all indications it is believed it will run about 400 heats or more, making an increase of about 50 per cent in its usual life. The repairs have been almost negligible as it has been possible to get almost 100 heats from back and front walls and approximately 80 heats off the gooseneck. (*The Iron Age*, vol. 110, no. 26, Dec. 28, 1922, pp. 1677–1679, 5 figs., *d*)

Ingot Corner Segregation in a Nickel-Chrome Steel, T. Henry Turner. In investigating by means of sulphur prints an octagonal chrome-nickel steel forging the author discovered the presence of planes of segregation. Such planes were found at the angular portions of the ingot and represent the meeting of crystals which have grown from the cooling faces into the still liquid metal. The author believes that such forgings should be rejected even though the mass of the material may possess good chemical and mechanical properties, as the defects, consisting in planes of segregation, entirely negative these good properties and make the forging as a whole treacherous and unreliable in the extreme.

The author makes the following recommendations:

1 That the bell-shaped cylinder design should never be used unless the supplier can guarantee—

a Absence of planes of segregation in the material

b Adequate working during the forging operations.

2 That in cases where the supplier cannot guarantee adequate working of the material during forging (owing to the nature of the design and the limitations imposed upon his work by the nature of his available tools), a composite ring made up of two or more rings, which can be manufactured by a satisfactory forging or rolling, would probably prove more reliable.

3 That the final rolling of such rings is to be preferred to forging them throughout, in that it would tend to produce greater uniformity of dimensions in the rough, and therefore economy in machining. Also it should produce a better and more uniform internal structure and greater uniformity of mechanical properties.

4 That in the case of all large forgings which will be subjected to appreciable circumferential loading, the supplier should be asked to face up both ends of the block of steel before forging is commenced. Sulphur prints should then be taken and forging only proceeded with after these have been passed as satisfactory. Such an operation would, of course, be costly, but it would only be advisable when appreciable hoop stresses are expected.

5 That in cases where the steel maker considers recommendation No. 4 impracticable, the elimination of ingot corner segregation may be achieved by forging down octagonally and machining off the corners which would still contain the segregation. This suggestion is perhaps the most useful and that most likely of successful adoption.

6 That the centrifugal casting of steel for such large cylinders or rings, and even for large turbo-generators rotors, is feasible and worthy of serious consideration. (*Engineering*, vol. 114, no. 2969, Nov. 24, 1922, pp. 662–664, 9 figs. Compare also abstract in *Iron Trade Review*, vol. 71, no. 25, Dec. 21, 1922, pp. 1695–1700, 5 figs. *dA*)

MOTOR-CAR ENGINEERING

Chevrolet Copper-Cooled Car, J. Edward Schipper. Description of an air-cooled car the particular feature of which is that it employs copper fins electrically welded to cast-iron cylinders.

To manufacture the copper-cooled engine it has been necessary to develop machinery to form the copper ribs, and apparatus to handle commercially the electric welding of the formed ribs to the cylinders. The copper fins are made in a special machine which takes the sheet copper and forms it into the proper shape, reducing the depth of the fins or loops at points where clearance for the valve push rods and adjacent cylinders is required. The copper is so formed that the loops are closed at points adjacent to the cylinder barrel, and in such a way that a continuous band of copper is in contact with the outer wall of the cylinder, which latter is machined both inside and out.

The cylinders are manufactured singly but are assembled in pairs. Between the cylinders in each pair, which are closely adjacent to one another, the fins are graduated in size so that there is no interference.

The cooling is by air forced through and around the fins and over the cylinder heads by a centrifugal blower made largely from sheet aluminum alloy. This blower is in front of the engine and is driven by a special form of V-belt from a pulley on the crankshaft. Air enters at the bottom of the fins around the cylinders. A light steel stamping forms a tubular draft tube which fits closely around the cylinders so that air can enter the fan only by passing upward through and around the copper fins and through the space above the cylinders. The V-belt employed has a woven-cord construction on its neutral axis and a durable elastic material on either side of the neutral axis permitting of the flexing necessary for the drive. The drive for the fan is triangular, the belt passing around the crankshaft fan and generator pulleys. Adjustment for the tension of the belt is secured by swinging the generator, which is mounted on the left side of the engine. The engine, it may be noted, is the first "square" one to be placed on the market for some time, both bore and stroke being $3^1/_2$ in. With a compression ratio of four to one it develops a maximum brake horsepower of 22 at 750 r.p.m. (*Automotive Industries*, vol. 47, no. 26, Dec. 28, 1922, pp. 1259–1265, illustrated, *d*)

PHYSICS

Temperatures at Which Physical Changes Occur, Henry D. Hibbard, Mem. Am.Soc.M.E. A list of some of the temperatures relating in one way or another to the production and heat treatment of steel and to the fusibility of steel and of its components. Of these the following, all belonging to the higher ranges, are of interest:

Degrees Temperature Cent.	Fahr.		Degrees Temperature Cent.	Fahr.	
1750	3182	Pure silica melts	2220	4028	Carborundum decomposes without melting
1755	3191	Platinum melts	2450	4442	Iron boils
1795	3263	Titanium melts	2500	4532	Zirconium oxide melts
1820	3308	Bauxite melts	2550	4622	Molybdenum melts
1900	3452	Manganese boils	2572	4662	Lime (CaO) melts
2050	3722	Chromite bricks melt	2750	4982	Vanadium carbide melts
		Pure alumina melts	2800	5072	Magnesia (MgO) melts
2059	3738	Chromic oxide (Cr_2O_3) melts	3176	5750	Tungsten melts
2165	3929	Magnesia brick belts	3600	6512	Molybdenum boils
2180	3956	Chromite melts	3700	6692	Carbon is vaporized
2200	3992	Chromium boils	5200	9392	Tungsten is vaporized
		Silicon boils			
		Aluminum boils			
		Graphite made from amorphous carbon (2200 to 2400 deg.)			

An interesting discussion is also submitted as to the proper definition of the melting point of a substance and the temperatures near the melting point which bear some relation to it. Some of these are practically useful and some have only a scientific value. These are:

1 The temperature at which the substance sinters, as a clay. This is useful. It is below the fusion point, No. 4.

2 The highest temperature at which a vessel made of the substance can be used. Instance a porcelain crucible. This is useful. It is lower than No. 1.

3 The temperature at which it softens in any degree which, as in a firebrick, limits its usefulness. This is useful. It is lower than the fusion point, No. 4.

4 The temperature at which its edges are rounded. This is often called the fusion point and is generally the one given in the table. It has only a scientific value.

5 The temperature at which it becomes fluid. Instance a slag. This is interesting, but taken alone is not useful. It is above No. 4.

6 The lowest temperature at which it may be handled molten in practice, as a slag or metal in a metallurgical operation. This is useful. The temperature may be 50 or 100 deg. cent. (90 to 180 deg. fahr.) above No. 5 as the substance leaves the furnace (*The Iron Age*, vol. 110, no. 23, Dec. 7, 1922, pp. 1492–1493, *g*)

POWER-PLANT ENGINEERING (See also Engineering Materials; Fuels and Firing)

Boiler-Tube Failures

Boiler-Tube Failures, Haylett O'Neil. The author claims that in a modern boiler plant, well designed and well operated, that is, where the boiler is clean and proper internal circulation is maintained, boiler-tube failures are infrequent. There may occur, however, conditions under which boiler tubes fail, and he describes one such case which gave considerable trouble.

In general, boiler tubes may fail where there is a condition producing sufficient unevenness of temperature to cause rates of expansion in adjacent parts of a tube varied enough to strain the metal. In a case described by the author it was found that little trouble was experienced from boiler-tube failures in the spring and summer, but the tubes would fail rapidly in the late fall and winter. An investigation showed that excessive scale was deposited from water during these two latter periods, no water softening being used. Furthermore, during the dry season feedwater was drawn

from a spring in which the water was charged heavily with bicarbonate of lime. Careful records presented in the form of curves in the original article show a clear relation between the use of spring water and tube failure. Scale deposited on the tubes would give a uniform heat insulation, therefore, blisters would not occur, but the tubes cracked square off at the front end in nearly all cases.

In the ordinary vertically baffled boiler the author has noticed that under similar scale conditions the tube generally bows down. This indicates that the under side of the tube has been heated hotter than the upper, which is reasonable with this arrangement of baffling, and hence has bulged toward the fire.

In a clean boiler the temperature of the metal is practically equal to that of the adjacent water, but scale insulates the metal of the tube from the water. In that case the hotter the gas is the hotter will be the metal, irrespective of the water temperature. How, then, does the top of the tube get hotter than the bottom? The answer in one case proved to be that the T-tile kept the top of the tube hot during both normal operation and part of the cleaning periods. The temperature of this tile according to the pyrometer was close to 2500 deg. fahr. The lower part of the tube was surrounded by furnace gas which fluctuated between 2500 deg. during firing conditions and about 1200 deg. during cleaning periods. Inasmuch as during a cleaning period the front doors had to be open, temperature variations could not be eliminated.

On account of the heat conductivity of the iron it would naturally be impossible to maintain for any considerable time a temperature difference between the top and bottom of the tube, but calculations have been made by the author indicating that only a few hundred degrees difference is required to curve an 18-ft. tube as much as 3 in. out of line. Such a temperature difference seems to be entirely feasible.

What actually happened is this: At first a tube would be humped upward slightly during a cleaning period and restraightened afterward as soon as the bottom could be expanded under the influence of the furnace temperature. Every time cleaning or banking took place the expansion and contraction cycle was repeated. Therefore the tube was subjected to repeated bending upward and downward several times a day. The strains were concentrated at the tube sheet, where finally the tube became brittle and lost its tensile strength. Finally, the tube would be strained beyond its elastic limit and take on a permanent set. When the boiler was cooled for cleaning the temperature was reduced nearly to room temperature, causing extreme tension in the tube due to contraction, and the tube would break.

The final solution of the trouble came in the regular adding to the boiler water of an internal treatment, the base of which was caustic soda. A given quantity of this was pumped into each boiler at regular intervals, and twice each week boiler waters were titrated for soda concentration. By keeping the soda concentration under 40 grains per gallon, excellent results were obtained. After a run of from 60 to 90 days on spring water only a thin film of scale was formed, and there was no foaming. The T-tile were finally replaced entirely.

Actual records of tube replacements have shown that this manner of handling the trouble was correct, and certainly no steam-power plant is even approximately safe unless the boilers are kept clean religiously. (*Power*, vol. 56, no. 23, Dec. 5, 1922, pp. 876–878, 7 figs. *pe*)

Tests of a Magazine-Feed Boiler with Special Method of Supplying Secondary Air, John Blizard, J. Neil, and A. Pincus. Data of steaming tests carried out by the Fuel Section of the U. S. Bureau of Mines at the request of the American Society of Heating and Ventilating Engineers on a magazine-feed boiler provided with special method of supplying secondary air to determine its thermal efficiency and other important factors when fired with various fuels.

It was also found that coke, anthracite, lignite char, and various bituminous coals could be burned with little poking and other attention to the fuel on the grate or in the magazine except when cleaning the fire or charging fuel, but that caking Pittsburgh coal was unsuited to this boiler since it had to be poked frequently to break up an arch which formed near the top of the grate.

The outstanding results of the tests were: That the method of admitting secondary air supply over the fuel bed permitted the combustible gases rising from the coke fuel bed to be burned so that only 29 to 58 per cent excess air remained after combustion, those from anthracite with only 35 to 62 per cent excess air, those from Illinois coal with 61 per cent excess air, and those from Colorado coal with only 23 per cent excess air. With all of these fuels the carbon monoxide left in the gas represented only about 1 per cent or less of the heat of the fuel. Therefore, for these fuels the methods of admitting secondary air was good. On the other hand, the carbon monoxide remaining in the gas when burning Pittsburgh coal with 35 per cent excess air represented 7 per cent of the heat energy of the coal, and the unscreened lignite char was burned with 221 per cent excess air, which was reduced in the trial with the screened char to 94 per cent.

The thermal efficiency with coke was highest when operating at about 90 per cent of the maker's rating; at this rating the efficiency was 76 per cent, and dropped to 67 per cent and 70 per cent when operating at 123 and 35 per cent rating, respectively.

Data have also been obtained for other kinds of coal, such as stove and chestnut-size anthracite, briquets, and Pittsburgh coal.

An interesting series of supplementary investigations were also carried on and temperatures above the fuel bed and in one of the central flues were measured; likewise temperatures in the flues of the first and second pass.

Among other things, it would appear that at the highest rate of steaming and the lowest rate but one, the furnace temperatures with coke and anthracite are approximately the same, while at the highest rate but one the temperature was higher with anthracite than with coke by 150 deg. fahr. and at the lowest rating the anthracite furnace temperature was 350 deg. fahr. lower.

Data for other temperatures are given in the original article. (*Journal of American Society of Heating and Ventilating Engineers*, vol. 28, no. 9, Dec., 1922, pp. 833–842, 5 figs., *e*)

Electric Drive in a Sugar-Manufacturing Plant, Roger B. Stevens. Description of the layout of electrical equipment of the recently completed Baltimore plant of the American Sugar Refining Co., the particular feature of which is that practically the entire drive is effected by means of direct-current motors.

There were several conditions which decided in favor of direct current. In the first place the sugar refinery consists of a number of closely grouped buildings with the transmitting distances short and the loads closely concentrated, which make transmission losses small. Furthermore, the conditions of sugar-refinery work are somewhat peculiar. The process from start to finish is continuous. Moreover, the materials are carried at a fairly high temperature and even a small delay leading to loss of heat produces stiffening of the material. Because of this the power required to start a given machine may be from five to ten times that required for operation after the running condition has been established. Nearly all of the refining processes are interdependent and continuous, so that unless large and expensive storage facilities between the various stages are available the several elements of machinery must be capable of close adjustment in speed. Furthermore, in the case of more than 80 per cent of the total horsepower required, either a speed adjustment was absolutely necessary or a very distinct advantage was to be gained by providing such adjustment.

In alternating-current machinery only the slip-ring motor with resistance is capable of an extensive range of speed variation, but it is then only the equivalent of a series-wound direct-current motor and has the disadvantages of moving contacts and vulnerable brush rings. The direct-current motor, on the contrary, is capable of good starting torque and adjustable speed, though it is slightly higher in the first cost. Furthermore, with the close grouping of the loads the comparatively low (230) voltage of the direct-current made the total cost of the distributing system lower than would have been the case with alternating current. This is principally because a large number of motors could be grouped on single feeders to take advantage of the low diversity factor thus obtainable.

The article describes in detail the installations used and the electrical distribution system. (Factors in Industrial Plant Distribution. *Electrical World*, vol. 80, no. 24, Dec. 9, 1922, pp. 1259–1262, 5 figs., *d*. Compare also editorial entitled, An Unusual Case in Industrial Power Design, same issue, p. 1254)

Exploding an Old-Time Boiler Fallacy, W. B. Roberts. Data of tests to show the fallacy of the belief that cold water sprayed upon a red-hot boiler plate instantly generates an uncontrollable volume of steam.

The article is based on tests carried out under the auspices of the Manchester Steam Users' Association on an ordinary Lancashire boiler 7 ft. 0 in. diameter and 27 ft. 9 in. long, shell plates $^7/_{16}$ in. thick and head plates $^9/_{16}$ in. thick. A number of precautions were taken to protect observers from the consequences of the expected explosion and, at the same time, permit them to take the necessary observations. The tests were carried out in such a manner that at 6.30 p.m. there was 25 lb. of steam pressure showing and the safety valves began to blow. At the same time the blow-off top was opened full bore, there being $9^1/_2$ in. of water covering the crown of the furnaces. Within about an hour the level of water was brought to $3\,^5/_8$ in. below the crown of the furnace, this latter laying bare and exposing a strip of plating 21 in. wide at a temperature of about 700 deg. fahr. with a pressure of $28^1/_2$ lb. on boiler, and the safety valve blowing freely. The feedwater having a temperature of 60 deg. fahr. was then turned on, sprayed directly on the red-hot plates with a rate of injection a little more than $4^1/_2$ cu. ft. per min. Showering the feedwater at a temperature of 60 deg. fahr. on a red-hot furnace crown was not attended by an increase of pressure. On the contrary, the pressure at once began to fall and in $2^1/_2$ min. had fallen from $28^1/_2$ lb. to 26 lb.

Upon looking into the furnaces the ring seams of the furnace tubes were found to be leaking freely. The overlaps of the first seven ring seams in each furnace were sprung at the crown, but the shape of the furnace tubes was practically unaltered except that the right-hand tube was slightly bulged in three places.

Other slight consequences of overheating were observable. The main thing, however, which the tests have shown is that spraying fairly cold water on red-hot plates and furnaces did not lead to the ripping of the plates circumferentially or longitudinally, and did not cause any increase of pressure due to a violent and sudden generation of steam. (*Power House*, vol. 15, no. 24, Dec. 20, 1922, pp. 19–21, 5 figs., *eA*)

Discussion of Vapor Refrigerating Condensers for Steam Turbines, F. C. Evans. One of the means of bettering the economy of the steam turbine is to reduce the back pressure. At the present time the back pressure employed is limited to around 1 in. of mercury absolute, corresponding to a temperature of the exhaust steam of about 79 deg. fahr. This limit has been reached with water as the condensing medium, and the author questions whether better results could not be obtained by substituting the cooling coils of a refrigerating system for the condensing-water tubes of the ordinary surface condenser, so as to reduce the temperature of the exhaust steam to about 35 deg. fahr.

For purposes of discussion the author considers a plant where steam is available from the boilers at 200 lb. per sq. in. absolute pressure and 200 deg. superheat, and ample condensing water at a temperature of 60 deg. fahr. but which must be raised 20 ft. He shows that under these conditions the available energy in the steam is 413 B.t.u. per lb. of steam less 1.5 B.t.u. required to handle the water, which gives a net energy for sale of 411.5 B.t.u. per lb. of steam.

When a vapor refrigerating condenser has been substituted for a water condenser, the available energy in the steam operating with the back pressure of 0.205 in. is 486 B.t.u. per lb. But the author shows that the refrigerating system consumes 90 B.t.u., thus giving as a final result 396 B.t.u. of energy available for sale per pound of steam, which is less than when a water condenser is used.

As a result of this analysis it appears that at the present time steps o increase the economy of the steam turbine must be taken in another direction. What this direction may be one cannot say, but it seems impossible to reduce the back pressure of the turbine economically by the use of a vapor refrigerating condenser. (*The Sibley Journal of Engineering*, vol. 36, no. 9, Dec., 1922, pp. 175–177 and 187, 3 figs., *tg*)

Steam and Steam Boilers

Steam and Steam Boilers. An editorial based on Mr. C. E. Stromeyer's report to the Manchester Steam Users' Association.

Among other things the report includes a partial description of some interesting experiments on the strength of very old boilers. Of these one was obtained from Messrs. Pilkington and had been constructed some sixty years ago. The other, supplied by the Metropolitan Water Board, was of somewhat similar date. The experiments are still incomplete, but they indicate pretty conclusively that the material of the shell plates has not deteriorated with time, and that injuries and cracks caused by the punching of the plates had not apparently extended during the very long life of the boilers. Specimens of the material tested showed somewhat erratic results, but it is probable that this was characteristic of the iron made at the period in question. The range of tensile strength was from 17 tons to 25 tons per sq. in. In many of the seams, cracks due to punching extended over several rivet holes, but these do not appear to have had any worse effect than that of reducing the net section of the metal. These observations seem to indicate that factors of safety might reasonably be reduced now in view of the uniformity of the material supplied, the great care exercised in its manufacture and the prevalent practice of drilling all rivet holes.

During a hydraulic test one of the boiler shells "barreled" as first described by Mr. J. C. Spence in a paper read before the North-East Coast Institution of Engineers and Shipbuilders in 1891. On making measurements on a model boiler tested to destruction Mr. Spence found that the shell stretched less at mid-length than it did at a certain short distance from the end plates. The observation was novel at the time, and the curious bulges in question received the name of "Spence humps."

Mr. Stromeyer states that it has generally been thought that the effect of the end plates was to relieve the circumferential stress. This may well be true, but there is no excuse for such misunderstanding for, in the discussion of Mr. Spence's experiments, which appeared in *Engineering*, Apr. 27, 1891, p. 468, it was shown that save in the case of extremely short boilers the effect of the ends was to cause a local increase of the circumferential stress. This was very clearly brought out in Mr. Spence's experiments, and was fully confirmed by the mathematical theory developed in a paper by Mr. (afterwards Professor) J. T. Nicolson, read at the same time as that of Mr. Spence. The subject was very fully discussed in *Engineering*, both editorially and in its correspondence columns, and that the other view should, as Mr. Stromeyer states, still be prevalent is not creditable to boiler designers and constructors.

In another section of his report, Mr. Stromeyer suggests that very slow alternations of stress are more serious than rapid ones. It appears quite possible that in the case of exceedingly rapid repetitions of stress the metal may fail to take the full deformation theoretically due to the load, since, with all materials, when a load is first applied the full strain is not simultaneously achieved. There is always some "after creep" and it is thus quite possible that the metal is less severely tried by very rapidly alternating stresses than by slowly applied ones. The general view has, however, been that at any ordinary rates of alteration the fatigue limit of our structural materials is independent of the rate of repetition. Mr. Stromeyer's view is, however, that the very slow rate of changes of stress to which a boiler is subjected, makes these much more injurious than if the variations were more rapid. This is contrary to the common belief and does not seem altogether consistent with the fact that slightly overstrained metal in time recovers its elastic properties. In support of his theory, Mr. Stromeyer instances the grooving found at the roots of the flanges of dished ends, but grooving is only indirectly connected with the stress on the metal as it is primarily an oxidation process, facilitated by the differences of E.M.F. which arise between strained and unstrained metal. It seems to us questionable, therefore, whether fatigue in the usual understanding of the term is involved in the matter any more than it was in the extraordinary failures of the high-tension bronzes adopted for the Catskill aqueduct. (*Engineering*, vol. 114, no. 2973, Dec. 22, 1922, pp. 775–776, *g*)

RAILWAY ENGINEERING (See also Engineering Materials)

Recent Tendencies in British Locomotive Practice. E. C. Poultney. Beginning of a series in which it is proposed to describe a number of typical recent locomotives built for service

on British railways which indicate the tendencies of modern practice.

Perhaps one of the most striking features is the use made of either three or four cylinders, with the three-cylinder arrangement rapidly gaining favor. (The ordinary British type of locomotive has two inside cylinders.)

Steam pressures have undergone some changes during recent years. Previous to the general introduction of flue-tube superheaters, boiler pressures ranged from about 170 to 200 lb. With the advent of superheating there was a general tendency to reduce pressures to about 160 lb. and increase the cylinder volume. The practice is now toward the higher pressures, and those of 180 to 200 lb. are considered necessary, while cylinder volumes are continually increased to furnish the necessary power; in fact, it is largely the greater cylinder capacity now required that has prompted the introduction of three- and four-cylinder locomotives.

Locomotives now built for main-line working are practically all fitted with flue-tube superheaters, and older engines when requiring extensive repairs and renewals, or to be rebuilt, are as a rule superheated; and when this course is adopted it is usual to fit new cylinders with piston valves. While the type of superheater used is in all instances the same, there are in some cases considerable differences in details. This applies more especially to the design of the headers.

Damper gear has been discarded now by all railways. Automatic air valves are quite often fitted to the steam chests and sometimes on the header (the wet-steam side). Cylinder by-pass valves are not generally used, neither are pyrometers.

From this the author proceeds to describe some of the new locomotives, and in connection with the Great Central 4–6–0 type describes and illustrates the Robinson piston and pressure-relief valve.

An interesting fitting used on the Great Central is what is called an Intensifore lubricator which works in much the same manner as a hydraulic intensifier. Briefly, the arrangement consists of a container filled with oil upon which pressure is applied by means of steam acting as a plunger. Oil is led from the lubricator by suitable piping to distributors mounted on the footplate, usually on the back head of the boiler. The distributors consist of sight-feed glasses fitted with suitable controls, from which the oil is led to the valves, pistons, and also to the driving boxes.

The three-cylinder fast freight engines of the North Eastern are next described and in this connection data are given of some trials made with a 0–8–0 type engine.

The Caledonian locomotive is one of the most powerful 4–6–0 type built for express passenger service. The engine has three cylinders which are all in line and drive on separate axles. The center cylinder drives the leading wheels through a crank axle, and those outside the center coupled wheels through connecting rods 11 ft. long as against 6 ft. 6 in. long for the inside rod.

Several other types are described, among them being a three-cylinder type built for the Great Northern. Here all three cylinders drive on to the center axle and a peculiar valve gear is employed, the valves being of the piston type. There are three of them with inside admission which are operated by two sets of Walschaerts gear applied to the outside motion. (First of a series. *Railway Mechanical Engineer*, vol. 96, no. 12, Dec., 1922, pp. 677–682, 7 figs., *d*)

Effect on Ton-Mile Cost of Reducing Train Loads. Data of tests carried out for the U. S. Railroad Administration on the Illinois Central, from which it would appear that the greatest economy is obtained with full-tonnage freight trains.

The original article describes the method employed in carrying out the tests and gives in tabular form some of the results obtained. Because of lack of space only some of the conclusions can be reported here, as follows:

1 There is no general agreement as to the percentage of tonnage rating which will bring the lowest cost. In the majority of cases this is effected by a load of 100 per cent, but in others the most economical load (considering the cost in one direction only) is about 85 per cent. Each division is governed by its own operating characteristics and no general law appears in the results obtained in this study.

2 The cost per ton-mile decreases as the gross carload increases, due probably to the lower train resistance per gross ton.

3 The cost per ton-mile increased with the delay on the road.

The practical application to that road of the facts developed by the tests is summarized by the following general conclusions in the report of the Federal manager of the Illinois Central:

1 It is not practicable to reduce the train load to avoid overtime because of the increased cost incident to the operation of the necessary additional trains in the direction of heavy traffic to handle the same tonnage and in the direction of light traffic to balance power.

2 To a large extent the cost of handling the most economical train load includes considerable overtime.

3 Increased cost resulting from overtime, like any other wage increase, must be met by increasing facilities instead of by reducing train load. This reduction, in a good many districts, would add train units in excess of present capacity. (*Railway Age*, vol. 73, no. 25, Dec. 16, 1922, pp. 1145–1148, *ep*)

Zeitler Self-Contained Gasoline Motor Truck for Railway-Car Bodies. In this car the truck conforms to a standard railway truck, the frames being cast steel and the engine crankcase forming the hollow bolster. The transmission is hung directly beneath the engine and forms almost an integral part of it. The engine is a four- or six-cylinder horizontal or forced type. The pistons are of the truck types carried in sleeves that act as crossheads and take the wear off the cylinder walls.

The control system is of the electropneumatic type. A small master controller located in the engineer's cab controls the electric starting motor and the carburetor, this latter being governed by a variable-speed electric motor operating the governor attached to the butterfly valve. An electropneumatic arrangement operated also the gear shift.

An interesting feature of the design is the support of the crankcase bolster. This crankcase bolster is spring-supported, a bracket at the ends being extended to a suspension link to permit lateral motion. This suspension link is attached to the frame and at a point on the frame which results in low stresses at the center of the side frame. The springs rest directly on the journal boxes with the ends attached to the side frames, thus giving the crankcase bolster both lateral and vertical movement. The center tie bars between the side frames are bolted in place and therefore can be removed readily. Then by disconnecting the suspension links at the frames, the drive shafts and control connections, the engine and transmission may be removed from the truck for overhauling. (*Railway Review*, vol. 71, no. 25, Dec. 16, 1922, pp. 852–854, 2 figs., *d*)

REFRIGERATION (See also Thermodynamics)

Tests on Ammonia Compressor and Tubular Condensers

Performance of Single-Acting Ammonia Compressor and Tubular Condensers, Geo. A. Horne, Mem. Am.Soc.M.E. Data of tests made in the Tenth Ave. plant of the Merchants Refrigerating Co., New York City. The machine on which the tests were made is a vertical, three-cylinder, single-acting, simple compressor of the enclosed type with pistons 18 in. in diameter and a 20-in. stroke. The machine is direct-connected to a synchronous motor and is operated at 164 r.p.m. The condensers are shell and tube, open type, with water pumped over the top and flowing by gravity through the tubes into an open pan. The condensed liquid is cooled in a double-pipe liquid cooler, from which it passes to a shell and tube brine cooler.

The article describes the equipment used in these tests which appears to be unusually complete for a commercial test. Ammonia was measured by a carefully calibrated meter, which is superior to any method of simply weighing or gaging the liquid during the test.

In view of the fact that the liquid is frequently cooled below the temperature corresponding to the boiling point at the condenser pressure, an interesting chart (Fig. 6) has been arranged so that the percentage of indicated horsepower per ton saved by liquid intercooling may be read directly without detailed calculation.

The chart is subdivided into three parts: (1) the upper left-hand corner gives the relation between condenser pressure, liquid cooling range and B.t.u. removed by water per pound of liquid ammonia;

(2) the lower right-hand corner gives the relation between condenser pressure, suction pressure, and B.t.u. available per pound of ammonia with no liquid cooling; (3) the upper right-hand corner gives the relation between available B.t.u. per lb. of ammonia with no liquid cooling, B.t.u. removed by water per pound of liquid ammonia and percentage of saving in horsepower effected by the liquid forecooling.

The following examples will show how the chart is used:

1 Given: Condenser pressure 190 lb. per sq. in. abs.; suction pressure 20 lb. per sq. in., abs. Find: Available B.t.u. per lb. of ammonia, without any liquid cooling.

Use the lower right-hand section of chart. Enter the right-hand vertical scale at 190 lb. (see dotted line on chart), move horizontally to the right to the 20-lb. suction line; then move vertically down and read 458 B.t.u. on the lower horizontal scale.

2 Given: Condenser pressure 190 lb. per sq. in., abs.; liquid forecooled 20 deg. fahr. (i.e., from 93.1 to 73.1 deg. fahr.) Find: B.t.u. removed by water per lb. of ammonia.

Use the upper left-hand section of chart. Enter the horizontal scale at 190 lb., move vertically up to the 20-deg. line, then move horizontally to the left and read 23 B.t.u. on the vertical scale.

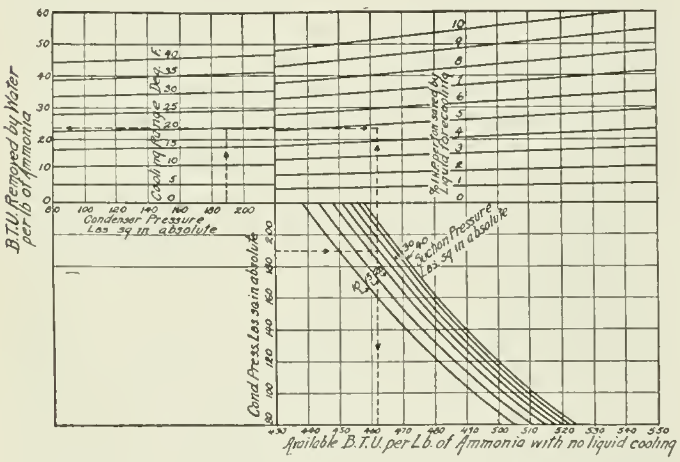

Fig. 6 Theoretical Compression of Ammonia (Simple Compression with Liquid Forecooling)

3 Given: Condenser pressure 190 lb. per sq. in., abs., suction pressure 20 lb. per sq. in., abs.; liquid forecooling range 20 deg. fahr. Find: The i.hp. per ton.

In the lower right-hand section of chart enter the vertical scale at 190 lb.; move horizontally to the right to the 20-lb. suction line, move vertically up; hold this vertical line. In the upper left-hand section of the chart enter the horizontal scale at 190 lb.; move vertically up to the 20-deg. line and then move horizontally to the right until the vertical line previously obtained from the other section of the chart is intersected. At the intersection read 4.8 per cent saving effected by liquid forecooling. From the i.hp. chart we find that the i.hp. per ton for 190 lb. condenser pressure and 20 lb. suction pressure but without liquid cooling is 1.525. Then the i.hp. per ton for the same conditions but with liquid cooling is $1.525 (1 - 0.048)$ or $1.525 \times 0.952 = 1.452$.

It should also be mentioned that the theoretical i.hp. as calculated does not include any saving due to water-jacketed cylinders. The machine which was used in these tests was provided with water jackets, which naturally increases the volumetric efficiency and decreases the horsepower per ton. The effect of the jacket water may be calculated from the data as shown for the various tests.

The table in the original article gives a summary of the condenser performance in these tests, of interest because of the high rate of heat transfer obtained with these condensers. (*Refrigerating Engineering*, vol. 9, no. 5, Nov., 1922, pp. 143–151 and 161, 11 figs., *eA*)

SPECIAL PROCESSES

Mauclere System of Pneumatic Handling of Inflammable Liquids. The apparatus is designed primarily for handling kerosene and other inflammable or toxic liquids. It may be used for any other kind of liquids as well, including viscous liquids and those holding solid matter in suspension.

The problem which the designer undertook to solve may be stated as follows: To assure in every instance by means of "interconnecting gage vessels" functioning alternatively the manipulation of the liquids contained in closed reservoirs in any position or dimension and under atmospheric pressure, with the further restriction that these liquids during the period of storing them in the tanks, withdrawing them from the tanks, and intermediary periods, should remain at all times out of contact with the air in order to avoid diffusion of inflammable or toxic vapors.

The original article describes the apparatus in detail as well as test data in connection with the separation. The apparatus is of such a character that it may be applied either to a large stationary plant or to a delivery truck. (*Le Génie Civil*, vol. 81, no. 23, Dec. 2, 1922, pp. 512–516, 9 figs., *d*)

An Improved Tube Rolling Mill

Improved Tube Rolling Mill. Abstract of British patent granted to R. E. Brock, an American. An interesting modification to the construction of tube rolling mills of the continuous type is described under this patent, the object being to secure more efficient operation in the manufacture of seamless tubing. In machines of this nature it is usual to pass the blank through a series of rolls in alignment with a gradually decreasing pass diameter, consecutive sets of rolls being arranged with the planes of maximum pressure perpendicular to one another. This, of course, results in a slight reduction in the diameter of the tube at each pass, with a corresponding elongation of the blank, so that the finished tube leaves the mill at a speed considerably greater than the speed at which the blank enters the opposite end. Actually, under average conditions the increase in speed is found to be approximately

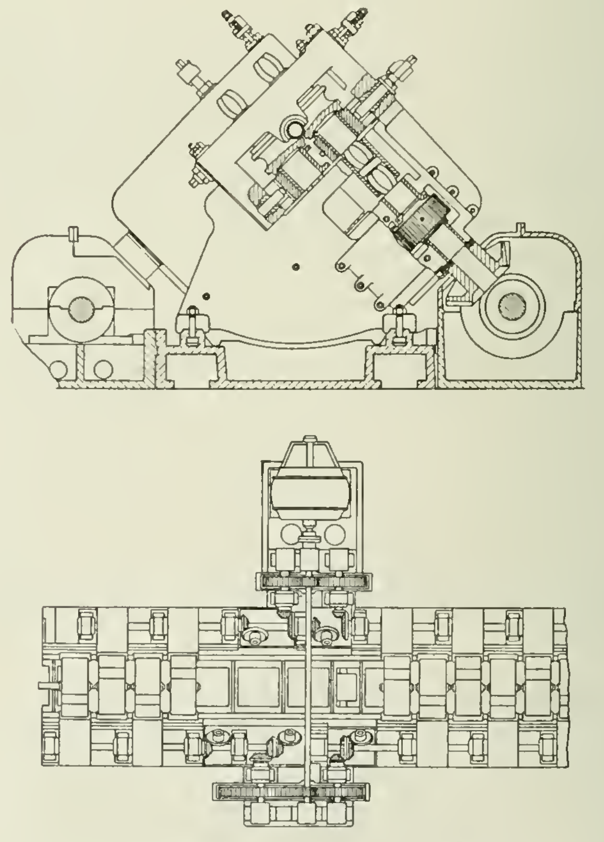

Fig. 7 An Improved Tube Rolling Mill

4 per cent at each pass, and it is to make allowance for this factor that the present improvement has been introduced.

Briefly, it consists in a particularly neat arrangement of the drive to each set of rolls, whereby a progressive increase of the speeds of the respective sets is obtained regardless of the speed of the primary driving shaft. The method of effecting this will be apparent from Fig. 7, which shows a part section through the mill in the

plane of the rolls, and a plan view from which the central sets of rolls has been omitted to show the drive.

It may be seen that the power is taken from a motor direct-coupled to a cross-shaft, which is fitted at either end with a pinion. Each of these pinions engages two spur gears, one on either side, while the spur gears are made with diameters progressively increasing, so that a corresponding range of speeds is obtained.

It may further be stated that the spur gears are keyed to short cross-shafts, each of which carries a bevel pinion at the inner end, and by this means the power is transmitted to four independent longitudinal shafts, which are thus driven at different speeds. The drive is then transmitted to each set of rolls by means of further bevel gears, arranged as shown in the upper view, and these members are also made so that the diameter increases progressively throughout the series. Thus, since alternate sets of rolls are driven from each longitudinal shaft, each pair may be driven at a speed approximately 4 per cent higher than the preceding set by suitably arranging the number of teeth in each bevel wheel.

In other respects the constructional features follow the usual practice with regard to rolling mills. (British Patent no. 185,543, abstracted through *Engineering Production*, vol. 5, no. 112, Nov. 23, 1922, pp. 501–502, 1 fig., *d*)

SPECIAL PROCESSES

Removal of Solid and Liquid Particles from Gases, A. F. Nesbit. Description of an apparatus of a type combining electrical and centrifugal action and intended chiefly for cleaning combustible gases such as coke-oven and blast-furnace gases to be used as a source of heat or motor fuel, though other gases may be similarly handled.

The apparatus may be purely mechanical or combined with certain electrical features. The purely mechanical cleaners do not remove as completely the dusts, tar, and other fogs constituting the recoverable contents of the gases as may be done by the use of combined electrical and mechanical cleaners, but they are free from the disadvantages always present when using electrical systems and they yield such a high percentage of recovery as to suggest a successful stage-refrigerating-type apparatus. (*Blast Furnace and Steel Plant*, vol. 10, no. 12, Dec., 1922, pp. 637–641, 5 figs., *d*)

TESTING AND MEASUREMENTS (See also Thermodynamics)

The Davon Microtelescope and Supermicroscope, F. Davidson. Description of two instruments invented by the author. As regards the microtelescope the principle involved is the application of a short-focus telescope objective in a tube with a series of diaphragms to the microscope, the microscope itself acting as a compound eyepiece. With that attachment, which contained a 6-in. telescope objective inserted into the Abbé rim of the microscope, there was an image of a distant object projected to the plane of the stage; the air image was magnified by the microscope proper and as a result objects could be seen as near as 6 ft. Its range was practically from 6 ft. to infinity. One could then, for example, view the scales of pyrometers or thermometers at any distance, inaccessible parts of machinery, and certain parts of a mine, provided, of course, that the light could be projected on to the object.

One of the characteristics of the observations with this instrument was depth of focus. One could look at an ordinary photograph with the instrument and see it in apparent stereoscopic relief. As an illustration of what can be done with the microtelescope, the author cites the case of a bird's nest which was photographed with this instrument at a distance of 50 yd.

Next, a short-focus attachment was provided for working with objects which, because of their size or shape, could not be put upon the stage of a microscope, for example, minerals, metal fractures, etc. Here a variation of magnification of from 30 to 90 diameters was possible without altering anything but the distance from the object, and even at the higher magnification the relative depth of focus was always maintained.

A third attachment was then provided, namely, another tube in which a microscope objective was placed at one end. At the other end of the tube was another achromatic combination, which the inventor called a collector. This gave the supermicroscope. By means of the collector the image of a microscopic object was projected at some distance beyond it. The position of the air image which was projected depended upon the distance that the collector happened to be from the front of the primary objective. This enabled them to carry the system of direct observation which was begun with a short-focus attachment up to very nearly 1000 diameters and still have sufficient working distance to eliminate an object from above.

It is of interest to note that anything that could be seen with either piece of apparatus could be photographed by it by simply removing the body tube of the microscope and substituting a camera. The same lens was used for telephotography as for observation. With a short attachment it was possible to photograph metal fractures and similar things, and with the supermicroscope the author photographed objects from life size to diatoms under a magnification of 3000 diameters. (*Chemical News*, vol. 125, no. 3270, Dec. 15, 1922, pp. 353–355, see also *Bulletin* of the Institution of Mining and Metallurgy, no. 218, Nov., 1922, pp. 1–5, *d*)

THERMODYNAMICS

Heat Transmission—Heat Measurements—Room Thermometers

New Methods and Investigations for Determining Heat Transmission, Prof. Oscar Knoblauch. Discussion of the meaning of the various coefficients of heat transmission and methods for their determination, including methods of measuring the temperature of the various elements entering into the problem.

The author devotes particular attention to the determination of the coefficient of heat transmission α which is the heat lost per unit area, say, 1 sq. m., of a surface, such as the wall of a building, to the ambient medium, such as air, per unit of time per hour per degree (centigrade) temperature difference. The great difficulty in determining this coefficient lies in the exact measurement of the air and wall temperatures.

In particular, as regards the measurement of air temperature, this should be measured in fairly close proximity to the wall. The difficulty of doing this, however, lies in the fact that if the thermometer is placed close to the wall, its reading may be materially affected by radiation losses, the direction of which would depend on whether the wall is colder or warmer than the thermometer. In the former case the thermometer would be losing heat by radiation to the wall and would show less than the true air temperature. In the latter case it would gain heat from the wall and would show an air temperature higher than the wall.

Experiments recently carried out by H. Hausen in Germany show that this error in thermometer reading may be quite material. All attempts to obviate this by such means as enclosing the thermometer in a metal sheath or using a rapidly moving thermometer or blowing the air over the thermometer and the like, are unsuitable for this particular purpose because they materially modify the conditions of the experiment.

Theoretically, the error in measurement due to the error of absorbed radiated heat may be considerably reduced by providing a thermometer with a surface of proper characteristics, namely, one that will absorb as little light and heat radiation as possible. The glass tube usual in mercury thermometers allows the majority of light rays to pass through, which therefore reach the mercury and are reflected by it. On the other hand, however, the glass absorbs powerfully the shorter-wave heat radiation and thereby contributes to the error in measurement discussed above. Since, however, gold and silver absorb only 2 per cent and nickel 5 per cent of the heat radiation, a substantial reduction in error due to heat absorption may be brought about by gilding, silvering, or nickeling the thermometer tube. If gold and silver are selected the error in measurement falls to about 3 per cent of the error of a thermometer with a plain glass tube, and this may be safely neglected in the majority of practical applications.

For measurements of precision, however, the readings of a thermometer even with the gilt and silver tube, are not sufficiently exact. There is, however, a way of obtaining an extremely exact reading by using two thermometers having tubes of different heat-absorption capacity, for example, one of plain glass and the other

gilt. In this case the true temperature of air t_0 may be expressed as—

$$t_0 = t' - K\,(t'' - t')$$

where t' is the reading of the thermometer with the gilt tube; K a coefficient depending on the constants of the two thermometers (in this case 0.15); and t'' the reading of thermometer with the higher heat absorption, as, for example, the plain glass tube.

If, for example, with such a double-thermometer outfit the glass-tube thermometer reads 23.0 deg. cent. and the gilt tube 20.0 deg., then the true temperature of the air t according to the above equation is—

$$t = 20 - 0.15\,(23 - 20) = 19.55 \text{ deg. cent.}$$

If such a double-thermometer outfit is suspended near a *cold* wall the temperature of the gilt-tube thermometer will be higher than that of the glass-tube thermometer and the temperature of both will be lower than the air temperature, all this being due to the loss of heat from the thermometers to the wall by radiation.

From this the author proceeds to the discussion of the ordinary method of measuring room temperature by means of a thermometer suspended on the wall. He finds that with the usual construction such a thermometer reads the room temperature fairly closely only where the room is so heated that it is maintained at a fairly constant temperature for a length of time sufficient for a fairly close equalization between air and wall temperature to be obtained. However, where the room is not heated for a greater part of the day and is only supplied with considerable amounts of heat for comparatively short intervals, so that the walls are not fairly cold, the temperature readings of a thermometer hung on a wall are extremely misleading. This is particularly so as the mercury bulb is enclosed in a wooden frame, and in addition is covered by perforated metal. Free contact with air is therefore materially precluded, while heat transfer between the wall and thermometer by conduction and radiation are encouraged. Such a thermometer is more suitable for measuring the wall temperature than the air temperature.

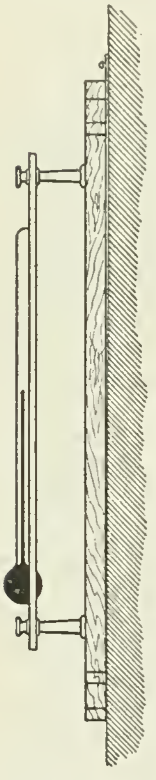

Fig. 8 The J. Greiner Wall Thermometer

A German concern is building a wall thermometer of the type shown in Fig. 8. Here the thermometer is supported on a wooden base suspended on the wall in the usual manner, but it is placed not in the base itself but on a milk-glass scale about 2 cm. (0.8 in.) from the wooden base. The mercury bulb is therefore freely in contact with the air while the wooden base protects the thermometer against a large share of heat radiation interchanged between it and the wall.

At the same time it is a question which of the two types of wall thermometer referred to above gives indications of greater practical interest. The human body in a room is subject to two kinds of temperature interchanges: namely, between the body and the air, and by radiation between the body and the walls. Where the room is rapidly heated up there may be a feeling of chill in a room where the true air temperature is as high as 68 deg., provided the wall temperature is low, and the latter may be as low as 50 deg. From this point of view a thermometer exposed to radiation losses to the wall loses more than one that is not so exposed, and, for example, under the above air and wall conditions a thermometer in a room having a true air temperature of 20 deg. cent. (68 deg. fahr.) will read only 17.3 deg. cent. (63 deg. fahr.).

The next problem which the author discusses is the measurement of the true wall temperature, which means the temperature of the surface of the wall exposed to the air. Here thermocouples present a sufficiently reliable means.

The author proceeds next to the discussion of methods for determining the heat transmission through walls of various tubes, hollow or solid, by means of numerical calculations, and shows that these have been developed to such an extent as to give results sufficiently reliable for all practical purposes. He points out also that of late a good deal more attention has been paid than formerly to the ability of walls to resist heat losses because of the greater cost and scarcity of fuel.

An extensive discussion of heat losses through windows concludes the article. In this case the author considers losses due both to heat flow through the window materials and air leakage due to lack of tightness in the window joints. In this connection extensive experiments made in Germany are quoted. (Paper before the annual meeting of the German Refrigerating Society, Munich, July 18, 1922, abstracted through *Zeitschrift für die Gesamte Kaelte-Industrie*, vol. 29, no. 10, Oct., 1922, pp. 177–183, 7 figs., *eg*)

VARIA

Industrial Situation in Japan. Data taken from a report by Sir E. T. F. Crowe and G. B. Sansom of Tokyo, issued by the British Department of Overseas Trade and dealing with the commercial, industrial, and financial situation in Japan during 1921 and up to June 30, 1922.

From this report it would appear that contrary to the common impression Japan is a country of high production costs. This is illustrated in the case of copper. Japan is one of the largest producers of copper in the world. Before the war her output averaged 60,000 tons a year, and next to silk and cotton yarns copper was the most important export. The principal mines were owned by a few of the richest families of the country and the copper business was looked upon as being very prosperous and profitable. In 1919 and 1920 for the first time copper began to be imported as consumption increased, while production fell off owing to increased costs. The imports fell off in 1921 but increased again in 1922. The copper-mine owners declared that they were unable to produce copper at a price which could compete with the imports from America, and the government, in order to protect an important domestic industry, accordingly increased the duty from 0.20 yen per 100 kin to 7 yen. For a short period imports ceased, but last June they were again beginning to come in.

It is estimated that the consumption of copper in Japan is about 6000 tons a month, while production has dropped below 5000 tons. In 1917 Japan produced on an average 10,000 tons monthly. The problem facing the mine owners is whether to attempt to produce more economically and meet competition or to maintain the price at a high level by reducing output.

The latter uneconomic policy has been followed by the colliery owners who curtailed output by $17^1/_2$ per cent in order to bolster up prices. It is this tendency, the report points out, of continually forcing up prices and preventing them from finding their natural level which must seriously damage Japanese trade unless it is remedied in time. The immediate effect has naturally been to keep the cost of living at the high level to which it mounted during the war.

As regards the iron and steel industries, it was pointed out in another report that Japan has made rapid strides in its wire-manufacturing industry and today is turning out wire rope, plain wire, and wire nails of good quality. The production of these commodities, however, is not sufficient to meet the needs of the Japanese, resulting in heavy purchases of foreign wire goods. The demand for wire products is principally in galvanized plain and bright wire and wire nails. To a less extent there is a call for wire rope and cable, insulated wire and cable, woven wire fencing, wire cloth and screening.

Boiler plates for the Japanese-made locomotive, war vessel, steamship, and other equipment are largely imported. In May, 1922, 1839 tons of boiler plates and 2189 tons of other steel plates of American manufacture were taken by the Japanese. (*The Electrical Review*, vol. 91, no. 2344, Oct. 27, 1922, pp. 605–606, *g*)

CLASSIFICATON OF ARTICLES

Articles appearing in the Survey are classified as *c* comparative; *d* descriptive; *e* experimental; *g* general, *h* historical; *m* mathematical; *p* practical; *s* statistical; *t* theoretical. Articles of especial merit are rated *A* by the reviewer. Opinions expressed are those of the reviewer, not of the Society.

Progress in the Art of Power Development

By A. G. Christie,[1] Baltimore, Md.

The Power Division concerns itself with all problems involved in the generation and transmission of power. Among the more important problems are those concerning the development of underlying theory, the design, construction, and operation of all classes of power machinery, both steam and hydraulic, the transmission and distribution of power, and economic questions concerning power development.

Since the greater portion of our power supply is developed from steam at the present time, much attention has been devoted to factors concerning the design and construction of steam stations. The increased costs of fuel and of labor have had a very material affect on plant design. Emphasis is now placed on the operation of the plant as a whole rather than on prime mover or boiler alone. This has led to careful study of the heat balance of the complete plant. Such studies often develop possibilities for improvements and have a very stimulating effect on the management. In new designs much thought is devoted to heat-balance studies of various schemes before a final selection is made. Minor heat losses such as those in the generator cooling air, transformer losses, bearing losses, and gland leakage are now being recovered and utilized. Systems of operating auxilaries to secure the lowest B.t.u. per kw-hr. of net station output are being developed which differ radically from former practice. In some cases house turbines are employed with motors on all auxiliaries. These, however, will probably be omitted from future stations where economizers are not used and all power for auxiliaries will be furnished from the main turbines which will be of the multiple bleeder type. Certain of the essential auxiliaries will be equipped with synchronous motors and a duplex steam drive in reserve that will pick up load in an emergency and will operate certain other auxiliaries with the synchronous motor acting as a generator.

Substantial progress is being made both in size and in designs of large turbo-generators. Types built under the stress of war conditions developed certain weaknesses, and as a result all the large companies both here and abroad have been redesigning and improving their machines. The newer designs are more compact and better built. The ideal turbine will provide the steam with the smoothest and most direct expanding passages free from sudden changes in cross-section or in direction, and with stationary and revolving guides or buckets whose curved surfaces offer the minimum of shock to the high-velocity steam. This ideal is being approached in recent designs. A uniform distribution of steam in the exhaust pipe and the utilization of the velocity energy leaving the blades are also attempted in some of the new units.

Multi-stage bleeding is becoming standard practice with large steam turbines. Engineers will soon demand that the builders themselves provide the turbine and bleeders and base all guarantees on the performance of the unit as a whole, resulting in better design and improved thermodynamic performance.

The characteristics and limitations of small steam turbines are becoming better known. New designs embody substantial improvement over earlier types. There is still need for further improvement in these units intended for auxiliary service. Small steam turbines have not been able to compete on the basis of economy with uniflow engines.

There is a decided tendency at the present time to increase steam pressures and temperatures. Mr. Orrok has ably discussed this subject in his recent paper on The Commercial Economy of High Pressure and High Superheat in the Central Station. He concludes that 1200 to 1500 lb. steam pressure is commercial but that temperatures are limited to about 750 deg. fahr. until better materials can be developed for valves and piping. The Benson system now being considered in Great Britain goes to pressures in the neighborhood of 3200 lb. per sq. in., but while sound theoretically has not been commercialized. Recent announcement of plants to use 550 lb. pressure seem to indicate conservative design as far as ultimate limitations are concerned.

Mr. Orrok pointed out that most of our discussions on high pressures and temperatures are academic in view of the lack of definite knowledge of the properties of steam under these conditions. The Steam Table Research when completed will be of inestimable value to engineers. Much discussion of the so-called "supersaturation" state of steam has developed in England. American engineers desire to be further enlightened on this subject, which up to the present time has not received much attention in this country.

The steam boiler and it auxiliaries are prime essentials in power generation. Boilers are steadily increasing in size and height. The Power Division has directed its attention to a study of heat absorption in boilers, and this is progressing satisfactorily under the direction of Mr. E. B. Powell. It is hoped that an early report can be made to the Division. The introduction of powdered fuel with increasing furnace temperatures has made the employment of water screens necessary and has suggested the use of radiant-energy superheaters in the side walls. The influence on furnace temperature of these added heat-absorbing surfaces will be watched with great interest, and will have considerable effect on future furnace design.

Boilers are now operated for varying periods at high ratings. This can only be done where the tube surfaces are free from scale and the feedwater free from foaming alkalis. Hence the feedwater must be kept pure. Many stations now employ evaporated make-up. If low-priced evaporators were available in small sizes it would be advisable to furnish distilled make-up for feedwater in a great many of our small plants where only impregnated water is available.

Rising coal prices have resulted in the wider adoption of economizers, which in high-pressure plants have steel tubes. Several new problems have been presented to engineers by the adoption of these steel tubes. In the first place corrosion is very rapid and very destructive if any oxygen remains in solution in the feedwater. Hence various methods and equipment have been devised to deaërate the feedwater. Difficulty with corrosion of the outside of economizer tubes has been encountered where coals high in sulphur are used. A study of the dewpoints of sulphur compounds may reveal the cause of this difficulty.

In plant economy the B.t.u. per kw-hr. developed has been steadily reduced and will be further lowered when some of the newer ideas on heat balance have been fully developed.

There is a wide interest nationally in the development of water power, and many new undertakings are being planned. Engineers have devoted their attention to the development of turbines of increasing size for large power developments and to new designs to operate efficiently under low heads. Definite progress has been made in improving the overall efficiency of turbines by the use of the hydraucone, the improved draft tube, and the regainer. Several of these developments have been discussed at meetings under the auspices of the Power Division and papers on new developments are planned for coming meetings.

Reduction gears produced during the urgency of the war period were in many cases not of the best materials nor carefully made. Gears of recent manufacture have been greatly improved and are now regarded as standard equipment for many purposes.

The increased interest being given to the question of conservation of the valuable products of coal and to the low-temperature carbonization process should make power engineers give some thought to the ultimate plant of the future. A scheme is already under consideration for at least one large station where a low-temperature carbonization process adjoining the steam plant will furnish rich gas to the city mains for domestic purposes and a low-volatile coke that burns without smoke for heating purposes. This semi-coke in pulverized form will serve as the fuel supply to the boiler furnaces of the electric plant. The motor fuels, alcohol, creosote, fuel oils, ammonium sulphate, and other valuable by-products will be available for sale. In the near future the power engineer may have to be a gas-house man as well as a steam-station expert if the present tendency continues.

---

ENGINEERING RESEARCH

A Department Conducted by the Research Committee of the A.S.M.E.

Personnel Methods—Recognition and Classification of Human Abilities

DURING the last decade there has grown up in industry a new branch of technology that has received the appropriate descriptive name of "human engineering." The development has come about through an increasing demand for means to assist managers in selecting men better suited, from the points of view of employee and of employer, to the work they have to do. There is wide demand for reliable information about the methods which have appeared in the form of mental tests, trade tests, rating scales, and other means of discovering human qualifications.

Standardized tests and measurements are widely sought by engineers, but the hazards incident to the activities of charlatans prevent the full utilization of this contribution of modern science. Recognizing the importance of the movement and the need for careful scientific appraisal of available methods, the National Research Council has initiated various activities for the benefit of managers who are dealing with human problems. To this end the Research Information Service of the Council is giving attention to the compilation of reliable information about personnel matters.

As a free clearing house for the promotion of research and its applications in industry, the Research Information Service is prepared to furnish critical information about modern personnel methods. Among the mechanisms especially designed for this informational service there is maintained a personnel file in which consulting psychologists, personnel specialists, and other reputable experts on problems of human adjustment are listed. Files of information about available tests and their particular usefulness are also maintained.

With specialists on these problems in the Council offices and with files of information at their disposal, mechanical engineers may profitably appeal to the Research Information Service for facts about methods of personnel classification. All communications should be addresses to Research Information Service, National Research Council, Washnington, D. C.

Research Résumé of the Month

A—Research Results

Explosives and Explosions A1-23. Study of Explosions of Gaseous Mixtures. The immediate object of the series of tests reported in the most recent Bulletin (No. 133) of the Engineering Experiment Station of the University of Illinois was a study of the physical phenomena involved in the explosions of various mixtures of illuminating gas and air. Prof. A. P. Kratz and Mr. C. Z. Rosecrans are the authors. The bulletin includes the determination of the effect of different-shaped explosion vessels, and of turbulence at the time of ignition, as well as a study of the heat loss from the burning mass of gas. Any problems connected with the chemical changes involved have not been considered within the scope of the investigation.

An investigation of explosions of gaseous mixtures at constant volume was undertaken by the Engineering Experiment Station in 1914, when C. R. Richards outlined an extensive series of experiments and defined the scope of the investigation which was to follow. Apparatus was designed and a few results were obtained showing the effect of the shape of the explosion vessel and of turbulence at the time of firing, but it was found necessary to discontinue the work. In 1919 part of the apparatus was redesigned and work was resumed. This bulletin is a preliminary report of the methods pursued and the results thus far obtained.

Address the authors in care of the University of Illinois, Engineering Experiment Station, Urbana, Illinois.

Gases, A1-23. Study of Explosions of Gaseous Mixtures. See *Explosives and Explosions A1-23.*

B—Research in Progress

Ceramics and Glass B1-23. Influence of Burning Fuel Oil on Refractories. See *Refractories B1-23.*

Fluid Flow B1-23. Flow of Water in Vertical Pipes. A considerable amount of laboratory work has been completed in an investigation of the possible rates of flow through vertical pipes. This study is being conducted at the University of Illinois by Mr. W. J. Putnam and is to include work on pipe of various lengths and with different entrance conditions. The pipes discharge into the air in all cases and the tests, therefore, apply to flow through down spouts, drains, industrial piping systems, etc.

Framed Structures B1-23. Stresses in Statically Interminate Frames. Bulletin No. 108 of the University of Illinois issued in 1918 presents equations for moments in frames due to any type of load. The work which Mr. W. M. Wilson has completed during the past year on this subject consists of the derivation of the corresponding equations for the stresses due to particular loads. This material will be published shortly as one section of the Structural Engineer's Handbook Library.

Framed Structures B2-23. Web Stresses in Beams. A study of the effect of spacing of stirrups and a comparison between the actions of rectangular and T-beams is now being made under the direction of Prof. A. N. Talbot at the University of Illinois. During the past year tests on 20 large rectangular and T-beams have been completed.

Gas, B1-23. Efficiency in Gas Combustion. An investigation has been recently undertaken by Mr. F. E. Vandaveer at the Engineeiing Experiment Station of the University of Illinois to determine the possible extensions in the use of fuel gas in the industries. As this study progresses it is proposed to take up (*a*) the catalytic chamber, (*b*) thorough mixing of air and gas, and (*c*) the effect of temperature at time of combustion.

Gases, B2-23. Amount of Water in a Nearly Dry Gas. An electrical device for detecting and approximately indicating the amount of water in a nearly dry gas, upon which a considerable amount of work was done several years ago at the Bureau of Standards, has been again tried out with surprisingly good results. The detector appears to have lost none of its sensitivity during nearly three years in the laboratory. This would indicate that it may be relied upon as an alarm device in the liquefaction and nitrogen-fixation industries where such a device is greatly needed. The Bureau hopes to prepare and publish a description of the device in the near future.

Mechanics, B1-23. Web Stresses in Beams. See *Framed Structures B2-23.*

Mechanics, B2-23. Fatigue of Metals. Bulletin No. 124 of the University of Illinois describing this important investigation by Professors Moore and Kommers was mentioned in these columns in the February, 1922, issue. It is now possible to announce that a second bulletin by the same authors is in preparation which will describe new tests of materials under a combination of steady tension and reverse bending and also under reversals of direct axial stress.

Non-Ferrous Metals B1-23. Contraction and Shrinkage of Non-Ferrous Alloys as Related to Casting Practice. One of the fundamental problems under investigation by the Bureau of Mines in its alloy work is the contraction of a series of light aluminum alloys, particulars of which will soon be published as Bulletin 287 of the Bureau. An investigation is now under way on the contraction of a series of commercial brasses and bronzes.

While the contraction of alloys is only one of the factors that bear on cracks in castings, as well as on the casting qualities of any alloy, still it is important; and comparative figures as to the contraction of various alloys will serve as a guide to their casting qualities and cracking tendency.

A "Report of Investigation" Serial No. 2410 prepared by Mr. Robert J. Anderson is a short discussion of the technical aspects of contraction in relation to foundry practice, and has been published in response to numerous inquiries for information, with the recommendation of the Advisory Committee.

On the basis of the available information, the following conclusions may be drawn as to the contraction and shrinkage of alloys as related to foundry practice:

1 The linear contraction of any alloy is a function of the exact chemical composition of that alloy, and relatively small amounts of impurities affect the contraction.

2 The wide variation in contraction among the alloys of a given class—for example, brasses, bronzes, or aluminum alloys—indicates that it is poor practice to employ a rough figure as the contraction of alloys of a given class in general, since by so doing much difficulty arises in producing master patterns and in obtaining castings with a minimum of wasters.

3 Theoretically, the higher the pouring temperature the greater the contraction, as less metal can be held in a mold cavity at a higher temperature than at a lower temperature. Actually, pouring at an intermediate temperature gives greater contraction than pouring at a high temperature or a low temperature on account of the effect of gas evolution in the case of alloys poured at high temperatures. The evo-

lution of gas referred to causes actual expansion, thus interfering with normal contraction and yielding less contraction.

4 Other things being equal, the smaller the cross-section, the less the contraction for a given length.

5 Other conditions being the same, the greater the length for a given cross-section the less the contraction.

6 The linear contraction of alloys is a function of the kind of mold employed, the contraction being greater in chill molds than in sand molds, other conditions being the same.

7 In sand molds the contraction in a casting depends upon the contour of the pattern, the mass of the casting, and the size and distribution of the gates and risers—that is, the method of molding.

8 Gas occlusion, owing to a high melting temperature, causes less contraction owing to evolution of the gas when the metal freezes.

9 The extent to which piping occurs on casting an alloy in an open-top ingot mold is a factor in determining the suitability of an alloy for casting purposes, as this is an indication of the contraction in volume. In general, the less the depth of pipe, the less the contraction in volume.

Railroad Rolling Stock and Accessories B1-23. Action of Exhaust Jet in Front End of Steam Locomotives. This investigation has been undertaken at the University of Illinois by Prof. J. M. Snodgrass to determine the action of the exhaust jet in producing draft. The study will seek to determine the influence upon draft of exhaust steam pressure and volume, jet velocity, and form of jet nozzle. It is intended to begin this work by means of a small model so constructed as to permit visual observations of the actions within the front end as well as the usual observations for draft, steam pressure, etc. Any conclusions or generalizations arising from work with the model will be checked on the locomotive in the laboratory, and possibly in road tests.

Railroad Rolling Stock and Accessories B2-23. Tractive Effort of Steam Locomotives Tests for the accumulation of additional experimental data are now in progress, being conducted jointly by the Illinois Central Railroad and the University of Illinois. The specific object for this investigation is the determination of a method for predicting the tractive effort of locomotives, knowing their dimensions and principal operating conditions. Address Edward C. Schmidt, care of the University.

Refractories B2-22. Study of Electric-Furnace Refractories. As the development of refractories for electric furnaces is now being undertaken, it is desirable to have a method and apparatus for measuring their conductivity at advanced temperatures, states the Federal Bureau of Mines. Moreover, data in regard to the conductivity of existing refractories at temperatures above 1400 deg. cent. are meager. It is proposed to study the leakage factor through refractories. The method of attack has been worked out and the furnace designed, the material for which is arriving at the U. S. Bureau of Mines ceramic experiment station at Columbus, Ohio.

Steel B1-23. Gage Steels. Progress reports on the work so far done by the Gage Steel Committee were considered at the meeting held in New York on November 17th and a program outlined for continuing the work. The samples of a steel selected by the committee for investigation have been received and preliminary work is well under way. Dimensional changes on hardening and changes with time after hardening are being studied; also the rate of wear of different specimens which have been subjected to various heat treatments.

C—Research Problems

Framed Structures C1-23. Strength and Action of Bolted and Riveted Connections. A number of companies interested in this investigation have supplied the University of Illinois with a considerable amount of material with which to begin work. Professors A. N. Talbot and A. F. Moore are to undertake this study as soon as the necessary assistants and machines are available.

F—Bibliographies

Explosions and Explosives F1-23. Gaseous Explosions. This bibliography contains references, not only on the subject of the physical phenomena involved in the explosions of gaseous mixtures but also in regard to the chemical transformations and other allied phenomena. Numerous references of a mathematical nature, particularly in regard to the subject of explosion waves, are also included, as well as some few references describing instruments and apparatus used in investigations of gaseous explosions. It consists of twenty-one closely printed 6 by 9-in. pages and forms Appendix C of the University of Illinois Bulletin No. 133.

Gases F1-23. Gaseous Explosions. See *Explosions and Explosives F1-23.*

Highways F1-23. Projects in Highway Research Current or Recently Completed. The October, 1922, Bulletin of the National Research Council is devoted entirely to a report on the Census which the Advisory Board on Highway Research recently completed. In Part IV, 479 research projects in highway engineering and highway transport are listed and briefly described. These projects are listed under the following five main headings: Economics, Operation, Design, Construction, and Material. Address The National Academy of Sciences Washington, D. C.

Road Materials and Equipment F1-23. Projects in Highway Research Current or Recently Completed. See *Highways F1-23.*

Framed Structures F1-23. Riveted Joints. The literature on this subject both European and American has been very carefully listed and briefly abstracted by Dr. A. H. Stang, connected with the Structural and Engineering Materials Section of the Bureau of Standards. It consists of twenty-six closely typewritten pages. Address Bureau of Standards, Washington, D. C.

Progress Report of A.S.M.E. Research Committee on Fluid Meters

After years of effort on the part of the Research Committee on Fluid Meters of The American Society of Mechanical Engineers, its report is complete and will be issued in pamphlet form within a few weeks.

This report takes the form of a reference book on flow meters of all kinds. It contains not only such practical instruction and information, including formulas, constants, etc., as may be needed by the actual or prospective user, but also more general information —the physical principles of design and operation—which may be useful to students, designing engineers, and inventors.

Part I treats the general types of flow meters as well as the principles and methods involved and gives information which may, in many cases, be applicable to various commercial meters. In this part individual makes of instruments are not discussed in detail, but are referred to only incidentally or for illustrative purposes. The general physical principles are in the body of the text, while the derivation of formulas and the refinements of the theory involved have been placed in the appendices which accompany the report.

In Part II will be found more detailed information concerning the practical use of all the flow meters now in common use. This information has been obtained from both users and makers and includes descriptions of commercial meters, and particulars with respect to operating characteristics, influence of installation, and the testing of meters.

Flow meters are of great and rapidly increasing importance, but hitherto the information available on this group of instruments has been incomplete. The material forming Chapters 1, 2, 3, 4, 5, 6, and Appendix C, were recently rewritten. This material contains a new presentation of the subject based on a mathematical analysis which is more specifically applicable to fluid flow than Bernoulli's theorem. The analysis did not include the additional experimental data now given in the report, but these data required no serious modification of the text.

The most important modern advance in experimental aerodynamics and hydraulics is the application to them of dimensional analysis. This is absolutely indispensable to an understanding of the behavior of moving fluids, for the phenomena of fluid motion are so complicated as to defy analysis by any other known method. The use of this method is especially valuable, in that it makes possible the reconciliation of data obtained from experiments with the venturi tube and the thin-disk orifice which were formerly thought to be irreconcilable. These data are now shown to be mutually confirmatory.

A few of the chapter heads will serve to indicate the scope of the material covered by this report: Classification of Fluid Meters, Weighing Meters, Volumeters, Current Meters, Head Meters including General Principles, Venturi Meters, Flow Nozzle, Thin-Plate Orifice, Pitot Tube, Area Meters, Force Meters, and Thermal Meters.

The Report was prepared and signed by the following men who constitute this special Research Committee on Fluid Meters: Messrs. R. J. S. Pigott, Chairman, J. M. Spitzglass, Secretary, E. G. Bailey, L. L. Borden, G. S. Coffin, A. R. Dodge, L. M. Goldsmith, F. G. Hechler, Horace Judd, Leo Loeb, P. S. Lyon, W. Maplesden, H. N. Packard and C. G. Richardson.

Those desiring copies of this report should address the Secretary, care of The American Society of Mechanical Engineers, 29 West 39th Street, New York, N. Y.

CORRESPONDENCE

CONTRIBUTIONS to the Correspondence Department of MECHANICAL ENGINEERING are solicited. Contributions particularly welcomed are discussions of papers published in this journal, brief articles of current interest to mechanical engineers, or comments from members of The American Society of Mechanical Engineers on activities and policies of the Society in Research and Standardization.

Mathematical Determination of the Modulus of Elasticity

TO THE EDITOR:

The letter in the December issue of MECHANICAL ENGINEERING from Mr. David Guelbaum, entitled Mathematical Determination of the Modulus of Elasticity, is a very interesting deduction from what is commonly known as the general equation of the elastic curve. It should be noted, however, that while a high degree of precision is claimed for the method and that while the derivation of the equations is mathematically correct, Mr. Guelbaum has apparently ignored the fact that he started with a formula which has decided limitations. The general equation of the elastic curve which states that the bending moment at any section of a bent bar is equal to the modulus of elasticity of the material multiplied by the moment of inertia of the section and divided by the radius of curvature at that section ($M = EI/\rho$), depends for its derivation on the assumption that the radius of curvature is practically infinite. This is far from being the case in the use of Mr. Guelbaum's method.

The equations derived and the mechanical device suggested may prove useful for approximate results where no testing machine is available, but I doubt very much the possibility of attaining the degree of accuracy with this device that is attained with the ordinary testing-machine method.

New York, N. Y. WM. R. BRYANS.

The Entropy of Saturated Steam: Its Relation to Specific Volume

TO THE EDITOR:

The object of this communication is to call attention to what appears to be a remarkable relation between the entropy of saturated steam and its specific volume. While the total entropy of the steam from water at 32 deg. fahr. cannot be calculated directly from the specific volume, if this quantity is determined for one temperature and pressure, then the entropy for all other temperatures and pressures can be calculated from the respective volumes, without the use of other data.

If V_0 and s_0 represent respectively the specific volume and the known entropy of saturated steam of any pressure; V_1 and s_1 the specific volume and entropy of steam at some higher pressure; and if V_2 and s_2 the same quantities at some lower pressure; then—

$$s_1 = s_0 - \phi\,(\log V_0 - \log V_1) \qquad [1]$$

$$s_2 = s_0 + \phi\,(\log V_2 - \log V_0) \qquad [2]$$

If the common system of logarithms is used, $\phi = {}^1/_5 = 0.2$.

In the examples which follow, values for V and s are taken from Goodenough's steam tables, 1915 edition. Steam at atmospheric pressure has been selected for the starting point of the calculations, on the assumption that our experimental knowledge of the properties of steam is probably more exact for that pressure than for other pressures. Therefore—

$$V_0 = 26.81 \text{ cu. ft.}$$
$$\log V_0 = 1.4282968$$
$$s_0 = 1.7589$$

For steam at 300 lb. pressure,

$$V_1 = 1.545 \text{ cu. ft.}$$
$$\log V_1 = 0.1889285$$

From Equation [1],

$$s_1 = 1.7589 - 0.2\,(1.4282968 - 0.1889285) = 1.5110$$

The entropy of steam at 300 lb. pressure in Goodenough's tables is 1.5092. The calculated value of 1.5110, while ${}^1/_{839}$ larger than the tabulated value, is smaller than the value assigned by Marks and Davis or by Peabody.

For steam at 1 lb. pressure,

$$V_2 = 333.3 \text{ cu. ft.}$$
$$\log V_2 = 2.5228353$$

From Equation [2],

$$s_2 = 1.7589 + 0.2(2.5228353 - 1.4282968) = 1.9778$$

The value given in Goodenough's tables is 1.9775, which is practically identical.

Table 1 gives the entropies as calculated by Equations [1] and [2] for several intermediate pressures between the extremes of 300 lb. and 1 lb., as well as the corresponding values given in the standard steam tables of Goodenough, Peabody, and Marks and Davis. It will be observed that wherever the calculated values differ appreciably from the tabular values of Goodenough, they lie between the values of Goodenough and those of the other authorities.

TABLE 1 VOLUME AND ENTROPY OF SATURATED STEAM

Absolute pressure, lb.	Volume, cu. ft.	—Total Entropy from 32 Deg. Fahr. According to— Eq. [1] and [2]	Goodenough	Peabody	Marks and Davis
300	1.545	1.5110	1.5092	1.5130	1.5129
200	2.292	1.5453	1.5456	1.5459	1.5456
125	3.593	1.5843	1.5858	1.5840	1.5839
50	8.53	1.6594	1.6601	1.6581	1.6581
14.7	26.81	....	1.7589	1.7566	1.7565
5	73.5	1.8465	1.8456	1.8435	1.8432
1	333.3	1.9778	1.9775	1.9762	1.9754

A study of reversible heat changes in a theoretically perfect gas indicates very emphatically a direct relation between change of volume and change of entropy. For example, if a perfect gas having the characteristics of air at ordinary pressures and temperatures—the constant value of PV being $53.35T$—be expanded from V_a to V_b by any reversible heat process, the initial and final temperatures being the same, the numerical value of the increase of entropy will be equal to—

$$\frac{1}{6^1/_3}\left(\log_{10}\frac{V_b}{V_a}\right)$$

In attempting to establish a similar relation in the case of a saturated vapor it was thought that since the change of volume occurred only during the process of vaporization, the direct relation would exist between the volume and the entropy of *vaporization*. After failing hopelessly to establish this apparently logical relation, it was found, by taking a seemingly forlorn chance, that the total entropy must be considered—i.e., the increase of entropy from the beginning of the liquid stage—until the transformation into a saturated vapor is complete. This indicates that the so-called "heat of the liquid" plays its part in increasing the volume of the fluid when the opportunity presents itself.

It is interesting to note that in the entropy calculations described the factors of heat and temperature are absent. Possibly they may enter indirectly through the volume ratios.

There may be a more exact value for ϕ—Equations [1] and [2]—than 0.2, but inasmuch as it gives results differing from those of recognized authorities less than these authorities differ from each other, its convenience justifies its use.

There are indications that some similar relation may exist between the volume and the entropy of superheated steam, but it is perhaps not so simple and direct. The relation changes very abruptly and very substantially at the instant that the region of superheat is entered.

This volume-entropy relation was not evolved by any scientific

investigation. It is merely something on which the author stumbled accidentally, and which on examination looked interesting. It is passed along in the hope that it may suggest a new line of thought to some one who is skilled and experienced in research work of this general character.

STRESSES IN ELECTRIC-RAILWAY MOTOR PINIONS

(Continued from page 95)

elastic method had predicted is to be found in the fact that beyond the elastic limit the stress-and-strain relation no longer follows Hooke's law. Therefore the stresses set up in the steel pinions by the shrinking process no longer correspond with those set up in the celluloid model.

While the flat shape of the break in Fig. 9 is one limiting case (torque without radial shrinking pressure), Fig. 8 may be considered as the other limiting case (radial shrinking pressure without torque), showing a V-shaped fracture for which the angle of the V has become equal to zero.

It may be concluded, then, that the inspection of the fracture may be a means of determining the cause of the failure. In this way, possibly, the responsibility may be established between builder and customer as regards pinion mounting.

The complete paper includes a detailed stress analysis which shows the comparative ease with which such a stress problem as the one dealt with can be handled by the photo-elastic method, whereas the use of ordinary engineering methods gives untrustworthy results and the exact mathematical solution based upon the theory of elasticity is impossible.

Acknowledgment is due to the Massachusetts Institute of Technology for permission to use in this article certain of the results included in the thesis submitted by Dr. Paul Heymans, University of Ghent, Belgium, as partial fulfilment of the requirements for the degree of Doctor of Science from the Institute.

Discussion

In opening the discussion, A. L. Kimball, Jr., one of the authors, stated that the importance of the investigation outlined in the paper lay mainly in the determination of perfections of pinion design as regarded stress. The similarity of celluloid to steel in the homogeneity of its elastic properties made it possible to study stress distribution in the celluloid models. Mr. Kimball stated that it was possible to study static stress distribution to gain information about stress due to impact as under both conditions the stress distributed itself in substantially the same way.

In answer to some questions asked by J. O. Madison,[1] Dr. Heymans stated that the celluloid models were mounted on steel shafts and that some of the differences in color indicating stresses in the models were due to variations in age of the celluloid used. Mr. Madison stated that in his practice railway pinions were forced on shafts by first boiling in water, putting them on hot and setting with a given number of blows of sledges of definite weights. E. O. Waters[2] emphasized the possibility of using the photo-elastic method to determine facts relating to stresses, pressure distribution, and wear. Dr. A. A. Adler[3] suggested the rotation of the celluloid models and the securing of pictures under actual operating conditions. He also emphasized the need for solving two-dimensional stresses before considering stresses in three-dimensions.

In this connection Dr. Heymans pointed out that in the three-dimensional elastic problem the stress distribution was not independent of the elastic constants of the material so that any determinations in celluloid might not be applied to other materials with different elastic characteristics.

In a written discussion received subsequent to the meeting Dr. S. Timoshenko[1] pointed out that the photo-elastic method of analysis of two-dimensional problems had a broad application within limits and it was important that these limitations be clearly understood. The method failed where the elastic limit of the material under test was exceeded. Dr. Timoshenko suggested that two observations be made by the authors, including the stress distribution from some external force acting on the tooth of the pinion and the stress distribution for similar pressure acting on the inner diameter. From these observations it was possible to obtain stresses at any point of the pinion by the vector sum provided the resultant stress lay within the elastic limit. He also pointed out that the presence of shafting would cause three dimensional stresses at the common boundary of pinion and shaft, rendering the photo-elastic method invalid. He also pointed out that in a study of the effect of pressure acting on the inner diameter it would have been valuable to have compared the pinion with a ring, the outer diameter of which was equal to the diameter at the root of the teeth.

In a plastic material, such was steel, it was impossible to foretell that a given section would prove weakest at the breaking point of the material, because this section contained the maximum stresses when the body was stressed within the elastic limits. Therefore, the photo-elastic results could not confirm any rupture tests on specimen. Moreover, no conclusions could be reached from the tests themselves. In all, only three were made and it seemed to him that on the basis of these alone, it was just as probable that the breaks through the thicker sections had been caused by the initial stresses in the materials as by the stresses produced by the applied forces.

The present paper would be of direct benefit to the designing engineer if, for any given tooth shape, it gave him a definite relation between the actual stresses across the "Minimum cross-section" of the tooth and those obtained by calculation from the cantilever formula. For example, taking the depth of the tooth above the cross-section considered as equal to $^1/_2$ in., the thickness equal to $^1/_3$ in. and the load at the end equal to 1500 lb., the maximum stress obtained from the cantilever formula would be

$$p_{max} = \frac{1500 \times {}^1/_2 \times 6}{\left(\frac{1}{3}\right)^2} = 40{,}500 \text{ lb. per sq. in.}$$

Comparing this with the stresses 72,600 and 80,000 given by the photo-elastic method, it would be seen that the increase of maximum stress due to the local stresses near the root of the tooth, over that given by the cantilever formula was respectively 79 per cent and 98 per cent.

WORK OF THE A.S.M.E. BOILER CODE COMMITTEE

The Boiler Code Committee meets monthly for the purpose of considering communications relative to the Boiler Code. Any one desiring information as to the application of the Code is requested to communicate with the Secretary of the Committee, Mr. C. W. Obert, 29 West 39th St., New York, N. Y.

The procedure of the Committee in handling the cases is as follows: All inquiries must be in written form before they are accepted for consideration. Copies are sent by the Secretary of the Committee to all of the members of the Committee. The interpretation, in the form of a reply, is then prepared by the Committee and passed upon at a regular meeting of the Committee This interpretation is later submitted to the Council of the Society for approval, after which it is issued to the inquirer and simultaneously published in Mechanical Engineering.

Below are given the interpretations of the Committee in Cases Nos. 408 to 410 inclusive, as formulated at the meeting of December 8, 1922, and approved by the Council. In accordance with the Committee's practice, the names of inquirers have been omitted.

Case No. 408

Inquiry: What thickness is required under Par. M-3 of the Code for Miniature Boilers for the plate forming heads which are not an

The Engineer of Tomorrow

Chas. F. Scott

Dean Kimball in his presidential address last month made a keen analysis of conditions prevailing in our modern life. He showed that the engineer has done his part in the past to bring about the civilization in which we live. The importance of the engineer in present activities was indicated, and he pointed out the larger sphere of action which the engineer should logically take in the future. In public affairs the military leader, the legal leader, and the business or financial leader must give way to the scientific or engineering leader.

Dean Kimball's statements have met with criticism and question. An editorial in a daily paper of one of our large industrial cities says that an engineer is a practical man who sees the things that need to be done and goes ahead and does them, but that he is not fitted temperamentally or by training for political positions of service.

What the engineer will be and what he will do depend upon the engineer himself. The engineering criterion of fitness and quality will be applied and if the engineer does play a leading part in the future, it will be because he is worthy of it.

What type of a man will the engineer of the future be? It is significant that the presidential address was delivered by one of our foremost engineering educators, by one who is directing a factory which is making engineers of the future. Whether his vision of a future in which the engineer will be a national leader will be realized will depend in large measure upon whether Dean Kimball himself and his associates in the engineering educational field are successful in giving men the training and the vision which will fit them for national leadership.

The engineer of tomorrow is the engineering student of today. The place which engineers will take in the future and the part they will play in solving the larger economic, social, and governmental problems which the spread of engineering has created, will depend upon how the engineering student of today develops into the engineer of tomorrow.

The importance of this matter is one which extends far beyond the schools themselves. Engineers, engineering societies, and society at large have a profound concern in the ideals and the training of the engineer. The Society for the Promotion of Engineering Education, of which Dean Kimball is a vice-president, has just organized a Board of Investigation and Coördination for the broad consideration of problems of this kind.

If engineers are to take an important place in the future of this country and of the world we may well ask that a survey be made of the number and type of engineers that will be needed. We should ascertain whether our schools are now equipped for producing the proper number of men of the right kind. If more are needed or if a different type of graduate is called for, then we must have more freshmen, and freshmen of a different type.

The members of this Board are M. E. Cooley, Past-President of the A.S.M.E.; F. W. McNair, President, Michigan College of Mines; D. C. Jackson, Massachusetts Institute of Technology; John H. Dunlap, Secretary, A.S.C.E., and C. F. Scott, Yale University. Dean Bishop, Secretary of the S.P.E.E. is also secretary of the Board. It is interesting to note that three of the members of the Board are members of the A.S.M.E. It is hoped that the Board will later on have funds for a director and staff for the carrying on of the work. One of the policies already adopted is that of securing the active coöperation of the schools themselves in the study of the new problems which are confronting engineering educators. Letters from many engineering schools, now being published in the S.P.E.E. Bulletin, show an active and significant interest in the new movement. The Board also anticipates the coöperation of the various engineering societies and is appreciative of the interest which is being taken by the Mechanical Engineers.

Charles F. Scott.[1]

Engineering Museum Requires Interest and Aid of Entire Profession

The project to establish an engineering museum has attracted wide interest both in the technical and lay press. The matter is now in the hands of a Committee of representatives of the four National Engineering Societies.

Most of the comments on the museum stress its importance as a storehouse for the records of engineering achievement and as an institution affording opportunity for research to the investigator or student. The Secretary of the Smithsonian Institute, in a recent report, concludes that a museum would be a suitable monument showing belated public appreciation of the fact that the commanding place reached by the United States in so short a time is due largely to the full development and utilization of mechanical power in the exploitation of her national resources.

However, a writer in the New York *Tribune* has recently emphasized the high value of such a museum to children in giving them an accurate and inspiring knowledge of mechanical processes. He has a vision of an arrangement of models of the stages of mechanical and industrial developments, a cross-section of the world's mechanical brain, in the various stages of growth, where no boy can spend a day without getting the spark in his soul that may ignite the inventive faculty. This writer's plea is, therefore, for the location of the museum in the midst of the largest number of children, and New York would therefore seem the logical selection. A correspondent has pointed out the industrial greatness of the Middle West and believes that Chicago should be favorably considered. And there are many other diverse ideas on the subject, with the problems multiplying as the interest increases.

The Committee of the Engineering Societies has visited the Smithsonian Institute at Washington and, in coöperation with it, is formulating a plan for a great national museum of engineering and industry similar to the Science Museum at South Kensington, London, the Conservatoire des Arts et Métiers at Paris, and Deutsches Museum at Munich, but suited to the needs of this country. The scheme provides a central institution with branches in different sections and proper exchange facilities.

Ideas regarding the character, scope, and location of the museum and the branches are earnestly solicited by the Committee. Engi-

[1] President, Society for Promotion of Engineering Education.

neers are also urged to preserve the models and records of their original work for eventual deposit in the museum.

Holbrook F. J. Porter is Chairman of the Committee, with offices at the Engineering Societies Building, 29 West 39th Street, New York, N. Y. The representatives of the National Engineering Societies are Edward D. Adams and Charles L. Clarke, representing the American Institute of Electrical Engineers, Frederick A. Delano and Dr. George F. Kunz, representing the American Institute of Mining and Metallurgical Engineers; Clemens Herschel and Nelson P. Lewis, representing the American Society of Civil Engineers; and Reginald P. Bolton and H. F. J. Porter, representing The American Society of Mechanical Engineers.

International Courtesies

The recent announcement of the appointment of Gano Dunn as Local Honorary Secretary in America of the Institution of Electrical Engineers of Great Britain directs attention to a particularly gracious form of courtesy that has just been shown to the United States by the British. Another example of this is the hospitality extended by the national engineering societies of America to the American Section of the Société des Ingénieurs Civils de France. The privilege of the Library and offices are extended to the American Section. This is reciprocated by similar welcome to members of the engineering societies of the United States who live in Paris.

Such incidents emphasize again the great common interests of all members of the engineering profession which can be broadened by still further coöperative effort especially in research and standardization. The engineer as a professional man is rapidly coming into his own sphere of importance in the maintenance and development of civilization and these international contacts will be of great assistance in maintaining a uniform front in engineering activity.

International Engineering Congress, 1926

On Tuesday, January 9, in the Engineering Societies Building in New York, a conference of engineers most experienced in matters relating to engineering congresses was held to discuss the plan, scope, and method of financing of a proposed International Engineering Congress to be held in Philadelphia in 1926 in connection with the Sesquicentennial of the Declaration of Independence of the United States. The movement for this proposed Congress was initiated by the Engineers' Club of Philadelphia, which invited the leading engineering societies to join with it on a committee to formulate a plan.

The secretaries of the engineering societies proposed a plan of organization for an International Engineering Congress which was subsequently approved by those societies and adopted at a meeting of the temporary organization committee held in Philadelphia last summer. Under this plan, a board of management was appointed to organize and conduct a congress under the sponsorship of the engineering societies, and the board appointed, among other committees, a committee on plan and scope. This committee was the body which conducted the public hearing being announced here.

The hearing was virtually an exchange of experiences between those competent to speak on the subject, and among those who addressed the meeting were Messrs. A. M. Hunt, H. Foster Bain, Henry A. Lardner, Fred Lavis, A. R. Ledoux, John W. Lieb, Elmer A. Sperry, M. E. Cooley, Charles F. Rand and F. M. Feiker.

The subjects discussed were scope of the Congress, finances, relation to meetings of engineering societies, relations with governmental agencies, and publicity.

Patent Office Salaries and the Public Interest

The individual members of the Engineering Societies by giving their powerful aid in securing the enactment on February 18, 1922, of the Lampert Patent Office Bill, H.R. 7077, helped to stop the disintegration of the Patent Office by constant resignations and prevented its complete collapse. Without this help it would soon have been swamped and ceased to function usefully.

The Lampert Bill raised the salaries of the Patent Office examiners to $3900 per year and stopped the resignations in the upper grades, where it was most important to stop them. However, the increase from $2750 to $3900 was by far the largest proportionate increase that had ever been obtained through any bill in Congress, and was all that it was possible to obtain at one time. The increased salary is not sufficient, however, to attract men who are highly qualified for the work and to induce them to make a life career of the position, as they must do in order to reach their highest efficiency—in such numbers as to supply all or nearly all of the examining divisions.

The work of an examiner is of great importance to the public interest. By having examiners with sufficient scientific and judicial qualifications and sound judgment and adequate personality, patents will be granted wherever the inventions warrant it, and not be refused because the distinctions of the prior art, although important, are not easily discerned. Such examiners will also with sound judgment detect those cases where the distinctions between the alleged invention and the prior art are not really practical commercial distinctions, but are mere paper differences, and will thereby prevent the granting of patents which can but result in useless litigation that is expensive not only to the patentee and his backers but to the innocent defendant and the Government in the waste of time of the courts.

The inventions which examiners must pass upon are often of great immediate value, and their ultimate value, through their permanent addition to the public domain, are beyond calculation. Therefore, the administration of the Patent Office under examiners of the high type mentioned will increase the market value of patents and thereby stimulate the production of inventions in general—to the great and permanent benefit of the American public.

It is believed that a salary of $5000 for a primary examiner would attract sufficient men of the type described to fill that position in practically all of the examining divisions. There is an excellent opportunity to obtain that salary for the position by aiding in bringing about the enactment of the Sterling-Lehlbach Bill for the Reclassification of Governmental Positions and Salaries, H.R. 8928. This bill has passed the House by a large majority, but in doing so the salary for the position of primary examiner was reduced from $5040 to $4600. The Civil Service Committee of the Senate has reported the bill recommending a restoration to $5040. As the bill affects appropriations, it was also referred to the Appropriations Committee of the Senate, and has been kept there nearly a year by the desire of Senator Reed Smoot to substitute another bill which, while having a different scheme of classification, has substantially the same schedule of salaries.

As the Sterling-Lehlbach Bill has already passed the House, it would obviously be much easier to enact than a substitute bill. The information is that if sufficient public interest is shown, a compromise not affecting the salaries could probably be brought about and the Sterling-Lehlbach Bill reported to the Senate; and if that is done the Bill can be passed through the Senate without great difficulty, after which it seems likely that the House can be induced to agree to the larger salaries.

The Bill has been approved by the following organizations:

The New York Patent Law Association
The National Federation of Federal Employees
The American Federation of Labor
The Federated American Engineering Societies
The American Association of Engineers
The National Civil Service Reform League, and others.

The engineers, chemists, scientists and manufacturers proved with the Lampert Bill that they could induce Congress to pass a just and wise measure in the face of intense opposition. There is no such opposition to the present bill as there was to that bill. Each member of each of the Engineering Societies is asked to write to Senator Smoot and to one of his own senators urging the immediate enactment of the Sterling-Lehlbach Reclassification of Salaries Bill, H.R.8928. If every member will do his duty, it seems more than probable that the bill can be passed and the Patent Office placed on that high plane which its great usefulness warrants.

The enactment of this bill would raise the standard of all professional service under the Government as well as that of Patent Office examiners. Let us all pull together and finish the work which we have so successfully begun.

Edwin J. Prindle.[1]

[1] Chairman, Patents Committee, American Engineering Council.

Dr. Millikan Awarded Edison Medal

THE Edison Medal for 1922 has been awarded to Dr. Robert A. Millikan, of Pasadena, Cal., for "his experimental work in electrical science." The experiments for which he is best known are those dealing with the isolation of the electron.

After receiving the degrees of A.B. and A.M. from Oberlin College Dr. Millikan began teaching physics at the University of Chicago, becoming professor of physics in 1910 and remaining in that capacity until 1921. Since that time he has been director of the Norman Bridge Laboratory of Physics and chairman of the administrative council of the California Institute of Technology. He was granted a Ph.D. from Columbia in 1895 and holds degrees from several other universities in this country and Germany.

Dr. Millikan has written a number of books on physics, besides contributing to the technical press on this subject. He has rendered valuable service as vice-chairman of the National Research Council since 1917 and was a member of the board of editors of the *Physical Review* from 1911 to 1914. In 1913 he was awarded the Comstock prize for research in electricity. Recently Dr. Millikan has been conducting experiments to bridge the gap between light and X-ray phenomena.

Among other recipients of the Edison Medal have been Elihu Thomson, George Westinghouse, Alexander Graham Bell, Benjamin G. Lamme, W. L. R. Emmet, Michael I. Pupin, and C. C. Chesney.

I.E.E. Appoints Gano Dunn Honorary Secretary for United States

THE COUNCIL of the Institution of Electrical Engineers, of Great Britain, has appointed Gano Dunn, president of the J. G. White Engineering Corporation, New York City, honorary secretary of the Institution for the United States, to succeed the late G. G. Ward.

Mr. Dunn is an eminent figure in engineering and will be able to render the Institution valuable service as its local secretary. His association with the J. G. White Engineering Corporation dates from 1913, and for two years previous to that he was vice-president in charge of engineering of the J. G. White & Co., Inc. He was born and educated in New York City, receiving the degree of B.S. and M.S. from the College of the City of New York, and E.E. and honorary M.S. from Columbia.

As a member of numerous technical societies and organizations Mr. Dunn has a wide acquaintance among the engineers of this country. He has served as an officer at two international electrical congresses, the one at St. Louis in 1904 and that at Turin in 1911. He was a delegate to the Second Pan-American Scientific Congress in Washington, 1915, and has served on the Nitrate Commission of the War Department and on the Engineering Committee of the Council for National Defense. He has been a member of the International Electrotechnical Commission, vice-chairman of the National Research Council, chairman of Engineering Foundation, and president of the A.I.E.E., the U.E.S., and the John Fritz Medal Board of Award. He belongs also to the National Academy of Sciences, the Association of Iron and Steel Electrical Engineers, the American Society of Civil Engineers, The American Society of Mechanical Engineers, and The Franklin Institute, as well as to many other technical and fraternal organizations.

New Honors for Colonel Dwight and Mr. Rand

"AN EVIDENT manifestation of the good feeling which exists between the technical men of South Africa and those of the United States" is the light in which the American Institute of Mining and Metallurgical Engineers, in its journal, *Mining and Metallurgy*, views the election of its president, Col. Arthur S. Dwight, to honorary membership in the Chemical, Metallurgical and Mining Society of South Africa. In the conferring of honorary membership upon Charles F. Rand, chairman of the Engineering Foundation, by the Association of Members of American National Engineering Societies in Cuba, a similar internationality of engineers is seen. Both of these engineers have been previously honored by foreign countries, France bestowing upon each the Cross of the Legion of Honor for distinguished service to France and to civilization, and King Alfonso decorating Mr. Rand for his achievements in the development of Cuban iron mines.

Dr. Rosenhain to Lecture in Eastern States

DURING February and March Dr. Walter Rosenhain, head of the metallurgical department of the National Physical Laboratory at Teddington, England, will tour the eastern states, lecturing before various universities and technical organizations on metallurgical subjects. Dr. Rosenhain comes to this country under the auspices of the Institute of Metals Division of the American Institute of Mining and Metallurgical Engineers, and will deliver the second annual Institute of Metals lecture, on Solid Solutions, before that body on February 19. Subjects of other lectures will be Hardness and Hardening, The Structure and Constitution of Alloys—to be delivered before Franklin Institute on February 15—Strain and Fracture in Metals, Aluminum Alloys, and Metallurgical Research at the National Physical Laboratory. His itinerary will include Lehigh, Columbia, and Yale Universities, Production Club (Waterbury, Conn.), Massachusetts Institute of Technology, Case School of Applied Science, American Society for Steel Treating (Detroit), University of Illinois, and Engineers' Club of Dayton.

The Charles A. Coffin Foundation

THE General Electric Company, as an expression of appreciation of the constructive service which its founder, Charles A. Coffin, has rendered the electrical industry, has established a fund of $400,000, the income from which is to be used to encourage and reward similar services.

Mr. Coffin, who has been identified with the development of the electrical industry since 1882, founded the General Electric Company and was its leader for thirty years. He retired from active business in May, 1922. The Charles A. Coffin Foundation, created at that time by the Board of Directors of the General Electric Company, is under the direction of a Foundation Committee appointed by the board. The income from the fund recently set aside by the company will be distributed annually in four ways, as follows:

1 Eleven thousand dollars in prizes for the most signal contributions by employees of the General Electric Company toward the increase of its efficiency or progress in the electrical art

2 A gold medal to the public-utility operating company within the United States which, during the year, makes the greatest contribution toward increasing the advantages of the use of electric light and power for the convenience and well-being of the public and the benefit of the industry. The company receiving the medal will also receive one thousand dollars for its employees' benefit or similar fund

3 A gold medal to the electric railway company within the United States which during the year, makes the greatest contribution toward increasing the advantages of electric transportation for the convenience and well-being of the public and the benefit of the industry. The company receiving the medal will also receive one thousand dollars for its employees' benefit or similar fund

4 Five thousand dollars to graduates of American colleges and technical schools who, by the character of their work, and on the recommendation of the faculty of the institution where they have studied, could with advantage continue their research work either here or abroad; or some portion or all of the fund may be used to further research work at any of the colleges or technical schools in the United States. The fields in which these fellowships and funds for research work are to be awarded are electricity, physics, and physical chemistry.

The progress report of the United States Coal Commission which was issued January 15, is the first tangible result of this experiment in basing important economic legislation upon careful investigation. John Hays Hammond, chairman, and George Otis Smith are the engineers on the Commission. E. E. Hunt, a member of the F.A.E.S. Committee on Elimination of Waste is Secretary to the Commission.

Art and the Engineer

VISITORS to the Engineering College of the University of Cincinnati are struck with the artistic atmosphere of the buildings. In place of the starkly framed photographs of machines and locomotives which usually add to the scholastic and technical atmosphere of an engineering school, they find there paintings in oils and water colors of a remarkably high order. Glances at the title plates on the pictures disclose the fact that the paintings in most cases have been presented to the University by the students themselves.

This interest in art at the Engineering College of the University of Cincinnati is of long standing. It has been fostered by Dean Schneider, who believes that the engineering student should be stimulated in art, music, and literature, not only because of the enjoyment and relaxation which an appreciation of art affords, but also because a student well grounded in cultural subjects makes a better engineer. It is possible to introduce him to the liberalizing influences of history and literature through the regular college courses, but a sustained interest in art can be secured only by furnishing him with actual and more or less constant contact with the artistic.

The transformation of the corridors into an art gallery was started in 1916 with the mural decoration of the Library. Upon graduation each class gives a fund varying from six hundred to twelve hundred dollars, while various groups, such as student branches of the national engineering societies, have donated smaller amounts. These gifts have been entirely voluntary and have resulted in a collection of more than fifty paintings, only six of which have not been given by the students.

To maintain the excellence of the collection, the standard for permanent hanging in the Cincinnati Art Museum has been adopted for pictures in the College of Engineering. The Director and Curator of the Museum are consulted in the purchase of pictures. This high standard, and the fact that the pictures become the property of the city of Cincinnati to be hung in perpetuity in a fireproof building of the University, have secured the coöperation of the artists, with resultant benefit to the collection.

The collection is worth study by any engineer who is within reach of it, whether he be an art connoisseur or not. The interest it arouses among students, apparent continually as one passes through the corridors, is ample proof that it must be effective in the lives and works of the engineers who graduate from the University. The competitive system of industry in America has left little time for technical men to study and appreciate the real economic value of culture. So rapid has been our industrial growth that the ideal and artistic aspects of industry have sometimes been forgotten.

Engineers, however, have recognized for some time that wall paper and bridges should be beautiful as well as utilitarian—that machinery should always be the servant of man and, wherever possible, the servant of art. The Engineering College of the University of Cincinnati is graduating men who have learned beauty of line and color through actual contact with it, and who carry with them into the business and industrial world an appreciation of art which is entirely in keeping with the dignity of the profession they have entered.

To fill properly his place, the engineer of tomorrow should be well-rounded in painting and architecture, the arts intimately associated with the guiding ideals of permanence and beauty.

Newly Elected Officers of American Engineering Council, Governing Body of the F.A.E.S.

Caetani Welcomed by Engineering Council

Italian Ambassador States Need for Engineering Logic in Public Affairs. Enthusiasm and Action Mark Second Annual Meeting of F.A.E.S. Dean Cooley Re-elected President. Constitution to Be Revised. Notable Resolution Adopted Stating Need for Broader Engineering Training

INTENSITY of purpose and enthusiasm marked the Second Annual Meeting of the American Engineering Council, the governing body of the Federated American Engineering Societies, which was held in the Cosmos Club, Washington, D. C., for two days, January 11 and 12, 1923. The climax occurred during the dinner on the opening evening of the session, at which the guest of honor and principle speaker was the Ambassador from Italy to the United States, Prince Gelasio Caetani, an American engineering graduate and for thirteen years engaged in engineering work in this country. Following the meeting of the Council, the executive Board met to organize the work for the current year.

The Dinner

Dean M. E. Cooley, re-elected President of the Council during the proceedings of the day, presided over the dinner at the Chevy Chase Club. The first speaker of the evening was the Honorable John James Tigert, United States Commissioner of Education. Mr. Tigert is an able orator and his address was a graphic picture of the popular conception of the engineer. He was followed by Secretary Calvin W. Rice, of the American Society of Mechanical Engineers who gave a résumé of his visit to South America where he represented a number of engineering and civic bodies at the International Engineering Congress and the Centennial Celebration of Brazil at Rio de Janerio. Afterwards he visited a number of South American countries and returned with the firm conviction that there is a remarkable opportunity for engineering coöperation with South America. Mr. Rice's inspiring report appeared in the January issue of Mechanical Engineering.

The third speaker was Dr. Elmer A. Sperry who has just returned from a trip to Japan where he presented letters of congratulation from American engineering societies to the semi-jubilee celebrations of two Japanese engineering bodies. He in turn emphasized the necessity for developing the most intimate relations with Japanese engineering organizations.

The messages of international coöperation between engineers and the sentiment expressed by Mr. Rice in his talk that an engineer visiting a foreign country is the most potent ambassador of peace and goodwill was clearly in the minds of those present when Prince Gelasio Caetani rose to begin his address. His fellow engineers gave him a sincere and warm welcome to the country where he had spent the best year of his life, leaving it only at the call of duty to perform feats of wisdom and valor for his own country in the last war. He returns as the representative of the Mussolini government and those who were privileged to meet him and hear him were convinced that his stay will be fruitful to both Italy and the United States. His personal charm and his sincerity held his audience and at the close of his speech he was given an enthusiastic ovation.

Address of Prince Gelasio Caetani

Your kind invitation to be a guest at the annual banquet of the Federation of American Engineering Societies reached me while I was preparing to leave for the United States. I read it with deep satisfaction for it made me feel that, besides sailing for America as Italy's Ambassador, I was going home to my old stamping grounds somewhat still invested with the qualifications of an engineer.

We pride ourselves in saying: "Once an engineer, always an engineer." Whatever may be the course of life followed by any of us, it will always be marked by the indelible seal of the scientific, practical and logical training to which an engineer is subjected during the early years of life.

Some have made the remark in criticism that engineers lack political intuition and ability; I would answer that a larger dose of logic and positiveness applied to politics would bring great advantages to public affairs.

Between Italy and the United States there has never existed political rivalry or serious commercial competition; our relations have been confined almost exclusively to contacts of labor, of engineering, of commerce, of science and of art. Much can be accomplished to the mutual advantage of our peoples; a large share of the success will depend upon the coöperation of the engineers and I know that I will always be able to rely on your goodwill.

I do not hesitate to state that Italy and the United States are at present the most youthful nations of the world. Italy is the oldest one in history and three times has ruled the world; once politically, once spiritually and once intellectually. However, as a political and social unit Italy did not exist from the fall of the Roman Empire to the middle of last century; as race and as nation it had an enforced rest of some fourteen centuries. With the forming of its national unity in 1870 it awakened to a new life; born again as a new being to play its role in world's history, it is healthy, fertile and exuberant of youthful energies. The best proof of this is given by the latest events which led to the establishment of a new national government. The younger and healthiest part of the people, the bulk of the nation, openly rebelled against the old ways which were leading Italy into a critical condition; not only bolshevism and anarchy have been wiped off the map, but also demagogy and all low grade politics aiming to the fostering of party and class interests. In an amazingly short time a complete change of all orders of things was effected, not a miraculous revolution, as some people have thought to style it, because the events were nothing more than a sudden realization of what had been the deep desire and the will of the people to which circumstances so far had not allowed expression. An event that within 24 hours raises the quotations of government securities and restores peace and general confidence, without a drop

of blood being shed or a windowpane broken, cannot be styled a revolution.

The other youngest nation in the world, I was saying, is the United States, the new great power of the history to come; unlimited in its financial powers, unrivaled in its capacity of organization and technical knowledge, wonderful in the possibilities of its vast empire. The coöperation of these two young countries will lead to remarkable results; both our people are laborious and have an inventive, engineering turn of mind.

Italy's largest asset is the remarkable quality of its people's labor; sober, intelligent, hardworking and plastic the Italian peasant or workman will in an incredible short time become efficient in whatever he is called to do.

Of all this many Americans are perhaps not yet fully aware for the reason that the wave of Italian emigration which shortly preceded the war was so sudden that it was not utilized to best advantage.

Much however is still to be done in Italy itself; its resources are far from being fully developed and there are many opportunities for American capital, machinery and technical organization to be usefully applied in Italy.

The electric industry in our country has made rapid strides and as to percentage of utilized water power, Italy ranks, I believe, foremost in the world. Its use results in an economy of about two billion lire, otherwise necessarily spent on fuel imports.

In 1898 the electric energy developed in Italy amounted only to 87,000 kw.; it increased to 426,000 kw. in 1908, to 1,240,000 kw. in 1918 and power plants for some other 1,000,000 kw. are planned or under construction. About 800,000 kw. are still to be developed. On the Tirso in Sardegna a reservoir of 416 million cubic meters capacity is being constructed. It will be the second largest in the world, ranging immediately after the Assuan dam and will develop some 50 million kw-hrs., and irrigate 60,000 acres of land. In the Trentino a reservoir is to be constructed on the Noce torrent of 180 million cubic meters capacity. The dam, 400 feet high, will be practically a concrete wedge driven in a mountain gully, measuring less than sixty feet wide at the base and only 100 feet wide at 300 feet above the bottom. In Southern Italy the large reservoir in construction on the Sila mountain will develop over 110,000 kw. and irrigate large tracks of fertile land. Another interesting plan which is gradually being carried through is to connect the northern power plants, fed by the summer streams of the Alps, with those of central Italy where water is plentiful in winter and rather poor in summer, by a network of high tension lines and by standardization of voltage to obtain a better seasonal compensation than could be secured by the use of even very large reservoirs.

Railroads are to be electrified and telegraphs and telephones are to be reorganized then gradually handed over to private enterprises; experience has proved that state administration of industrial concerns ends always in a financial and technical failure.

I should mention also the large works for reclaiming waste or marshy land by irrigation or drainage. There are 148 enterprises of this kind in Italy for the reclamation of some three million acres of land; of these 35 have been completed covering an area of about 820,000 acres.

My experience in the United States has been my most valuable asset in life. Before leaving Rome, at a dinner given to me by the Italian engineers, I exhorted the young engineers to get a few years of practical training in America. I hope you will do likewise by encouraging your students and graduates to spend some time in Italy as nothing broadens the mind more than to breathe an atmosphere different from that of one's own town and country. Italy's atmosphere is vibrating with wonderful reflexes of a long and glorious past and full of promise for a remarkable future. It is a great art in life to single out and appreciate other people's good qualities and try to make them your own. Similar intercourse between our young students who, in a few years, will be the active men of our countries, will be a powerful factor in reaching the principal and ultimate aim I will have in view in carrying out my duty as Ambassador, that is to strengthen the bonds of friendship and esteem between Italy and the United States.

The Business Session

The opening event at the first business session on January 11 was the presentation of a report by President Cooley, who told of his visits to many local engineering societies during the year. He called for the support of each member of the Council in interesting and inspiring the engineers of the country in the tremendous problems that are facing present day civilization.

Secretary Wallace then related the progress that had been achieved in the work of the Council during the past year. In addition to the routine matters handled by the executive office, Mr. Wallace told of the international interest expressed in the report on Waste in Industry and the Twelve-Hour Shift in Industry. He stated that the Council was firmly established in the mind of official Washington as the representative of a profession that was striving to give disinterested service for the common good. He related the efforts in presenting the facts about a national hydraulic laboratory for the study of river flow and the successful outcome of the struggle on the floor of the House of Representatives for an increased appropriation for topographic mapping. He pointed out however, that while the general information among engineers about the Council and its work was very much better during 1922 than in preceding years, still there was a very severe problem of conveying to every engineer in the United States the importance, the significance and the potentiality of the Federated American Engineering Societies and the American Engineering Council, its governing body.

The report of the treasurer, W. W. Varney, showed a balance of about five hundred dollars for the fiscal year of 1922. Later in the day a budget for the year 1923 of $45,000 was approved. The representatives of the local societies signified their willingness to pay the full assessment of one dollar per member instead of accepting a reduction voted.

Election of Officers

Under the interpretation of the Constitution that the ineligibility of a president for re-election does not apply when the present incumbent is filling out an unexpired term, Dean Mortimer E. Cooley was re-elected as president of the American Engineering Council for a term of two years. Dean Cooley is a member of the delegation of The American Society of Mechanical Engineers. Calvert Townley of the American Institute of Electrical Engineers Philip N. Moore, of the American Institute of Mining and Metallurgical Engineers and Gardner S. Williams of the Detroit Engineering Society were elected as vice-presidents. Mr. Williams was chosen to fill the unexpired term of Dean Dexter S. Kimball of one year and the others will serve the term of two years. Dr. Harrison E. Howe, of the American Institute of Chemical Engineers was elected Treasurer.

Publications

Several times during the meeting the question of the scope and character of a publication for the Council was taken up and discussed. The representatives of the local engineering societies were convinced that a publication was vitally essential and seemed in agreement that it be frequent and of small size. Many expressed the opinion that a publication was the answer to the problem of getting and holding the interest of the individual member of the constituent bodies. The matter was thoroughly discussed and was left to the executive board for the determination of a policy. The present monthly bulletin is to be continued and a resolution was passed which will make it possible to secure second-class mailing rates. The Council also favored the suggestion that a joint news publication of the national engineering societies and the F.A.E.S. be established.

Revision of Constitution

The Council acted favorably on the recommendation of the Executive Board that a committee be appointed to revise the constitution of the Federated Engineering Societies. In the discussion of this motion it was apparent that the members of the Council were in agreement that this be no mere editing but a thorough revision based on a study of the fundamental principles that have been established during the two years of the Council's operation. One action of the Council which may have some effect on the revision of the governing laws was the passage of a resolution that advice and assistance be solicited from each constituent body in so far as this can be done without delaying action.

Two revisions of the by-laws amounting only to interpretations were passed and one change relating to allied technical organizations in foreign countries was laid on the table. It was also decided to provide by constitutional amendment for alternates both for members of Council and for the Executive Board. The consensus of sentiment favored the practice of alternates to the Executive Board being members of the Council.

Government Activities

Several very important actions of the Council related to activities of the Government.

The Council passed the resolution proposed by a committee of the Council at the request of the Boston Society of Civil Engineers recommending that the administration of the Federal Water Power Act be rendered more effective by the maintenance of a permanent, adequate, trained personnel solely for this purpose.

A second resolution recommended that the Bureau of Foreign and Domestic Commerce be authorized to collect and disseminate facts relating to the operation of business.

Compensation and classification of government employees, especially engineers and patent examiners, was given long and careful consideration. The Patents Committee pointed out the need for high grade examiners in the Patent Office which the present government regulations will not permit. The importance of uniform rates of pay for similar kinds of work in different departments was also emphasized. Accordingly, the Council passed a resolution recommending to Congress that adequate rates be provided for the technical employees of the government.

Reforestation

The Committee on Reforestation reported a program by which the entire engineering profession and the public will be educated as to the need for immediate action in reforestation. The perpetuation of the timber supply of the country is a problem that vitally affects, not only the industries that use lumber but also the water supply and the water-power of the future.

Industrial Ideals and Education

Perhaps the most important pronouncement of the Council during the recent meeting was the resolution proposed by the Committee on Industrial Ideals. This resolution relates primarily to the increased present day responsibility of the engineering educator. Many times in discussion of other topics, this responsibility was emphasized and after the passage of this resolution, Professor C. F. Scott, a delegate of the American Institute of Electrical Engineers and President of the Society for the Promotion of Engineering Education told of the remarkable plan developed by the last named society for the preparation of a statement of the fundamentals of engineering education, vital if the engineer is to undertake his great responsibility in the maintenance and development of civilization.

The resolution follows:

Resolved That: The American Engineering Council by action at its meeting on January 11, 1923, desires, on behalf of the Federated American Engineering Societies, to bring to the attention of the engineering colleges throughout the country the need of pointing engineers toward leadership in public affairs.

For a century engineers have directed their energy toward the utilization of the physical forces and the materials of nature. The developments which they have brought about have created an epoch in human history. While these developments have been of inestimable benefit, and modern society could not exist without them, they have introduced many public problems and social readjustments, so closely related to the engineer's activities, that it is increasingly evident he must assume an active part in their solution.

Recognizing this growing need, the engineers of the country formed the Federated American Engineering Societies, primarily to place their knowledge and training at the public service on all public matters affecting engineering, or affected by it.

Engineering education, reflecting closely the attitude of engineers heretofore, has confined its work almost exclusively to scientific and technical training, giving little, if any attention to the social and human aspects of engineering enterprises The American Engineering Council therefore, speaking for the engineering profession, urges upon engineering colleges an increased attention to the social aspects of engineering activities, and a broadening of their technical training, in every way possible, to develop in engineering students the spirit of, and a capacity for, active leadership not only in industry, but in public affairs.

Wellman Memorial Meeting

A notable meeting in honor of Samuel T. Wellman, Past-President A.S.M.E., was held in Cleveland, Ohio on Tuesday Evening January 9th, by the members of the local sections of national engineering societies coöperating with the Cleveland Engineering Society in a series of meetings on the "Iron and Steel Indystry," which are being given by the Associated Technical Societies of Cleveland. The Sections coöperating were:

The American Association for Steel Treating,
The American Chemical Society,
The American Society of Mechanical Engineers,
The American Institute of Mining and Metallurgical Engineers,
The American Association of Iron and Steel Electrical Engineers.

The attendance was large and among those present were many of the prominent engineers of Cleveland and the vicinity, especially the older men who had known Mr. Wellman and his achievements from personal observation over a period of many years that they had together struggled in not only the development of the steel industry but also of the many devices originated in Cleveland, which have contributed so much to the success of the iron and steel industry in America. Mr. Wellman was Past President and also an Honorary Member of the Cleveland Engineering Society.

The meeting was presided over by Mr. F. L. Sessions, Chairman of the Cleveland Section of the American Society of Mechanical Engineers.

The first speaker was Mr. James H. Stratton, a former associate of Mr. Wellman and Engineer of Construction at the Wellman-Seaver-Morgan Co., Cleveland, Ohio. Mr. Stratton in his very fitting remarks regarding Mr. Wellman, stated that one of the best records we have of his achievements were written by Mr. Wellman himself for use in his presidential address[1] before the Annual Meeting of the American Society of Mechanical Engineers in December, 1901.

The first speaker was Ambrose Swasey who had been a life-long friend of Mr. Wellman. Mr. Swasey related many incidents that occurred in their extended travels together which displayed the remarkable qualities of the man. In closing, Mr. Swasey said:

"Mr. Wellman built along broad lines, with noble purposes. He gathered himself friends who were the captains of the steel industry, such as Alexander Holley, Captain Jones of Pittsburgh, and John Fritz. It was Mr. Wellman who called a number of prominent engineers and manufacturers together to give consideration to the celebration of Mr. Fritz's eightieth birthday. The outcome of that conference was a dinner held in the fall of 1902 to celebrate that birthday and at that dinner, the John Fritz medal was established, the greatest honor in the hands of the engineers of America."

The splendid, exceptional steel which Mr. Wellman produced, the wonderful mechanisms which he designed and constructed and sent out into the world, contained those same genuine, dependable qualities which Mr. Wellman possessed to such a remarkable degree. And how true are the words of the young poet Longfellow as regards Mr. Wellman's life and work, "We potters make our pots of what we potters are."

Mr. Clifford C. Smith paid a tribute to Mr. Wellman's foresight shown in his work of improving and developing the basic open-hearth process, the open-hearth charging machine, the ingot charger for the blooming mill and the lifting magnet for handling steel. He also testified to Mr. Wellman's knowledge of paintings, pottery and photography and architecture and the manner he stimulated admiration for these finer things in all those with whom he had contact.

The other speakers were John McGeorge, E. Francis, F. Moeller, A. D. Hatfield and W. G. Hildebran all of whom had been closely associated with Mr. Wellman in various capacities. They related many of the intimate incidents of his life that showed his all around greatness.

In later meetings of the year, the Cleveland Sections of the National societies will discuss the technical phases of the iron and steel industry. Each section will have charge of one meeting.

Standards for Herringbone Gears for General Commercial Use

Proposed by the A.E.S.C. Sectional Committee on the Standardization of Gears

THE May, 1922, issue of MECHANICAL ENGINEERING contained reprints of the first five gear standards prepared by the Sectional Committee on the Standardization of Gears for which the American Gear Manufacturers Association and The American Society of Mechanical Engineers are joint Sponsors. These five standards having been carefully revised as a result of the criticisms and suggestions received are now before the Sponsor Bodies for final approval and submission to the American Engineering Standards Committee as Tentative American Standards.

At the September meeting the Committee put the finishing touches to the sixth of the gear standards to be completed, and it has recently presented to the Sponsor Bodies this proposed standard for Herringbone Gears for General Commercial Use. This standard is printed below in full for the information of the readers of MECHANICAL ENGINEERING and also to enable them to criticise and comment on this proposal to the Sponsor organizations. All communications should be addressed to Mr. C. B. LePage, Assistant Secretary, The American Society of Mechanical Engineers, 29 West 39th Street, New York.

STANDARD TOOTH FORM

1 *Pressure Angle.* The pressure angle in plane of rotation of gear equals 20 deg.

NOTE: The angle of the cutting tool in the normal plane of the gear at the pitch is 18 deg. 31 min.

2 *Addendum* $= \dfrac{0.8}{P}$

NOTE: P = diametral pitch in plane of rotation.

3 *Dedendum* $= \dfrac{1}{P}$

4 *Clearance* $= \dfrac{0.2}{P}$

5 *Whole Depth* $= \dfrac{1.8}{P}$

6 *Helical Angle.* The helical angle of teeth with axis equals twenty-three (23) degrees.

NOTE: The helix angle of a helical gear is the angle between the helix at the pitch diameter and a plane which contains the axis of the gear.

7 *Enlargement for Pinions.* The enlargement for pinions with 17 teeth or less is given in Table 1.

NOTE (*a*): Enlargement for any given pitch is found by dividing the value given for 1 pitch for the number of teeth desired, by the pitch required.

NOTE (*b*): Calculate the outside diameter as usual, then add the amount of enlargement to the pinion and subtract the same amount from the gear. Use only when pinion has 17 teeth or less.

GEAR-BLANK DIMENSIONS

8 *Pitch diameter* $= \dfrac{N}{P}$

NOTE: N = number of teeth.

9 *Outside diameter* $= \dfrac{N + 1.6}{P}$

10 *Active Face.* Minimum width of active face $= \dfrac{1.6}{P}$

NOTE: Total face is the width of the gear including the groove. Active face equals the total face minus the width of the groove.

11 *Groove.* The width and depth of groove in center of blank for gears cut with hobs at right angles to the axis of the gear are given in Table 2. The letters A, B, and C in the table refer to Fig. 1.

Coöperation between Federal Specifications Board and Industry Promoted by A.E.S.C.

AN IMPORTANT step toward the elimination of the differences between specifications for Government purchases and the usual practice of commercial suppliers has been taken through the appointment by the American Engineering Standards Committee of a standing Committee on Coöperation with the Federal Specifications Board. Such differences in practice between Government and commercial orders are often responsible for the statement, common in commercial circles, that it costs 10 per cent more to do business with the Government than with other customers.

The members of the Committee on Coöperation with the Federal Specifications Board are:

A. H. HALL, *Chairman*, assistant treasurer and superintendent of distribution, Central Union Gas Company, New York City.

JOHN A. CAPP, chief of the testing laboratory, General Electric Company, Schenectady, New York.

SULLIVAN W. JONES, chairman, Structural Service Committee, American Institute of Architects, 19 West 44th Street, New York City.

The appointment of this committee is the culmination of conferences between Dr. S. W. Stratton, Chairman of the Federal Specifications Board, other Government officials, and representatives of industry extending over a period of several months. It is expected that in future editions a large part of the specifications will go through the regular procedure of the American Engineering Standards Committee, in order that the industrial and government specifications may be unified, resulting in truly national specifications recognized by industry and Government alike.

It is the unanimous opinion of the Federal officials and the officers of the A.E.S.C. that this coöperation between manufacturing industries, the Government and other consumers produced a widening of the source of supply for all Government requirements and in economies running into many millions of dollars yearly.

The Federal Government is one of the largest purchasers of industrial products, both as to the amount and the range of supplies. The diversity of the various Government specifications, their departures from usual commercial production, and the special features frequently required became very troublesome to the manufacturing industries; this remained true to a large extent until very recently. This Board has adopted nearly 40 specifications and is actively at work on many more.

It is the aim of the Federal Specifications Board to bring into line with the best commercial practice, not only the specifications which are to be approved by the board in the future, but also those which have already been approved. The latter will be accomplished when the approved specifications come up for review and possible revision. Such review is planned at intervals of one year.

System for Numbering Steels to be Developed Under Procedure of A.E.S.C.

A SYSTEM of designating kinds or qualities of steels by code numbers, each of which would represent a definite specification, will be developed as a result of the decision of a conference of the principal producers and users of steel held at Washington, D. C., December 6, at the call of the American Engineering Standards Committee. The conference recommended that this code be developed under the procedure of the A.E.S.C. and suggested to that organization the appointment of the Society of Automotive Engineers and the American Society for Testing Materials as joint sponsors for the code.

The agreement to go ahead with this project was arrived at after a spirited discussion concerning the necessity for and practicability of a numbering system. Strong opinions in favor of the designation of steels by number were voiced by heavy buying interests, such as the U. S. Navy Department, the Electrical Manufacturers' Council, the Society of Naval Architects and Marine Engineers, the U. S. War Department, and the Federal Specifications Board. It was pointed out during this discussion that shipbuilders use every conceivable variety of steel. Opposition to the inclusion of tool steel was voiced by tool-steel makers.

The conference voted that it is desirable to have a uniform numbering system, based on specifications, for forging steels, casting steels, structural steels including plates, tool steels, and other steels, this decision, with the exception of tool steels, being taken without dissent. Whether the basis for such a numbering system should be chemical composition, physical properties, or heat treatment was left to be determined by a Sectional Committee the personnel of which is to be approved by the American Engineering Standards Committee. It was also left to the Sectional Committee to decide whether there are any existing systems which can be used as a basis for numbering codes for any or all of the various groups of steels. The question of whether brand names can be accommodated to and associated with a numbering system was brought up, but the consensus of opinion was that this is not practicable.

The conference was opened by a résumé of present American practice in designating steels by Dr. G. K. Burgess, Chief of the Division of Metallurgy of the U. S. Bureau of Standards, and a résumé of European practice by L. H. Fry, representing the American Society for Testing Materials. Mr. Fry said that Switzerland and Germany have already taken definite steps toward a numbering system. The method proposed in Switzerland provides a system of symbols intended to be universal and definite, and capable of expansion to suit new requirements. In France a method is offered by which steels will be numbered with relation to a definite specification for the type, augmented by a letter indicating the method of manufacture, and a number showing the minimum tensile strength. In Great Britain a numbering system is employed for aircraft steels, and a tendency is appearing to develop symbols for automobile steels. Some limited symbolization is used in Holland also. A copy of Mr. Fry's full report, which is based on information obtained from abroad by the A.E.S.C., will be sent upon request to the American Engineering Standards Committee.

Dr. Burgess presided at the conference, which was attended by thirty-two men representing twenty-two organizations.

The recommendations of the conference were presented to the American Engineering Standards Committee, at its meeting on December 14. The Committee took the following action:

Resolved, That the American Society for Testing Materials and the Society of Automotive Engineers be designated joint sponsors for the development of a numbering system for forging, casting, and structural steels, including plates, but not including tool steels, the numbering system to be based on definite specifications, and—

Resolved, That for the present the question of developing such a numbering system for tool steels be held in abeyance.

Standards for Herringbone Gears

(*Continued from page 145*)

for gears cut by planing or shaping methods equal respectively:

Width = $1^1/_8$ in.

$$\text{Depth} = \frac{1.8}{P} + \text{suitable clearance.}$$

14 *Horsepower Rating.* For Pitch-Line Velocities up to 2000 Feet per Minute:

$$\text{Horsepower} = \frac{WV}{33{,}000}$$

where $W = \frac{S}{2} PFYK$

(Formula safe for wear when well oiled. For grease lubrication multiply by factor of from 0.8 to 0.62)

W = load in pounds
S = working stress (no speed) (See Table 4)
P = circular pitch
Y = tooth-form factor from Table 4
F = width of active face in inches. (For continuous contact of teeth, minimum face = 6 P)
K = speed factor from Table 4
V = pitch-line velocity in feet per minute

LIBRARY NOTES AND BOOK REVIEWS

A Dictionary of Applied Physics

Dictionary of Applied Physics, Edited by Sir Richard Glazebrook, in 5 Volumes. Vols. 1 (Mechanics, Engineering, Heat) and 2 (Electricity) Macmillan Co., London, 1922. Cloth, 6 × 9 in., 1067 pp. and 1104 pp., illus. Price $15.00 each.

A fundamental work, the various sections of which have been prepared by men of international reputation in their particular lines.

The mechanical engineer will be particularly interested in the first volume, which covers mechanics, engineering, and heat. As an illustration of the extensiveness of treatment of the various subjects considered, it may be noted that the physics of the steam turbine are treated by Gerald Stoney and Telford Petri in a 20-page article, and that the development of the steam turbine is discussed by Robert Dowson in an additional 18 pages. Other subjects are dealt with on a similar generous scale, both as regards the space devoted to them and thoroughness of handling. Many of the articles represent a successful attempt to bring together in a concise and craftsmanlike form the latest information on recent tendencies in machine design. Such, for example, are the article on the balancing of engines and prime movers (Vol. 1, pp. 252–267), by Wm. Ernest Dalby and the extremely interesting contribution on elastic constants (Vol. 1, pp. 115–241) by Reginald G. Batson.

One cannot help feeling, however, that certain subjects have been treated all too briefly. For example, the eleven pages devoted to the theory of elasticity by R. V. Southwell, notwithstanding their interest, do not present the matter as completely as the importance of the subject warrants.

It would appear generally that the Dictionary of Applied Physics places limits on the space devoted to strictly engineering developments that have been extensively covered by treatises: for example, the whole subject of refrigeration receives only 13 pages, and even the important matter of cryogenation (liquefaction of gases) is handled in eight pages; on the other hand, the subject of the realization of an absolute scale of temperature is given thirty-five pages.

Notwithstanding this apparent (and it is only apparent) inequality of treatment, the two volumes thus far issued represent not only a tremendous amount of work, but what is more, a fairly complete summary of our knowledge of applied physics within the range treated, and as such they are on a par with works such as Thompson and Tait's Natural Philosophy.

Among the subjects to which considerable space is devoted the following may be cited: Ship Resistance, Geo. S. Baker; Kinematics of Machinery, Chas. H. Bulleid; Reciprocating Steam Engine, Andrew Cruickshank; The Water-Cooled Petrol Engine, Aubrey T. Evans; Simple Harmonic Motion, Horace Lamb; Stream-Line Motion, Horace Lamb; Friction, T. E. Stanton; Thermodynamics of Internal-Combustion Engines, Sir Dugald Clerk; Theory of Steam Engine, Sir James A. Ewing; Latent Heat, Ezer Griffiths; Conduction of Heat: Mathematical Theory, Horace Lamb; Thermal Expansion, Alfred Wm. Porter; and Specific Heat of Gases, David R. Pye.

Analysis of Rubber. By John B. Tuttle. Chemical Catalog Co., N. Y., 1922. (American Chemical Society. Monograph Series.) Cloth, 6×9 in., 155 pp., $2.50.

A detailed critical summary of methods for the analysis of rubber and rubber goods, addressed primarily to chemists in consumers' laboratories and to those without previous experience in the technology or analysis of rubber. Includes an extensive bibliography. In addition to analytical methods, the book contains brief accounts of the composition of crude rubber, the preparation of rubber compounds, the theory of vulcanization and methods for physical testing.

Chauffage des Chaudières au Charbon Pulvérisé. By Michel Sohm. Chaleur et Industrie, Paris, 1922. Paper, 9×11 in., 38 pp., illus., diagrams, 4 fr. 25.

The Compagnie des Mines de Bruay has recently installed, in its electric plant at Labuissière, a powdered-coal plant for firing its boilers, which is one of the largest in Europe. This pamphlet, by the engineer in charge, describes the plant in great detail, together with its constituent parts, gives a record of the results obtained in operation and conclusions as to the merits of pulverized coal.

Diesel Engines for Land and Marine Work. By A. P. Chalkley. Fifth edition. D. Van Nostrand, N. Y., 1922. Cloth, 6×9 in., 330 pp., illus., diagrams, tables, $6.

Since the last edition of this work was published in 1915, the Diesel engine has been greatly developed and adopted much more widely. Many new manufacturers have arisen and many new types have been developed. In the present revised edition, these new engines have been dealt with as fully as possible and their salient features described. In addition to descriptive matter, the theory, installation, testing, operation and design of Diesel engines are treated.

Elasticity and Strength of Materials Used in Engineering Construction. Section 1. By C. A. P. Turner. Published by the Author, Minneapolis, Minn., 1922. Cloth, 6×9 in., 85 pp., illus. tables.

This volume is intended to demonstrate the fundamental principles upon which rational analysis may be founded and to discuss the properties of the commonly used materials from the point of view of elasticity. It presents, for the first time, a development of the relations of residual to elastic strain sufficient to account for elastic phenomena not understood heretofore and discusses the error resulting from general misunderstanding of these relations. Here is also demonstrated, for the first time, that there is but one independent modulus of elasticity for the resistance of a homogeneous isotropic solid. The relative value of the coefficients for such a body and their modification by residual strain are investigated.

Engineering Inspection. By E. A. Allcut and Chas. J. King. Van Nostrand Company, N. Y., 1922. Cloth, 7×10 in., 187 pp., illus., diagrams, tables, $5.

Much descriptive matter has already been written on the details of the various inspection methods used in different engineering works, but the object of this work is to present a convenient description of the various principles involved in the inspection of an engineering job from the raw material to the finished job. The examples given are representative ones, illustrating the different principles of inspection and measurement in common use. The book is confined to mechanical-engineering operations.

Engineering Workshop Handbook. By Ernest Pull. Fifth edition. D. Van Nostrand, N. Y., 1922. Cloth, 4×7 in., 175 pp., illus., diagrams, tables, $5.

This little pocketbook is intended for apprentices and machinists. It includes workshop mathematics, the heat treatment of metals, descriptions of the common tools and machines and of the usual operations, lathe work, screw cutting, drilling, planing, milling, grinding, etc. The book will be useful to beginners.

Etude sur le Ballon Captif et les Aéronefs Marins. By Charles Lafon. Gauthier-Villars et Cie, Paris, 1922. Paper, 7×10 in., 206 pp., 20 fr.

Although the elongated captive balloons known as "sausages" have been used by the French navy since 1917, there has not existed, until now, an exact theory of the equilibrium of the balloons watching over moving vessels. The present volume presents important scientific ideas upon towed balloons and naval aerial tactics. It also contains new data and diagrams of interest in the navigation and maneuvers of naval forces.

Flow of Gases in Furnaces. By W. E. Groume-Grjimailo. With an Appendix upon The Design of Open-Hearth Furnaces, by A. D. Williams. John Wiley & Sons, N. Y., 1923. Cloth, 6×9 in., 399 pp., illus., $5.50.

Upon the basis of extended observations in practice and careful experimental researches, Professor Groume-Grjimailo has formulated a hydraulic theory of flow of heated gases, developed the laws governing this flow, and shown how these may be applied in designing furnaces for industrial purposes. Extensive appendices, amounting to over one-half of the text, contain formulas and tables upon gas flow and arch brickwork, together with several articles by Mr. Williams, treating of the design of open-hearth furnaces and hot-blast stoves, combustion and boiler settings, and heat-capacity and calorific-intensity curves.

La Force Motrice Electrique dans L'Industrie. By Eugéne Marec. Gauthier-Villars et Cie., Paris, 1922. Paper, 7×10 in., 613 pp., illus., diagrams, 55 fr.

A practical treatise for engineers interested in the industrial application of electric power. Intended to explain the fundamental characteristics of commercial electric machines, in order to facilitate the choice of proper equipment, and to explain how this equipment should be installed, operated, and maintained. Includes descriptions of accessory machinery and equipment, and shows many examples of the application of motor drive to various classes of machinery.

Les Hélicoptères. By W. Margoulis. Gauthier-Villars et Cie., Paris 1922. Paper, 6×9 in., 90 pp., diagrams, 10 fr

Part one of this volume is based on M. Margoulis's experimental investigation of screw propellers, which has enabled him to trace, for the first time, the characteristic curves of the most general action of a screw propeller. In the second part, the results of experience are applied to the study of the flight of a helicopter, in vertical and oblique flight.

Industrial Applications of X-Rays. By P. H. S. Kempton. Isaac Pitman & Sons, London, 1922. (Pitman's Technical Primers.) Cloth, 4×7 in., 112 pp., illus., 2s. 6d.

A concise account of the apparatus used to produce X-rays and the methods of using them to examine metals, non-metals and composite structures of various kinds. A bibliography is also included.

Introduction to the Calculus. By William F. Osgood. Macmillan Company, New York, 1922. Cloth, 5×8 in., 449 pp., $-.90

A revision of the author's First Course in the Differential and Integral Calculus. The plan of treatment is the same, but the presentation is fuller. The objects of the book are to set forth the application of the calculus to problems of geometry and physics of the first order of importance, and to make clear the thought that underlies the calculus. The book is intended for the engineer, the physicist and the student of pure mathematics.

Lubrication and Lubricants. By J. H. Hyde. Isaac Pitman & Sons, London, 1922. (Pitman's Technical Primers.) Cloth, 4×7 in., 114 pp., illus., diagrams, tables, 7×4 in., cloth, $0.85.

Outlines, in as simple a manner as possible, consistent with the assumption of a general knowledge of engineering terms, the function of lubricants, the types, their application, the nature of friction and the theory of lubrication. Methods of mechanical, physical and chemical testing are described, recent developments in lubrication are discussed and a number of important examples of lubrication and lubricators are given.

Measurement of Gas and Liquids by Orifice Meter. By Henry P. Westcott and John C. Diehl. Second edition. Metric Metal Works, Erie, Pa., 1922. Fabrikoid, 5×8 in , 434 pp., illus., diagrams, tables, $4.50.

Authoritative information on the orifice meter and its uses for measuring air, steam, water and oil. The first section of the book gives general information on the meter. Section two discusses the physical properties of fluids. Section three is devoted to measurement by orifice meter, while the remaining sections describe its application for various purposes.

Mechanical Handling and Storing of Material. By George Frederick Zimmer. Third edition. D. Van Nostrand, N. Y., 1922. Cloth, 8×11 in., 804 pp., illus., diagrams, $15.

An elaborate monograph on methods and machines for handling materials continuously or intermittently, for loading and unloading, and for automatic weighing. The most complete work in English on elevating and conveying machines, cableways, bridge cranes, warehousing machinery, etc. In this edition obsolete installations and devices have been deleted or replaced by modern examples, and the examples of American or Continental practice have been replaced by examples of British manufacture. The text has been carefully revised throughout.

Motor Vehicle Engineering; The Chassis. By Ethelbert Favary. First edition. McGraw-Hill Book Co., New York, 1922. Cloth, 6 × 9 in., 468 pp., illus., diagrams, $5.

In this volume, as in the preceding volume on engines, the author endeavors to present, in simple language and with only elementary mathematics, the information required by the automotive engineer and the designer. It is not intended as a history of automobile development, nor as a mere description of present practice as exemplified in the vehicles now being manufactured, but to explain the theory that underlies the design of the automobile chassis.

Production Engineering and Cost Keeping for Machine Shops. By William R. Basset and Johnson Heywood. First edition. McGraw-Hill Book Co., New York, 1922. Cloth, 6×9 in., 311 pp., illus., $3.50.

Written to bring practical assistance to the production managers, foremen and cost accountants of machine shops, and to give higher executives a knowledge of good shop-management practice, so that they may judge the effectiveness of the methods of their subordinates. Methods are given in detail, and the reasons explained. Language devoid of technicalities is used. The costkeeping methods described are suitable, in the author's opinion, for nine-tenths of all the American machine shops.

Production Grinding. By Fred B. Jacobs. Penton Publishing Co., Cleveland, 1922. Cloth 6 × 9 in., 238 pp., illus., $3.

Describes the methods used in representative plants for cutting and finishing machine parts. Includes the practice of the Marmon, Packard, Oakland, Chevrolet, and Ford automobile plants, methods for finishing chilled-iron valve cams, ball and roller bearing production, grinding operations in the making of dental tools, finishing calender rolls, reconditioning automobile engines, die grinding and the making of milling cutters. Full data are given concerning methods and output.

Railroad Construction. By Walter Loring Webb. Seventh edition, revised and enlarged. John Wiley & Sons, New York, 1922. Fabrikoid, 4 × 7 in., 847 pp., illus., diagrams, tables, $5.

Important changes and additions have been made in relation to the shrinkage of embankments; the laws governing the life of ties; substitutes for wooden ties; rail specifications, testing, failures, wear; rail-joint failures; water-tank construction; hump yards, yard grades; train resistance; and stresses in track.

Reign of Rubber. By William C. Geer. Century Co., New York, 1922. Cloth, 5 × 8 in., 344 pp., illus., map, $3.

An interesting account of the rubber industry, written in popular style and fully illustrated. Describes the development of the industry from its beginnings and explains how certain representative rubber products, such as tires, footwear and clothing, golf balls, electric conductors, hose, belting, packing and balloon fabrics, are made. Intended for users of rubber goods, rather than for makers.

Researches on Cellulose, Vol. 4, 1910–1921. By Charles F. Cross and Charles Dorée. Longmans, Green & Co., New York, 1922. Cloth, 5 × 8 in., 253 pp., diagram, tables, $5.

These volumes of researches, of which this is the fourth, are intended as supplements to the original volume on cellulose, published in 1895. They provide a review and critical evaluation of the research work upon the constitution and properties of cellulose which has been published in various technical journals, together with certain new matter contributed by the reviewers.

Short Handbook of Oil Analysis. By Augustus H. Gill. Tenth edition. Lippincott, Philadelphia, 1922. Cloth, 5×8 in., 223 pp., tables, $2.50.

A concise manual, primarily for beginners, giving the methods of applying the usual physical and chemical tests to mineral, animal, and vegetable oils. Discusses only the more commonly occurring oils, as regards their preparation, properties, analytical constants, uses and adulterants. This edition has been revised and a section on motor gasoline and a description of the MacMichael absolute viscosimeter have been added.

Shield and Compressed-Air Tunneling. By B. H. M. Hewett and S. Johannesson. First edition. McGraw-Hill Book Co., New York, 1922. Cloth, 6 × 9 in., 465 pp., illus., diagrams, tables, $5.

The authors state that so much tunneling has been done with the aid of the shield and the art of such work has been developed to such a point that it is now possible to formulate, to some extent at least, certain principles and rules of practice on which to base the design and construction methods of future work. This they have tried to do in the present book, which treats of tunnel design, stresses in tunnel linings, methods of lining, tunnel shields, plant and equipment, methods of construction, maintenance and inspection, progress, cost, and surveying. A chapter is devoted to compressed-air sickness. A good bibliography is included.

Sparking Plugs. By A. P. Young and H. Warren. Isaac Pitman & Sons, New York, 1922. (Pitman's Technical Primer Series.) Cloth, 4 × 6 in., 106 pp., illus., diagram, tables, $0.85.

This little book reviews briefly the history of spark plugs and discusses the general principles of electric ignition. The operation and design of spark plugs is then considered in detail. The questions of electrodes and voltages are treated in detail, with data from researches by the authors. This is followed by a consideration of the composition and properties of spark-plug insulators.

Steam Turbine; Theory and Practice. By William J. Kearton. Isaac Pitman, New York, 1922. Cloth, 6 × 9 in., 456 pp., illus., diagrams, $4.50.

In the opinion of Mr. Kearton, many recent books on the steam turbine have been over-developed along certain lines, and few have been generally useful to the student. The present work is written for the student, and should prove useful to engineers and draftsmen desiring a wider knowledge of theory.

After introductory chapters on the properties of steam and entropy, the book treats of the steam-turbine cycle, the flow of steam through nozzles and blades, efficiency, lubrication, stresses, critical speed, and turbine design. This is followed by descriptions of commercial turbines of various types.

Steam-Engine Principles and Practice. Terrell Croft, editor. First edition. McGraw-Hill Book Co., N. Y., 1922. Cloth, 6×8 in., 513 pp., illus., diagrams, $3.50.

This book has been very carefully prepared, the author states, to satisfy the demand for a "practical" book containing the information concerning steam engines which is wanted by an operating engineer or plant superintendent. Nothing pertaining to design has been included. The treatment has been directed to the selection, operation, care and repair of steam engines and to questions of economic operation.

A.S.M.E. Boiler Code Committee Work

(*Continued from page 137*)

integral part of the boiler? The thickness for heads which have riveted construction is not definitely specified in this paragraph.

Reply: It is the opinion of the Boiler Code Committee that the term "riveted shells" in the first sentence of this paragraph is intended to cover heads, in case they are not used as tube sheets.

Case No. 409

Inquiry: Is it permissible, under Par. M-11 of the Code for Miniature Boilers, to weld on to the shell a half-coupling for the reinforcement to give the necessary four full threads?

Reply: It is the opinion of the Committee that the reinforcing may be accomplished only by a riveted pad or its equivalent, or by building up the thickness of the plate by welding, and that the welding of the half-coupling on the outside of the plate is not permissible under this requirement.

Case No. 410

Inquiry: Is it the intent of Par. M-16 of the Code for Miniature Boilers that non-ferrous metal shall be used for the valve seat and also that the lifting device shall be of non-ferrous metal, as are required by Pars. 282 and 283 of the Power Boiler Section of the Code?

Reply: Attention is called to the fact that where the Rules of the Code for Miniature Boilers do not apply, those as above referred to in the Power Boiler Section of the Code are applicable.

Some Technical Bibliographies

THE following list of bibliographies on technical subjects has been compiled by Raymond N. Brown, of the Engineering Societies Library, 29 West 39th St., New York, N. Y., where all of the publications named are to be found. The photostatic service as described in The Engineering Index may also be used in connection with this index. Bibliographies upon any technical subjects will be compiled by the Library, upon request, at the rate of two dollars an hour.

Alcohol, Power. Power Alcohol, Its Production and Utilization. H. Frowde, London, 1922, 323 pp. Extensive lists of references are found at the end of each chapter.

Beams, Vierendeel System, Calculation of. Statik der Vierendeeltrager, Karl Kriso. J. Springer, Berlin, 1922, 288 pp.; bibliography, pp. 287–288. About 50 references, mostly to German publications.

Cast Steel. Der Stahlguss als Werkstoff, Rudolf Schafer. Giesserei-Zeitung, vol. 19, pp. 463–472 and 474–482; bibliography, p. 482. Sixty-four references, all in German.

Chrome Refractories. Chrome Refractories, J. S. McDowell and H. S. Robertson. American Ceramic Society, Journal, vol. 5, pp. 865–887; bibliography, pp. 882–887. About 130 references arranged chronologically.

Combustion, Surface. Surface Combustion, R. F. Bacon and W. A. Hamor. American Fuels, 2 vols., McGraw-Hill Co., Inc., New York, 1922. Bibliography in vol. 2, pp. 1091–1094. About 80 references arranged chronologically.

Duralumin. Duralumin: A Digest of Information, H. C. Knerr. American Society for Steel Treating, vol. 3, pp. 13–42; bibliography, pp. 41–42. Twenty-eight references.

Dust Explosions. Dust Explosions: Theory and Nature of Phenomena; Causes and Methods of Prevention. National Fire Protection Association, Boston, 1922, 246 pp.; bibliography, pp. 241–246. About 150 references arranged chronologically.

Graphic Charts. Graphic Charts in Business—How to Make and Use Them, A. C. Haskell and J. G. Breaznell. Codex Book Co., Inc., New York, 1922, 250 pp.; bibliography, pp. 239–246. Over 40 books and about 140 periodical articles are listed. The latter are classified.

Lumber. Lumber, Its Manufacture and Distribution, R. C. Bryant. John Wiley & Sons, Inc., 1922, 539 pp.; bibliography, pp. 439–448. About 180 references arranged by classes.

Metals, Non-Ferrous, Season Cracking of. Bibliography on Season Cracking. British Non-Ferrous Metals Research Association, Bulletin, no. 6, July, 1922, pp. 14–18. Forty-seven references in chronological order.

Partitions, Sound-Proof. Sound-Proof Partitions, F. R. Watson. University of Illinois, Engineering Experiment Station, Urbana, Ill., Bulletin 127, 1922, 85 pp.; bibliography, pp. 77–78. Thirty-four references.

Steel, High-Speed Tool. Bibliography of High-Speed Tool Steels. American Society for Steel Treating, Transactions, vol. 3, pp. 47–89. About 360 references with descriptive notes covering period from 1900 to May, 1922. Divided into parts entitled: I, Manufacture of High-Speed Steel; II, Heat Treatment; Uses and Tests. Arranged chronologically in each part.

Steel, Rustless. Rostfreie Stahle, Karl Daeves. Stahl und Eisen, vol. 42, pp. 1315–1320; bibliography, pp. 1319–1320. Thirty-two references.

THE ENGINEERING INDEX

(Registered United States, Great Britain and Canada)

Exigencies of publication make it necessary to put the main body of The Engineering Index (p. 101-EI of the advertising section) into type considerably in advance of the date of issue of "Mechanical Engineering." To bring this service more nearly up to date is the purpose of this supplementary page of items covering the more important articles appearing in journals received up to the third day prior to going to press.

AERODYNAMICS

Standardization. Standardization and Aerodynamics, William Knight. Aerial Age, vol. 15, no. 21, Dec. 1922, pp. 593–598. Writer refers to suggestions contained in his report to Nat. Advisory Committee for Aeronautics made in 1919 on desirability of calling a congress of representatives of leading aerodynamic laboratories, without discrimination between former allies and enemies and gives comments of the various countries on proposed congress.

AIRSHIPS

Girders. Improvements in Built-Up Airship Girders, S. H. Phillips. Aviation, vol. 13, no. 26, Dec. 25, 1922, pp. 828–830, 3 figs. With special reference to strength of girders as a whole.

AIR COMPRESSORS

Rotary. Rotary Air Compressors. Engineering, vol 114, no. 2972, Dec. 15, 1922, pp. 740–742, 15 figs., partly on p. 744. New compressors constructed by Swiss Locomotive & Machine Works, Winterthur, Switzerland.

AMMONIA CONDENSERS

Comparative Reports. Comparative Ammonia Condenser Reports Point Out Inefficiencies, P. Wilson Evans. Power, vol. 57, no. 1, Jan. 2, 1923, pp. 28–30, 1 fig. By compiling weekly averages of ammonia condenser temperatures and pressures from various plants operated by Armour & Co., it has been possible to detect and remedy inefficient operating conditions with resultant saving in power and operating expense.

BLAST FURNACES

Air Intake, Elevated. Elevated Intake for Blast Furnace Air, Alfred Gradenwitz. Iron Age, vol. 110, no. 26, Dec. 28, 1922, p. 1700, 1 fig. Tests at Rombach Iron Works, Coblentz, Germany, with view to ascertaining whether upper strata of air are cooler and less capable of absorbing water than those in immediate vicinity of ground; 138-ft. suction tower for air intake affords considerable reduction of moisture.

BOILER ROOMS

Efficiency in. Modern Management Methods in the Power Plant, Browning Robinson. Indus. Management (N. Y.), vol. 65, no. 1, Jan. 1923, pp. 57–61, 2 figs. Problems of boiler-room efficiency.

BOILERS

Design. Principles of Boiler Design, C. E. Stromeyer. Engineer, vol. 134, no. 3495, Dec. 22, 1922, pp. 672–673, 1 fig. High-furnace-temperature effects; convection and velocity; costly natural draft; air heaters; superheaters; economizers; high velocity of flames; reductions of furnace temperatures; oil burning.

BONUS SYSTEMS

Packard Motor Co. A New Departmental Bonus System, E. F. Roberts. Indus. Management (N. Y.), vol. 65, no. 1, Jan. 1923, pp. 43–45, 3 figs. Method adopted by Packard Motor Car Co. for stimulating efficiency.

BOXES

Cardboard, Machinery for Making. Cardboard Box-Making Machinery. Engineering, vol. 114, nos. 2965, 2966, 2967, 2968, 2969, 2970, 2971 and 2973, Oct. 27, Nov. 3, 10, 17, 24, Dec. 1, 8 and 22, 1922, pp. 517–520, 542–543, 578–579, 609–610, 640–641, 670–671, 698–699 and 760–762, 103 figs. Complete range of machinery used in manufacture of cardboard boxes.

CENTRAL STATIONS

Pulverized-Coal Burning. Cahokia Station. Power, vol. 57, no. 1, Jan. 2, 1923, pp. 20–22, 4 figs. Outstanding engineering features of new station of Union Elec. Light & Power Co., St. Louis, Mo., as example of large central station using pulverized coal as fuel.

CORROSION

Metals, Industrial. Corrosion as Affecting the Metals Used in the Mechanical Arts, W. H. Hatfield. Engineer, vol. 134, no. 3494, Dec. 15, 1922, pp. 639–643, 21 figs. Results and other data of set of experiments undertaken to decide upon relative resistance to various corroding media of typical industrial metals. Paper read before Sheffield Assn. Metallurgists & Met. Chemists.

COST ACCOUNTING

Factory. A New System of German Factory Accounting, Schar Schlesinger and Wallichs. Management Eng., vol. 4, no. 1, Jan. 1923, pp. 27–31. Describes system of cost accounting developed by Ernst Just and Elizabeth Vöhl, based on principle of applying analytical methods as substitute for experience and intuition. Presents and discusses seven propositions upon which system is based. If generally adopted a radical change will take place in industrial organizations.

Measuring Management by. Measuring Management by Cost Accounting, William R. Basset. Am. Mach., vol. 58, no. 1, Jan. 4, 1923, pp. 37–38. Effect of human factor; lack of unit of measurement; cost-finding methods considered most effective present measure.

DIE CASTINGS

Dies for. Dies for Die-castings, A. G. Carman. Machy. (N. Y.), vol. 29, no. 5, Jan. 1923, pp. 369–370, 3 figs. Specific examples of design and construction of dies for making die castings of more intricate type.

DIES

Shells, Blank Diameters of. Blank Diameters for Drawn Shells, W. L. Tryon. Machy. (N. Y.), vol. 29, no. 5, Jan. 1923, pp. 349–354, 19 figs. Formulas and graphical methods for finding blank area and diameter of various types of shells.

DIESEL ENGINES

Nobel. The Two-Stroke-Cycle Diesel's Superiority for Large Powers, Edwin Lundgren. Power, vol. 56, no. 26, Dec. 26, 1922, pp. 1015–1016, 2 figs. Points of superiority of two-stroke-cycle engine illustrated with data on Nobel-Sweden 1600-hp. Diesel.

ELECTRIC FURNACES

Levoz. Designs New Electric Furnace, R. Sylvany. Foundry, vol. 50, no. 23, Dec. 1, 1922, pp. 962–963. Principles of construction of furnaces of latest French development, by T. Levoz, employed during war in production of high-speed steel; metal melted in crucible-shaped vessel with only one opening; electrode through roof sheathed to prevent ingress of air.

ELECTRIC MOTORS

Selection and Control. Selection and Control of Motors, Roger B. Stevens. Elec. World, vol. 80, no. 27, Dec. 30, 1922, pp. 1433–1437, 7 figs. Avoidance of service interruptions without trained and expensive maintenance crew and under necessity of operating with common labor was chief problem in Am. Sugar Refining Co.'s plant.

EMPLOYMENT MANAGEMENT

Engineering Department. The Successful Operation of an Engineering Department, W. E. Irish. Indus. Management (N. Y.), vol. 65, no. 1, Jan. 1923, pp. 19–22. Plan of action in dealing with labor. Assembling and operating the "man-machine."

FLOW OF FLUIDS

Electric Measuring Instrument. Electrical Instrument Applied to Measurement of Fluids, E. H. Freeman. Power, vol. 56, no. 26, Dec. 26, 1922, pp. 1008–1009, 2 figs. Electrical integrating instrument developed by author which is practically free from voltage error; adopted by Republic Flow Meter Co., Chicago.

FORGINGS

Nickel-Chrome. Studies Nickel Chrome Forgings, T. Henry Turner. Iron Trade Rev., vol. 71, no. 25, Dec. 21, 1922, pp. 1695–1700, 7 figs. Defects found on machined surfaces of hollow cylindrical bells are traced to ingot corner segregation; investigation showed depth of these segregations extended from 2 to 3 in.: recommendations.

FOUNDATIONS

Power Stations. Foundation and Framing Design of Colfax Power Station, M. E. Thomas. Eng. News-Rec., vol. 89, no. 26, Dec. 28, 1922, pp. 1102–1105, 7 figs. Concrete mat foundation on gravel; column loads distributed by reinforced-concrete walls; special retaining wall and sea wall held by ties.

FOUNDRIES

Ford's River Rouge. Ford Principles and Practice at River Rouge, John H. Van Deventer. Indus. Management (N. Y.), vol. 65, no. 1, Jan. 1923, pp. 11, 23 figs. Plant facilities of world's largest foundry.

GEAR CUTTING

Formed Cutters. Cutting Bevel Gears with Formed Cutters, Franklin D. Jones. Machy. (N. Y.), vol. 29, no. 5, Jan. 1923, pp. 363–365, 6 figs. Brown & Sharp automatic gear-cutting machines of formed-cutter type designed for cutting either spur or bevel gearing.

GRINDING

Automobile Parts. Grinding Data from the Pierce-Arrow Shop, Fred H. Colvin. Am. Mach., vol. 57, no. 26, Dec. 28, 1922, pp. 997–998, 3 figs. Testing cylinder gages; grinding bronze connecting-rod bushings; forming steering balls; grinding aluminum transmission covers.

HYDROELECTRIC DEVELOPMENTS

Western States. Outstanding Features of Western Water-Power Development in 1922. Eng. News-Rec., vol. 90, no. 1, Jan. 4, 1923, pp. 14–16, 2 figs. Forward steps in design and construction; stabilized tendency toward municipal ownership or control; economic aspects of Western water-power situation.

INDUSTRIAL MANAGEMENT

Factory Planning. Factory Planning, H. E. Taylor. Engineering, vol. 114, nos. 2972 and 2973, Dec. 15 and 22, 1922, pp. 756–758 and 786–788, 8 figs. Survey of systems of shop planning for various methods of production. See also Eng. Production, vol. 5, no. 115, Dec. 14, 1922, pp. 557–563, 9 figs.

Machine Jobbing Shop. Management of the Machine Jobbing Shop, H. L. Wheeler. Am. Mach., vol. 58, no. 1, Jan. 4, 1923, pp. 13–18, 1 fig. Distinction between manufacturing and jobbing; systems, operations and methods; how orders are received and handled; what jobbing-shop management should avoid.

Process Planning. Notes on Process Planning. Engineering, vol. 114, no. 2973, Dec. 22, 1922, pp. 778–780, 4 figs. Principal aim when planning sequence of processes is to secure maximum economy of production as a whole.

Production Executives. What the Production Executives Should Know from the Financial Records, William M. Lyband. Management Eng., vol. 4, no. 1, Jan. 1923, pp. 19–23. Coördination of divisional planning and operation; information for foremen; facts in regard to department operation; overhead expenses; spoilage, waste and idleness; reports in shop language; information for production executives; cost of idle equipment and time; operation of inventory; etc.

Quality Control. Quality Products, G. S. Radford. Management Eng., vol. 3, nos. 5, and 6, Nov. and Dec. 1922, pp. 261–266, 3 figs. and vol. 4, no. 1, Jan. 1923, pp. 51–56, 5 figs. Control methods used by leading manufacturers to maintain standards. Answers to questionnaire sent to number of representative firms.

LOCOMOTIVES

Developments 1922. A Year of Innovations in Locomotive Design, A. F. Steubing. Ry. Age, vol. no. 1, Jan. 6, 1923, pp. 41–43, 4 figs. Steam-turbines locomotives in Europe; mechanical draft receiving increased attention.

MACHINERY

Power, Erecting. Erecting Power Machinery Having Cast-Iron Bedplates, N. L. Rea. Power, vol. 56, no. 26, Dec. 26, 1922, pp. 1021–1023, 6 figs. Proper supporting of machine base; preparing top of foundation; handling bedplate; leveling and aligning; grouting bedplate to foundation; assembling machine and putting it in operation.

OIL FUELS

Calorific Value. The Determination of the Calorific Value of Liquid Fuels, H. Moss and W. J. Stern. Engineering, vol. 114, no. 2972, Dec. 15, 1922, pp. 729–731, 6 figs. Experiments undertaken to investigate methods of determining calorific values, with view to evolving one by means of which absolute values for any fuel undergoing engine test could be obtained quickly and accurately.

OPEN-HEARTH FURNACES

Loftus. New Type of Open-Hearth Furnace. Iron Age, vol. 110, no. 26, Dec. 28, 1922, pp. 1677–1679, 5 figs. Loftus furnace involves new way to apply blow-torch principle; details and results of unit operating several months.

PIPE

Stresses in. The Stresses in End-Supported Filled Pipes (Ueber die Spannungen in freitragenden gefüllten Rohren), E. Schwerin. Zeit. für angewandte Mathematik u. Mechanik, vol. 2, no. 5, Oct. 1922, pp. 340–353, 3 figs. Study of influence of bending and torsional strength of pipe wall, not only under stress of liquid, but also under natural weight of pipe itself.

PUMPING ENGINES

High-Head. Hackensack Water Company's High-Head Pumping Engines. Power, vol. 56, no. 26, Dec. 26, 1922, pp. 1006–1008, 4 figs. Vertical, triple-expansion pumps designed to operate against unusually high head of 293 lb. per sq. in., maintain high efficiency over wide range of operating conditions.

RAILWAY MOTOR CARS

Gasoline. Motor Driven Rail Car with High Power Unit. Ry. Mech. Engr., vol. 96, no. 12, Dec. 1922, pp. 697–698, 3 figs. New equipment for Maryland & Pa. has 120-hp. engine and seats 76 passengers.

RAILWAY SHOPS

Shortcomings. What's Wrong with the Railroad Shops? Am. Mach., vol. 57, nos. 17, 20, 23 and 25, Oct. 26, Nov. 16, Dec. 7 and 21, 1922, pp. 677–680, 755–757, 879–881 and 955–957 and vol. 58, no. 1, Jan. 4, 1923, pp. 1–3, 2 figs. Information based on critical survey of situation. Mechanical departments said to be badly handicapped by poor equipment; lack of contact with other shops. Nov. 16: Shop equipment as it is, with suggestions for more efficient use of what is available and replacing obsolete units with new ones. Dec. 7: Small-tool situation; lack of coöperation between mechanical and purchasing departments; inadequacy of tool-sharpening equipment. Dec. 21: Suggestions regarding interchange of information and standardization of parts and methods; cost-keeping systems. Jan. 4: Underlying causes of present shop troubles; how to remedy shortcomings of methods, equipment and personnel.

Price 50 Cents a Copy, $4.00 a year: to Members and Affiliates, 40 cents a Copy, $3.00 a Year. Postage to Canada, 75 Cents Additional; to Foreign Countries, $1.50 Additional. Changes of address should be sent to the Society Headquarters.

Entered as second-class matter at the Post Office at Easton, Pa., under the Act of March 3, 1879.
Acceptance for mailing at special rate of postage provided for in section 1103, Act of October 3, 1917, authorized on January 17, 1921.

Contributors and Contributions

The Machine-Tool Industry

E. F. DuBrul

Speakers at a recent joint meeting of the Philadelphia Local Section and the Machine Shop Division of The American Society of Mechanical Engineers, the Engineers' Club of Philadelphia, and the Philadelphia Section of the American Institute of Electrical Engineers, approached the subject of the machine-tool industry from three different angles. Ernest F. DuBrul, Cincinnati, Ohio, discussed some of its economic features, Benjamin P. Graves and James A. Hall, Providence, R. I., the effect of variations in design of milling cutters on power requirements and capacity, and Dexter S. Kimball, Ithaca, N. Y., the development of machine tools.

Mr. DuBrul, who is general manager of the National Machine Tool Builders' Association and president of the Pyro Clay Products Company, was graduated from Notre Dame University and did graduate work at Johns Hopkins University. From 1897 to 1911 he was director and superintendent of the Miller, DuBrul & Peters Mfg. Co., and its president from 1915 to 1919. Mr. DuBrul analyzes costs and compares productivity of large and small shops.

The paper by Messrs. Graves and Hall, setting forth the results of investigations to determine the effect of changes in the design of milling cutters, will be found of great practical value. Mr. Graves is a graduate of the Rhode Island School of Design, class of 1904, where for six years he instructed evening classes in machine-tool design. Since 1915 he has been milling-machine engineer for the Brown & Sharpe Manufacturing Co., in charge of all milling-machine designs and problems, both for shop use and outside sources.

The co-author of the paper, Professor Hall, was graduated from Brown University in 1908 and has been giving instruction and conducting research there since that time. He is now associate professor of mechanical engineering. He is also president of the Providence Engineering Society.

Dean Kimball's address pays tribute to all those who have contributed to the development of machine tools from their crude beginnings to the modern standards of accuracy and output.

Progress in Steam Research

The first record of progress in the research of the properties of steam for the formulation of new steam tables appears in this issue. Dr. R. V. Kleinschmidt gives the results obtained in experiments at Harvard on the Joule-Thomson effect and Dr. Keyes of M.I.T. and Mr. Osborne of the Bureau of Standards tell of the progress made in designing apparatus for the parts of the work they are to carry on. These reports were originally presented at the A.S.M.E. Annual Meeting in December, 1922.

Elasticity of Pipe Bends

Sabin Crocker and Sterling S. Sanford, both of whom are associated with the Detroit Edison Company, have contributed to this issue an article on the elasticity of pipe bends. Both Mr. Crocker and Mr. Sanford were born in Mt. Clemens, Mich., and were graduated from the University of Michigan. Except for their war service they have since been connected with the Detroit Edison Company, where Mr. Crocker is now piping engineer and Mr. Sanford research engineer.

Vocational Training for the Industries

This issue contains a review of the present status of the many types of industrial education which proves that such education has already advanced in a truly remarkable way and promises much for the future. Members of the A.S.M.E. Committee on Education and Training for the Industries who prepared this report are James A. Moyer, Robert L. Sackett, and Charles R. Richards. Professor Moyer was graduated from Harvard University in 1899, and taught engineering, mathematics, and experimental engineering there until 1904. After two years in engineering work for the General Electric Company and one for Westinghouse, Church, Kerr & Co., he reëntered the teaching profession as professor of mechanical engineering at the University of Michigan. In 1912 he transferred to Pennsylvania State College, and since 1915 he has been director of the university extension work of the Massachusetts Department of Education.

Dean Sackett is a University of Michigan graduate, class of 1891. Previous to 1915 he was professor of sanitary and hydraulic engineering at Purdue University, and since that time he has been dean of the school of engineering at Pennsylvania State College and director of its engineering-experiment station and engineering extension.

Professor Richards received the degree of M.E. from Massachusetts Institute of Technology in 1885. He has served successively as director of the Department of Science and Technology, Pratt Institute, director of the Department of Manual Training, Teachers' College, Columbia University, and director of Cooper Union. He has also been special agent of the N. Y. Department of Labor, and was for two years secretary of the National Society for the Promotion of Industrial Education.

Design of Woodworking Machinery

Woodworking machinery of the future will be greatly influenced by such factors as the adoption of high-speed steel, demands of greater economy, power and speed, the use of ball bearings, and the direct application of the electric drive. Sern Madsen discusses these factors in the present issue. He was graduated from the State College at Ames, Iowa, in 1911, receiving his M.E. from that institution in 1916. He was for a time superintendent of maintenance and power for Curtis Brothers & Co., Clinton, Ia., and since 1918 has been superintendent of plant equipment for the Curtis Companies, Inc., of Clinton.

Economic Features of the Machine-Tool Industry

Some of the Features Brought Out as a Result of Analyzing the Statistics of the 1919 Census of Manufacturers—Problems of Management—Trade Evils and Their Remedies

By ERNEST F. DUBRUL,[1] CINCINNATI, OHIO

VERY few people give thought to the vital economic fact that without the organizing, imaginative minds of business leaders there would have been little material progress in the world. Those who propose untried industrial systems for dreamlands never think of it at all. Without free play for the adventurous, creative, pioneering spirit of those who can organize and direct industry, the world would soon slip back in its achievements of the comforts and luxuries that it enjoys. Only the joint effort of business brains and mechanical brains keeps us as we are, and pushes us on.

We hear much loose talk about the rich getting richer and the poor getting poorer in these days when the streets are full of poor men's automobiles. By the use of machinery, directed by the organizing minds of business leaders, the productivity of the nation has increased in the last century about twenty times as fast as the population, and cold statistics prove the truth to be that the poor are getting richer with the rich. Progress will continue at an increasing rate, unless stopped by attempts to put in practice such suicidal dreams as have been tried in Russia.

Consider how little of man's work continues in existence for 100 years. Most of it is replaced before worn out by better and more adaptable plant. Even if we made no advances in methods we would have to keep on replacing the old, as the forces of nature soon destroy the handiwork of man. All this requires that some men must look forward many years to a demand from unborn generations.

Only because some men looked far ahead to such demands of our present generation have we the comforts we enjoy. Only because some men could save capital, and do so in reasonable security, are present productive processes giving us these comforts. Only as this generation saves something out of consumption and puts it to work, can future generations have greater comfort.

An impression of the rapid growth in productivity is obtained from comparison of the estimated value of manufactures which in 1812 was $170,000,000 for the United States, whereas in 1919 it was over $62,000,000,000. Of this total, $1^1/_2$ per cent, or nearly one billion, was industrial machinery alone, to say nothing of of electrical equipment, automotive or other vehicles, tractors, agricultural machinery, railway cars, and locomotives. Of the industrial machinery, machine tools form the largest single class and in value it is about twice as large as the next largest class, textile machinery.

Because the blacksmith made the tools for all the other workers who built the temple of Solomon, the legend is that King Solomon honored the blacksmith above all the other workers. The modern machine-tool builder now stands in that blacksmith's place, producing the master tools for all other crafts.

TABLE 1 DATA FROM U. S. CENSUS OF MANUFACTURES, 1919
Reduced to "Per Shop" and "Per Wage-Earner" Basis

	All Industries			Machine Tools		
	Totals	Per Shop	Per Wage Earner	Totals	Per Shop	Per Wage Earner
Number of establishments	290,105	....	......	403	....	......
Average number of wage earners	9,096,372	31	......	53,111	132	......
Nunber of salesmen, clerks, etc	1,033,507	5	......	6,186	15	......
Number of superintendeots aod managers	281,253		......	1,696		......
Number of corporation officers	132,467	2	......	637	5	......
Number of proprietors	269,137		......	132		......
Total number of persons engaged	10,812,736	38	......	61,762	152	......
Capital employed	$44,558,593,771	$153,594	$4,898	$231,039,843	$573,298	$4,350
Turnover	140	......	....	92	......	....

Value added by manufacturer	25,041,698,490	86,319	2,753	153,365,850	38,056	2,887
Wages paid	10,533,400,340	36,308	1,157	66,178,969	164,215	1,246
Salaries paid	2,892,371,494;	9,971	318	18,037,856	44,759	340
Contract work	464,403,700	1,601	51	1,469,844	3,648	28
Rents	212,043,089	731	23	476,353	1,182	9
Taxes—federal	1,790,197,060	6,170	197	15,755,796	39,096	296
Taxes—state	289,172,297	997	32	2,083,106	5,169	39
Tot. (Deductions from Av.)	$16,181,587,980	$ 55,578	$1,778	$104,001,924	$258,069	$1,958
Residue	8,860,110,510	30,541	974	49,363,926	122,491	929
Interest on capital at 7 per cent	3,119,101,563	10,752	343	16,172,789	40,130	304
Net residue	$ 5,741,008,947	$ 19,789	$ 631	$ 33,191,137	$ 82,361	$ 625

I shall give you an outline picture of the machine-tool industry through some analysis of the statistics of the Census of Manufactures of 1919. This census gives the number of establishments, capital employed, value of product, costs of material, fuel, power, wages, salaries, contract work, rents, taxes, number of wage earners and salaried employees. To get our first comparison we reduce this data to a "per shop" basis, and also to a "per wage earner" basis as set forth in Table 1.

From the "per shop" figures we see that the average machine-tool shop is about four times as large as the average of all industries, as shown by the items of capital, number of wage earners, added value, wages, salaries, etc.

The size of his shop shows the machine-tool man to be a good manager, and some other things confirm this. He paid his men better than the average employee got elsewhere, but his salary roll was less in proportion and the number of supervising personnel also smaller in proportion. While salaries formed 27.3 per cent of the payroll of the average shop, they show as only 21 per cent of the payroll of the machine-tool shop.

[1] General Manager, National Machine Tool Builders' Association. Mem. Am.Soc.M E.

Presented at a joint meeting of the Philadelphia Local Section and the Machine Shop Division of The American Society of Mechanical Engineers, the Engineers' Club of Philadelphia, and the Philadelphia Section of the American Institute of Electrical Engineers, Philadelphia, February 27, 1923. Slightly abridged.

TABLE 2 DISTRIBUTION BASED ON VALUE ADDED BY MANUFACTURE AS 100 PER CENT

	All Industries		Machine Tools	
		Per cent		Per cent
Value added by mfr.	$25,041,698,490	100	$153,365,850	100
Capital employed	44,558,593,771	177	231,039,843	150
Value of product	62,418,078,773	249	212,400,158	138
Material used	35,730,393,727	142.5	56,048,334	36.5
Fuel and power rented	1,645,986,556	6.5	2,985,974	1.5
Wages paid	10,533,400,340	42.1	66,178,969	43 2
Salaries paid	2,892,371,494	11.6	18,037,856	11 8
Contract work	464,403,700	1.9	1,469,844	1.0
Rents	212,043,089	0.8	476,353	0.2
Taxes—federal	1,790,197,060	7.1	15,755,796	10.3
Taxes—state	289,172,297	1.2	2,083,106	1.4
Residue	8,860,110,510	35.3	49,363,926	32.1
Interest on cap. @ 7%	3,119,101,563	12.4	16,172,789	10.5
Net Residue	$ 5,741,008,947	22.9	$ 33,191,137	21.6

TABLE 3 DISTRIBUTION BASED ON VALUE OF PRODUCT AS 100 PER CENT

	All Industries		Machine Tools	
		Per cent		Per cent
Value of product	$62,418,078,773	100	$212,400,158	100
Capital employed	44,558,593,771	71.4	231,039,843	108.7
Material used	35,730,393,727	57.3	56,048,334	26.3
Fuel and power rented	1,645,986,556	2.6	2,985,974	1.4
Value added by mfr	25,041,698,490	40.1	153,365,850	72.3
Wages paid	10,533,400,340	16.9	66,178,969	31.2
Salaries paid	2,892,371,494	4 6	18,037,856	8.5
Contract work	464,403,700	0.7	1,469,844	0.7
Rents	212,043,089	0.3	476,353	0.3
Taxes—federal	1,790,197,060	2.9	15,755,796	7.4
Taxes—state	289,172,297	0.5	2,083,106	1.0
Residue	8,860,110,510	14 2	49,363,926	23.2
Interest on cap. @ 7%	3,119,101,563	5.0	16,172,789	7.6
Net Residue	$ 5,741,008,947	9.2	$ 33,191,137	15.6

The item of added value is the index of manufacturing activity. This item excludes material from the total value. The manufacturer's function is to convert material into finished product. Of this added value the machine-tool salary roll was only 11 per cent while the average was 16 per cent, so evidently he was not extravagant in that particular.

After taking out of the total value all the amounts specified, there still remains a balance, designated as "residue" for want of a better term. As the census figures do not go into further detail, we can only say that this residue still includes costs like depreciation, obsolescence, insurance, advertising repairs, interest, legal, patent, auditing, traveling, and all other expenses not covered by the specific expenses mentioned. It would be proper to deduct from this an allowance for interest on capital which in 1919 at the going rate was easily 7 per cent. This would allow the average shop $19,720 and the machine-tool shop $82,361. From the "per wage earner" figures we note that the machine-tool builder used $600 less capital than the average.

TABLE 4 FIGURES CLASSIFIED ACCORDING TO SIZE OF SHOPS

	Machine Tools					
	All Shops	$20,000 & Under	$20,00 to $100,000	$100,000 to $500,000	$500,000 to $1,000,000	Over $1,000,000
No. of establishments	403	66	110	134	41	52
Per cent	100	16.4	27 3	33.2	10.2	12.9
No. of wage earners	53,111	245	1,941	8,162	7,235	35,528

The average manufacturer took $4100 worth of material and fuel per wage earner in 1919, and by processing added to it $2752 worth of utility, or 66 per cent. But the creative machine-tool builder took $1100 of material per wage earner and added $2887 or 262 per cent of utility to it. As the real function of all manufacturers is to add utility, it would seem fair to compare them by using, as a base, the value added. Table 2 reduces the various factors to a percentage of this base. From this we deduce that to produce $100 of added value at the market price of his goods, the average manufacturer employed $177 of capital against the machine-tool builder's $150. The average used $149 of material against the machine-tool builder's $38. It cost them both about the same in expenses specified, except that Federal taxes took $3 more out of the machine-tool builder. If now we allot 7 per cent interest on the capital invested in each case, the average manufacturer got a net residue somewhat greater than the machine-tool builder.

Table 3 gives the various components of total value, and shows the machine-tool builder as having a larger percentage of residue.

Table 4 is an attempt to get the residue down to a "per wage earner" basis, by classes according to the size of the establishment. Deducting wages from added value shows a still greater concentration of the remainder in the large shops. We next distribute the salaries, taxes, etc., in proportion to this last balance. This is overloading the small shop with Federal taxes that it may not have paid, as its earnings were smaller per man and it had an exemption of $2000. On the other hand, there is some counterbalance to this overload, because the overhead per wage earner is larger in the small shops than in the large ones. This is true in spite of the notions of many proprietors of small shops and officers of small corporations who do not pay themselves the salaries they could earn elsewhere, and thereby deceive themselves into thinking their overhead is low. On the whole, the method here used probably gives them a better showing in wages, in expense items, and in residue per wage earner than the facts warrant.

From these figures some interesting suggestions arise as to machine-tool builders. Note the small residue per wage earner left in

shops below the $100,000 line, which is not enough to pay interest, to say nothing of allowing for other expenses and profit. The men who have these small shops seem to be taking a very long chance that they can ill afford to take. Yet 44 per cent of the machine-tool builders were doing that very thing

It is worth noting that although machine-tool shops must employ a highly skilled force of wage earners, and their force is larger in each class than the average, still in each class the residue per wage earner was less than the average, though this residue increases with the size of the shop, as we would expect.

Table 5 throws some interesting light on the concentration of industry in large establishments. The net residue percentage for each class compared to the percentage of number of establishments would indicate that while a larger proportion of machine-tool shops are in the million-dollar class, and while the proportion of net residue is also higher in this class of machine-tool shops than for all industries, the relative concentration is over three times greater in all industries than in the machine-tool industry.

Table 5 shows that while small shops are numerous, the greatest bulk of production is effected in shops turning out $1,000,000 worth of product or more. While the shops turning out less than $100,000 per year are nearly 80 per cent of the general total, they employ only 12 per cent of the wage earners, to say nothing of the mass of proprietors, etc., not listed as wage earners. Then they succeed in producing less than 10 per cent of the added value. The small machine-tool shops, almost 44 per cent of the number, produce only 3 per cent of the added value with their proprietors and 4 per cent of the wage earners.

Note the concentration of 70 per cent of the added value in about 13 per cent of the machine-tool shops that averaged $2,000,000 of added value and $3,000,000 of capital. Nobody ordered this concentration, it developed very naturally. Consolidations have been very few in the industry; it got its million-dollar shops, its half-million dollar shops and its hundred-thousand dollar shops by grinding thrift and hard work.

The high level of management in the machine-tool business is indicated by the fact that 13 per cent of the machine-tool builders are in the $2,000,000 group of value adders, whereas only 3½ per cent of the average manufacturers are in the $500,000 class. Moreover 10 per cent of the machine-tool men are in the $500,000 class compared to 3 per cent of average manufacturers in the $300,000 class. Again, 33 per cent of machine-tool men are in the $250,000 class, while only 13 per cent of average manufacturers are in the $100,000 class. And only 44 per cent of adventurous machine-tool builders are in the two lower classes compared with 79 per cent of all manufacturers in those classes, and the figures seem to indicate that such small shops must have very hard sledding in the machine-tool business.

Problems of Management of Machine-Tool Shops

The fluctuating nature of the demand for machine tools creates serious problems in different stages of the business cycle. It is evident that the more regular an industry's demand, the lower can be its costs and the easier its managerial problems. The peculiarities of human nature as manifested in business cycles compel the builder of machine tools to face relatively short and sharp peaks of activity, followed by relatively long and deep depressions. The industry has a naturally bad load factor for some very human reasons. The first is that most people do not look very far ahead, and most machine-tool users are no different in that particular. Therefore, comparatively few users forecast their machine-tool requirements to any great extent. In a period of depression the user's shop is more or less idle, and he has more than enough machinery to supply the restricted demand for his own goods. He is mentally so depressed by dull business that he cannot bring himself to even think of a time just a few months ahead when his business will be more active, when the natural growth of population and wants will demand more of his goods than he was able to make in his last boom. Not forecasting what the future has in store, and how long the depression in his own business will last, he simply will not spend money on plant improvements when he could be making them to the best advantage.

Consider now the difficulties of the machine-tool builder in trying to regulate his operations. At the height of his own previous boom he had as full a force of men as he could get, working night and day. He had also a lot of contracts out for castings and other material, placed far in advance, in large quantity, at high prices, to be able to supply his customers' wants without delay. Even though he had been quoting six to eighteen months' delivery, his orders had been piling in on him with increasing speed. When his orders began to fall off he had this large impending inventory thrown on his shoulders. Then he got many cancellations, from those who should have been compelled to live up to their contracts. If he was unwise enough to accept them he was stuck with large inventories in all stages of completion, but without sale.

Being of the adventurous rather than of the prudent type, and of the inventive rather than of the commercial turn of mind, he had not given much consideration to the progress of the business cycle. As the economics of the cycle had not been pointed out to him, he did not realize that his industry is among the first to slump in a cycle, and that the slump in machine-tool orders is merely one of the signs of coming trouble elsewhere. He took counsel of hope rather than of prudence. It had cost him so much in money and effort to get his working force together that he hated to break it up. If his product was not of a type built only to order, he kept on working and built stock instead of shutting down his plant. Then, too, he had a goodly share of that human sympathy that leads any decent employer to keep his men employed as long as possible rather than to throw them out of work. Looking back now he realizes that it would have been better both for his men and for himself to have shut down as his orders were filled, and to have waited to build his stock at the bottom of the depression rather than at the crest of a boom.

When his own financial strength was threatened, even the most adventurous and sympathetic could no longer keep on producing, at high costs, machines for which there was no sale at any price. So the industry finally had to do late what it should have done early in the slump, that is, shut down and wait for improvement in conditions in other lines to revive demand for machine tools.

Not only is the period of carry over likely to be long, but another danger of carrying large stocks must be reckoned with. That danger lies in obsolescence of designs. Necessity is the mother of invention, and the necessity of getting work for idle shops always produces a good-sized family of new and improved designs after a depression has been on for some time. When these are brought forth, their greater utility to the user kills the demand for the older types. In a depression, machines of new design can generally be made for less than the old types had cost in the boom. Even if not obsolescent the replacement cost of the older type is less in a depression that it was in the boom. Some competitor who has no knowledge of unchangeable economic facts is almost certain to hatch the bright idea that by making very low prices while his competitors are asleep, he can get a much larger participation out of a dull market than his natural participation had been in a more active market. He thinks he can thereby carry some of his overhead at their expense. But as the competitors are not asleep, this bright idea fails to get the anticipated results. All have a natural desire to keep their own places in the sun and they meet his low prices and all get that much less to carry overhead with. While all these factors lead to great losses in a depression, the low prices do not lead to much, if any, stimulation of sales.

For 15 months in the last two years machine-tool-sales volume was down to less than 15 per cent of what it had been in the first quarter of 1920. For 32 months past the demand has averaged about 23 per cent of that figure. In some cases prices were made that would just about cover material and labor, in attempting to coax out orders enough to hold a force of good men together. Some people think that because demand for cheap automobiles can be stimulated by slight reductions in price, the demand for machine tools acts in the same way. The cheaper the automobile, however, the wider is the stratum of demand it can tap, until a saturation point is reached.

Because of these long periods of depression through which the machine-tool builder must carry his plant and organization, he must put a heavy stand-by charge on his goods. He must cover this cost of necessary idleness—over which he has no control—by accumulating a reserve in good times out of which to draw in bad

(*Continued on page 200*)

The Development of Machine Tools

By DEXTER S. KIMBALL,[1] ITHACA, N. Y.

IN THESE days of many books and much learning we are prone to overlook or forget the fact that man's upward progress in all times has been dependent primarily upon the tools and mechanical appliances at his command. Originally little better than the beasts of the field, man lifted himself from their company by discovering the use and control of fire, and with the invention of the bow and arrow he began to assume his lordship over all created living things. The ability to make pottery advanced him from savagery to barbarism, and the domestication of animals gave him a supply of physical strength far greater than his own to assist him in conquering an unfriendly environment.

The ability to smelt copper and tin into bronze gave him tools and weapons of greatly increased efficiency and enabled him to establish himself securely in permanent habitations where he could till the soil, tend his herds, and have some leisure for thought. From this opportunity to think came the alphabet and written language, and with this ability to record and transmit his thoughts came civilization. Finally the discovery of iron and steel and of almost unlimited power from coal and water power have enabled this master animal to push his ideas of civilization to a height undreamed of by his ancestors, and it has not been possible to predict what the end may be.

Man is distinguished, therefore, from other inhabitants of the animal world principally by his power to make and use tools and with their aid to subdue his physical surroundings to satisfy his needs. These tools are of two distinct kinds. First come those that he has developed to supplement his own puny strength and to increase his effectiveness. The story of the development of power-supplying devices from the first crude hatchet to the monster power stations of today is in itself an epic unequaled by anything else except, perhaps, the parallel development of the art of transmitting intelligence. The story of man's progress from signaling with fire or smoke to modern radiotelephony is without doubt man's most spectacular achievement as it is also one of his most useful accomplishments.

But a supply of power of itself alone would not have been sufficient for man's needs. Methods of utilizing and guiding this power so that it would perform useful work were essential requirements for progress. Of a necessity machines were needed that would perform the operations of industry as well or better than they could be performed by the human hand. The second great division of this field, therefore, comprises the tools that involve "transfer of skill." Practically all tools that are actually used in productive processes involve this principle. The stone ax, the bow and arrow, and all handicraft tools have come into being in answer to a desire on the part of some one to improve his product in quality or quantity by the aid of some one of these implements.

Until the middle of the eighteenth century the use of tools as then developed still required a considerable degree of skill on the part of those operating them. The tool was still only an adjunct to the skill of the worker. About that time, however, a series of interesting inventions demonstrated the possibility of making machines involving such a large transfer of skill as to make the worker an adjunct to the machine in many industrial processes. This is the essence of the Industrial Revolution, so called, and today automatic machines that perform the necessary operations with little or no human aid are in common use.

Back of the amazing array of productive tools and processes that now fill the land, stand a group of tools that are in a class by themselves. These may be called the "Master Tools of Industry" since the production of all other tools and processes, in the construction of which metal working is a necessity, depends upon the possession of some or all of these tools. This group consists of the lathe, the planer, the drilling machine, the boring mill, the milling machine, and the grinding machine, with their several modifications and derivatives. They constitute the group commonly known as "machine tools" and are familiar to all who are acquainted with machine production. This group of tools are worthy of special notice for they are basic implements and, as formerly remarked, accurate machine construction of all kinds depends absolutely upon them.

The primitiveness and inaccuracy of the machine tools in use when Watt began to build his steam engines are almost unbelievable. We find him complaining of one of his steam cylinders that "at the worst place the long diameter exceeds the short by three-eighths of an inch" and there is much other evidence that indicates similar crudity in all machine processes. The development from these crude beginnings to the modern standards of accuracy and output is something of which every engineer may well feel proud. It is difficult always to give due credit for great improvements in any line to all who have contributed to the accomplished result. Great inventions, so called, are usually the result of a long train of thought and experiment on the part of many men. But it is customary to give the greatest credit to the man who first makes a great idea a real working possibility. For this reason there are a few outstanding men among those who brought this great change about, though undoubtedly the ideas they put into practical working machines had occupied the minds of many of their predecessors. Wilkinson's boring machine solved Watt's difficulties so that Boulton writes of a fifty-inch cylinder that "does not err the thickness of an old shilling in any part." And there are many other names among these old pioneer English mechanics that should be held in everlasting remembrance when the names of all great warriors have been forgotten.

Outstanding Names in Machine-Tool History

There are, in the history of machine-tool development, three names that stand out in bold relief. The first of these is Henry Maudslay, who was born in 1771. Of the many inventions and improvements in machinery that came from this master mind the most important is the slide rest and its combination with the lead screw and change gears whereby threads could be machined. Until Maudslay's time the turning of metal had been accomplished by hand tools. In fact, this method persisted for many years after his day and there is now preserved in the rooms of The American Society of Mechanical Engineers a turning tool that was used by the late John Fritz not so many years ago. Maudslay finished the sides of his lathe bed and mounted upon it a saddle exactly as used on modern lathes, this saddle carrying a cross-slide in which the tool was rigidly held. The saddle was actuated by a lead screw and change gears as in all modern lathes. As Professor Roe truly says, "Too much value cannot be placed upon the slide rest and its combination with a lead screw operated by change gears. It is used in some form in almost every machine tool and is one of the great inventions of history." Maudslay's improvements constituted a transfer of skill that did much to start the modern industrial era.

The second great improvement in machine tools was the application of the turret to the slide rest so that a series of operations can be performed repeatedly without resetting the cutting tools. Here again we have an idea that was undoubtedly an old one; but it remained for an American, Henry David Stone, to make it a working possibility in the turret lathe built by him in 1858. Stone's first semi-automatic turret lathe carried four cutting tools on the cross-slide and six in the turret. His improvements rank in importance with those of Maudslay and they made possible most of the modern semi-automatic machine tools. Lastly came the invention of the universal cam or "brain wheel" by another American, Christopher Mines Spencer, which provided an automatic control for the combination of Maudslay's slide rest and Stone's

Effect of Variations in Design of Milling Cutters On Power Requirements and Capacity

A Study of the Effect of Changes in the Number of Teeth, Spiral Angle, Rake Angle, and Cutting Speed of the Cutter on Power Consumption, Tendency to Chatter, and Stresses Set Up in the Machine

By BENJAMIN P. GRAVES[1] and JAMES A. HALL,[2] PROVIDENCE, R. I.

THE rapid development of the milling machine during the last two decades into a leading position in heavy machine work has brought about many improvements in the design of milling cutters. The old cutters with many teeth, no rake angle and a small spiral angle were very inefficient from a power standpoint, and it was only about twelve wears ago, following the delivery of a paper before the Society on Milling Cutters and Their Efficiency by A. L. DeLeeuw,[3] that "coarse-tooth" cutters having few teeth, a moderate rake angle, and a much larger spiral angle began to replace the earlier type.

While these cutters rapidly came into almost universal use for production work, little further was done to put the subject on a scientific basis until 1921 when the report of an elaborate piece of research work was presented before the annual meeting of the Society by Prof. John Airey and Carl J. Oxford.[4] Some of the conclusions which they presented differed so greatly from present practice that it seemed desirable to undertake a series of investigations at the plant of the Brown & Sharpe Mfg. Co. to determine the effect of changes in the design of milling cutters. The results obtained are presented in this paper, which comprises a study of the effect of changes in the number of teeth, spiral angle, rake angle, and cutting speed of the cutter on power consumption, tendency to chatter, and stresses set up in the machine.

Choice of Methods

The first consideration in the choice of methods to be followed was that all tests as far as possible should be made under actual shop conditions, using, however, sufficient refinement of measurement to give a high degree of accuracy in the results. On the other hand, as cutters and not machines were to be compared, any variables due to the machine alone must be eliminated. It therefore seemed best to make most of the tests with the work held rigidly on the milling-machine table and to determine the power used by the cutter from the figures of the input into the motors driving the machine.

An old-style Brown & Sharpe No. 3 heavy plain milling machine with a constant-speed drive shaft was available for the tests. Upon the table of this machine a fixture was placed into which dovetailed steel specimens 6 in. wide and 18 in. long could be fastened by mean of a gib. This made about as rigid a means of support as could be devised. The cutters were also rigidly held as they were keyed on to a $1^1/_2$-in. arbor, arbor supports were used on both sides of the cutter, and the outside braces were bolted during all of the tests. In this way errors due to distortion or vibration in the machine or arbor were eliminated as far as possible.

Measurement of Power Used by Cutter

The power figures desired in making comparisons between cutters are the amounts required by the cutters alone and should not include the friction losses in the machine unless the friction has some direct relation to the pressure exerted or power required by the cutter. The problem is complicated by the fact that the power delivered to the milling machine is divided between a slow-moving table and a cutter running at a relatively high speed. Furthermore, these two drives are of widely different efficiencies.

The first step toward getting definite information concerning power requirements was obviously to drive the spindle and table by separate motors. A prony brake was then placed on the arbor and a series of tests run to get the efficiency of the spindle drive at different capacities and speeds. The power input required to run the arbor at no load varied slightly with the speed and condition of lubrication. The brake-horsepower output, however, was always nearly the same for any added kilowatt input over the no-load reading. A horsepower-kilowatt curve was then drawn where the power delivered to the arbor was one coördinate, and the difference between the no-load kilowatt reading and the reading under load the other. One objection to the above method might be that the pressures between the arbor bushings and arbor supports are much greater under cut than on a prony-brake test and that the authors have charged this friction loss to the cutter. However, not only is this a very small amount but it is one that is properly charged to the cutter rather than to the machine.

The proper treatment of the power required by the table is a more difficult problem. Here the no-load kilowatt reading includes the motor losses and the friction losses in all of the bearings up to the table clutch, and these losses remain nearly constant for all loads. The additional power required when the table is operating under load is not only that needed to overcome the pressure of the cutter, but a much greater amount due to the friction loss in the lead screw and thrust bearing caused by that pressure. As this friction varies with the pressure, it seems obvious that it should be charged against the cutter if conditions calling for different pressures are to be compared. The authors therefore took as the net power required by the table the difference between the motor output under load and that when driving the feed mechanism alone.

Any milling-machine table drive is necessarily of low efficiency due to the fact that the table must not continue to move and drive the lead screw after the table clutch is thrown out. This limits the efficiency of the drive to a reasonable margin of safety below 50 per cent when operating on a high-speed return and of course gives a much lower figure at cutting speeds. This low efficiency makes little difference under ordinary conditions as a very small proportion of the total power of the machine is taken by the table. This would be changed if the practice of using low cutting speeds were carried to an extreme. Considerable attention was paid to this condition in the tests and it is further discussed later in the paper.

Cutters

High-speed-steel cutters $3^1/_2$ in. in diameter were used on practically all of the tests, the only exception being a few tests with two 6-in. side milling cutters. All of the $3^1/_2$-in. cutters used in the tests to determine the effect of the number of teeth had 30-deg. spiral angles and 10-deg. rake angles. As the formula derived by Professor Airey and Mr. Oxford called for 20 teeth in such a cutter, this was put at one end of the series, a Brown & Sharpe standard cutter with eight teeth came in the middle, and a four-tooth cutter was added to give an extreme condition of coarse spacing. A number of tests were also made with a 10-tooth cutter. Additional comparisons were made between the two 6-in. side milling-cutters, one of which had 12 teeth and the other 26 teeth, or two less than given by the formula mentioned above. The latter cutter was $^{15}/_{16}$ in. wide and the former 1 in., but otherwise they were exactly alike.

Other sets of cutters alike in every particular except the element to be studied were used in the tests to determine the effect of variations in spiral angle and rake angle. The sizes of these cutters are given in the discussion of the results.

[4] The Art of Milling, Trans. Am.Soc.M.E., vol. 43 (1921), p. 549.

Presented at a joint meeting of the Philadelphia Local Section and the Machine Shop Division of The American Society of Mechanical Engineers, the Engineers' Club of Philadelphia, and the Philadelphia Section of the American Institute of Electrical Engineers, Philadelphia, February 27, 1923. Slightly abridged.

Metal Used in the Tests

As the only object of the investigation was to compare cutters, mild steel was used in all the tests. This was done to enable the authors to make enough cuts to be sure of their results and to eliminate as far as possible variations due to lack of uniformity in the metal being cut. Fortunately most of the tests were made on blocks which were fairly uniform. The tabulation of the figures on the study of spiral angle, however, showed certain unexpected results occurring somewhat uniformly throughout the tests. A little later a cut was taken along the full length of the 18-in. block, the depth, feed, and speed being held constant throughout. The average power required was about six horsepower and the maximum variation was over seven per cent. A repetition of this cut gave the same variations at the same places, showing that it was not accidental. In the authors' studies enough tests had been made so that the average gave results which could be reasonably depended upon. However, this shows how much faith can be placed on the results of tests to determine small variations in power unless a considerable number of runs are made or unless steps are taken to eliminate the effect of these variations on the results.

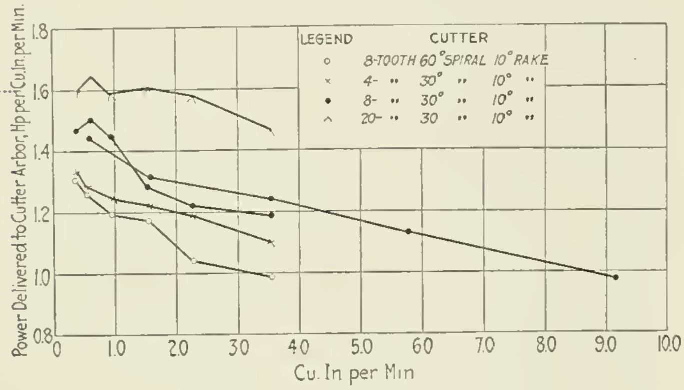

Fig. 1 Power Required By Coarse- and Fine-Tooth Cutters—Constant Depth of Cut and Variable Feed

(Material cut, mild steel; width of cut, 5.5 in.; depth of cut, 0.100 in.; cutting speed 94 ft. per min.)

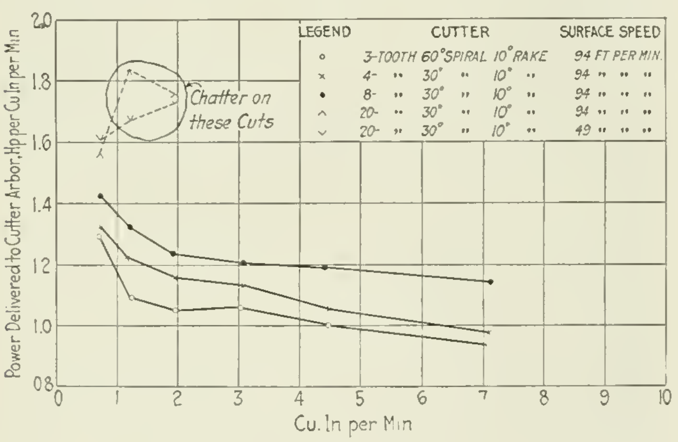

Fig. 2 Power Required by Coarse- and Fine-Tooth Cutters—Constant Speed, Constant Depth of Cut, and Variable Feed

(Material cut, mild steel; width of cut, 5.5 in.; depth of cut, 0.200 in.)

The properties of the steel in all the specimens used in the tests were about the same with the exception of the $^1/_2$-in. bar. The values for tests on specimens 0.505 in. in diameter and 2 in. long are given below:

	$^1/_2$-in. Bar	Other Specimens
Elastic limit, lb. per sq. in.	50,300	42,000
Breaking load, lb. per sq. in.	73,500	68,000
Elongation, per cent	34	35
Reduction of area, per cent	62	62
Brinell hardness	126	126

Method of Making Tests

A light cut was always taken along the specimen before starting any test to guarantee that the depth of cut would be constant. The table was then fed up the desired amount, and from two to six tests were made at this depth of cut in the 18 in. of length of the block. At the end of the first cut the table was run back and the depth of cut checked. The exact figure for the feed was determined by taking the time with a stop watch and measuring roughly the distance traveled with a steel scale and correcting this figure to the thousandth of an inch by reading the dial on the lead-screw handwheel. In this way the exact amount of metal removed per minute was determined.

The electrical instruments were carefully calibrated before starting the investigation and found to be practically correct over their whole range. Before and after each test, readings were taken to determine the friction load and several readings were made during the test to determine if the power remained constant. The differences between the readings under load and the no-load figures multiplied by the proper constants gave the horsepower delivered to the cutter arbor and to the table lead screw.

A number of tests were also made on a special fixture to measure horizontal and vertical pressures by use of two Kenerson traction dynamometers. This was mounted on the table of the machine and calibrated in position by the application of known weights. The method of making these tests was exactly the same as in the others

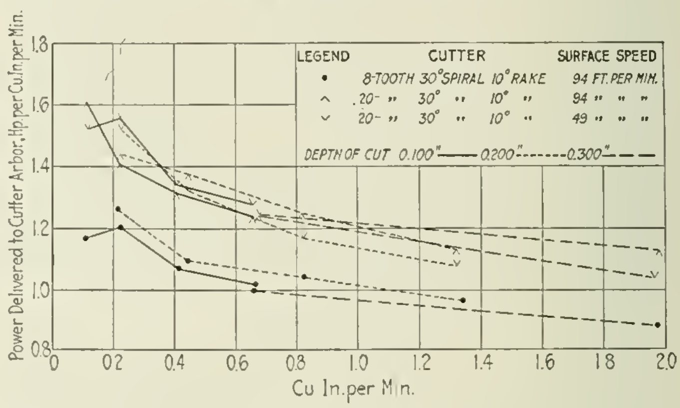

Fig. 3 Power Required by Coarse- and Fine-Tooth Cutters—Constant Speed, Variable Feed

(Material cut, mild steel; width of cut, 1.012 in.; depth of cut, 0.100 in. to 0.300 in. as indicated in figure.)

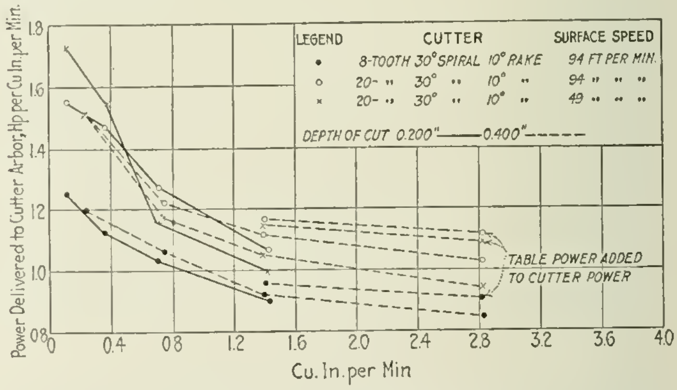

Fig. 4 Power Required by Coarse- and Fine-Tooth Cutters—Constant Speed, Variable Feed

(Material cut, mild steel; width of cut, 0.535 in.; depth of cut, 0.200 in. and 0.400 n. as indicated in figure.)

except that the reading of two dynamometers was added. For moderate cuts this apparatus combined in a high degree rigidity and accuracy, and gave some very interesting results.

As far as possible comparative tests on different cutters were made on the same block of steel and their order was arranged so that corresponding runs came as nearly as possible at similar positions on the the block. In this way errors due to lack of uniformity in the metal were reduced to a minimum.

The results are plotted in the form of curves having as one coordinate either horsepower per cubic inch per minute or pressure along the table. The former figure is used instead of the more common cubic inches per horsepower, as in some cases the sum of the cutter and table power is given as well as the cutter power

alone. For the other coördinate cubic inches per minute, feed per tooth, or maximum chip thickness are used. The latter quantity was used extensively in the paper by Professor Airey and Mr. Oxford, and they claim that the power required per cubic inch of metal per minute will be the same for the same maximum chip thickness for all cutters having similarly shaped teeth irrespective of the number of teeth.

Effect of Number of Teeth in Cutter

Several groups of tests were run in the studies of the effect of varying the number of teeth in the cutter. In the first group the speed and depth of cut were kept constant and the feed varied. This of course varied the chip per tooth and the output in cubic inches per minute and gave the comparison between cutters where equal finish is required for corresponding capacities. The second group contains tests where the feed and depth of cut were kept constant and the cutting speed varied. This gave a constant output and a variable chip per tooth. For the same feed per tooth the best surface finish is secured with the coarsest-tooth cutter. In the third group the depth of cut was kept constant and the cutting speed varied with the feed so as to give a constant chip per tooth. The output of course varied with the speed. This made a good study of the effect of the cutting speed on power requirements.

The tests in the first group are plotted in Figs. 1 to 4, each set

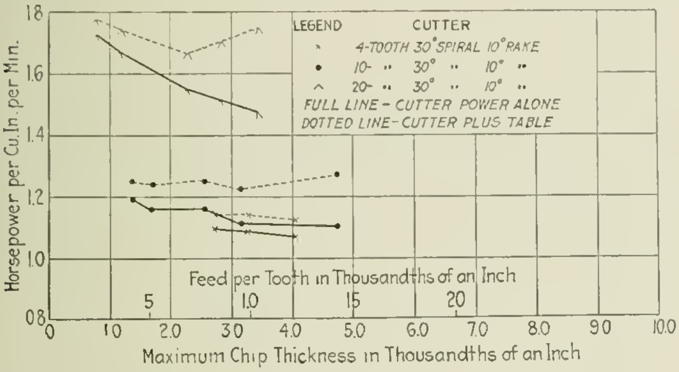

Fig. 5 Power Required by Coarse- and Fine-Tooth Cutters—Constant Feed, Constant Depth of Cut, and Variable Speed

(Material cut, mild steel; width of cut, 5.5 in.; depth of cut, 0 100 in.; feed, 4.1 in. per. min.)

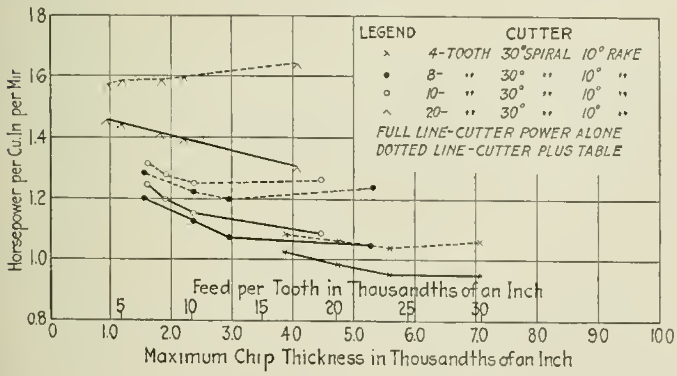

Fig. 6 Power Required by Coarse- and Fine-Tooth Cutters—Constant Feed, Constant Depth of Cut, and Variable Speed

(Material cut, mild steel; width of cut, 5.5 in.; depth of cut, 0.050 in.; feed, 8.20 in. per min.)

of tests being made with a different width or depth of cut. These show that for the same cutting speed the cutter with the smaller number of teeth always takes less power and that this difference is more noticeable on wide cuts. Moreover the fine-tooth cutter gave considerable trouble from chatter on these cuts, especially when the depth was 0.200 in., where it was impossible to use it beyond a limited capacity. This shows that the width of the work is a necessary factor in the determination of the number of teeth in the cutter.

In a number of the tests plotted in Figs. 3 and 4 the fine-tooth cutter was run at approximately half the standard speed to see what effect this had on power consumption. When compared on the basis of cutter power alone, the slower speed showed a saving but not enough to bring it down to the coarse-tooth cutter. When the table power was added to the cutter power as was done in several tests in Fig. 4, the relative advantage of the slower cutting speed practically disappeared.

The real criterion of the effect of chip size on power requirements can best be determined from tests where the feed per tooth is variable but the output is constant. The second group of tests was carried on with this point in view and some of the results are plotted in Figs. 5 and 6. These show that the power efficiency is greater with coarser-tooth cutters even when compared on a chip-per-tooth basis and when only the power required by the cutter is

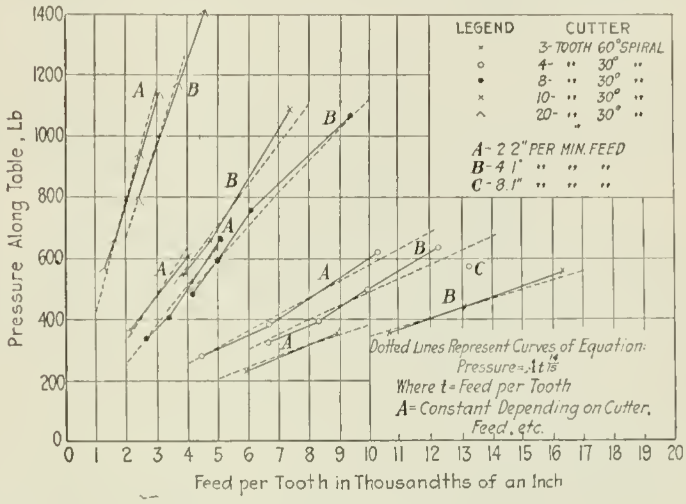

Fig. 7 Effect of Number of Teeth in Cutter on Horizontal Pressure along Milling-Machine Table

(Material cut, mild steel; width of cut, 5.5 in.; depth of cut, 0.050 in.)

considered. When the table power is added to the cutter power, the advantage of the coarse-tooth cutter is even more apparent.

An interesting point about these curves is that the sum of the cutter and table power comes to a minimum as the cutting speed is reduced, after which the table power increases more rapidly than the cutter power is reduced by the increased size of the chips. This point will be referred to again a little later.

Fig. 7 gives the results of a series of tests where the horizontal thrust along the table was measured at several different cutting speeds and two different outputs for each of five cutters. As the depth of cut was small, the power required by the cutter is practically equal to the product of the pressure multiplied by the velocity of the cutter. This checked rather closely with the amount determined from the wattmeter readings where these were taken.

The first point to be noted in this figure is that the pressure increases as the cutting speed is decreased to give a larger feed per tooth. Also if two cutters with different numbers of teeth are operated at the same total feed and also the same feed per tooth, the pressure caused by the cutter with the larger number of teeth is greater by a somewhat larger amount than given by the tooth ratio. The eight-tooth cutter is a little high on this basis, but this is due to the fact it was somewhat duller than the others. Machines and fixtures have limitations in the pressures for which they are designed, and this certainly limits the extent to which it is desirable to go in running fine-tooth cutters at slow speeds to give a large chip per tooth.

Another point of interest is that the curves for higher feeds all fall below those for lower feeds when plotted on a feed-per-tooth basis. The main difference between these tests is that the cutting speed is higher for the larger feeds. This raised a question as to the accuracy of the assumption often made that the cutting speed has no effect on the energy required per cubic inch of metal removed, and a special series of tests were made to study the effect of this variation. The results of these tests are presented a little later in the paper.

The data given in Fig. 7 were plotted on logarithmic cross-section paper and found to form a family of curves of the equation:

$$P = At^{14/15}$$

where P = horizontal pressure along table

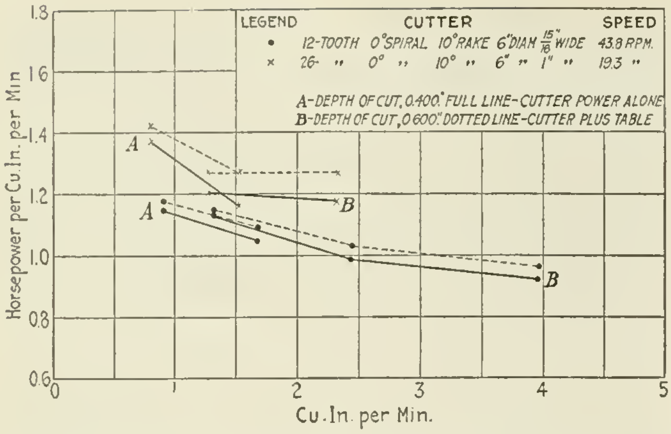

Fig. 8 Power Required by Coarse- and Fine-Tooth Side Milling Cutters Cutting Mild Steel—Constant Speed, Variable Feed

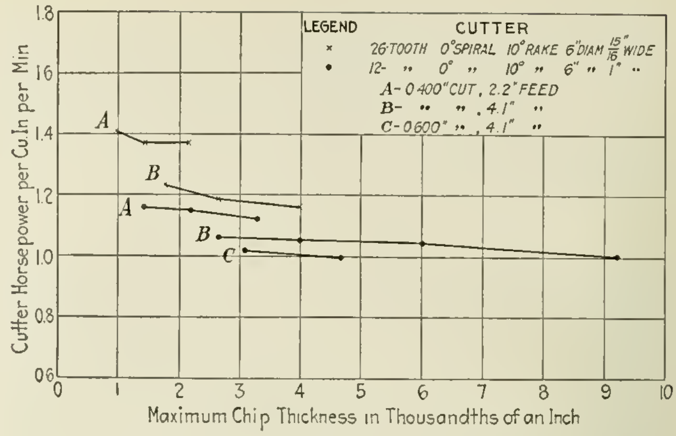

Fig. 9 Power Required by Coarse- and Fine-Tooth Side Milling Cutters Cutting Mild Steel—Constant Speed, Variable Feed

t = feed per tooth, and

A = a constant depending on cutter and feed.

Curves of this equation are plotted in Fig. 7 to show how they conform to the actual results. The number of tests involved is not sufficient to commit the authors absolutely to the power "$^{14}/_{15}$" but they feel sure that the correct figure is only a small amount below unity. In this connection it is interesting to note that the above figure is the one given by Frederick W. Taylor in his Art of Cutting Metals in the results of his experiments with lathe tools cutting mild steel.

Having an equation in the above form, it is possible to calculate for shallow cuts the proper relation of cutting speed and table feed to give the minimum power noted in the discussion of Figs. 5 and 6. Given—

V = cutting velocity in feet per minute

v = table velocity in feet per minute

E = efficiency of the table

$$\text{Horsepower} = \frac{P}{33000}\left(V + \frac{100\,v}{E}\right) \quad \ldots\ldots\ldots\ldots [1]$$

But $P = At^x$ and $t = Bv/V$, where B = a constant depending on the cutter. Substituting these values in [1] and solving for the value of V to make the power a minimum for any given feed and table efficiency,

$$V = \frac{100\,x}{(1-x)E}v \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

For example, if $x = {}^{14}/_{15}$ and E = 14 per cent, $V = 100v$.

Equation [2] gives a limit beyond which there is no saving in power when the cutting speed is lowered to give coarser chips per tooth.

Figs. 8 and 9 give the results of the studies with the side milling cutters. The two cutters were exactly alike except for the number of teeth and a slight variation in width. Fig. 8 shows tests where the cutting speeds were so arranged that the fine-tooth cutter took practically the same chip per tooth as the coarse-tooth on corresponding cuts. When compared on the basis of cutter power alone the coarse-tooth cutter was superior, and this advantage became still more pronounced when the table power was added. In attempting to carry the cut of 4 cu. in. per min. with the fine-tooth cutter the key in the arbor sheared, giving an illustration of the limitations of the machine in applying the chip-per-tooth theory.

Other series of tests with these cutters are shown in Fig. 9, the comparison being on a maximum-chip-thickness basis. Here again the fine-tooth cutter required more power and also proved inferior from the standpoint of chatter, as it was impossible to carry some cuts with it which were taken by the coarse-tooth cutter without a sign of distress.

Frequently in comparing results on a feed-per-tooth or a maximum-chip-thickness basis the power required per cubic inch per minute and the pressures along the table have been less for higher cutting speeds. The tests shown in Fig. 10 were therefore run to check up this relation. A set of cutting speeds and table feeds were arranged so as to keep the chip per tooth nearly constant as the cutting speed was increased. The power delivered to the cutter was taken from the wattmeter readings and checked by the horizontal-pressure figures. The results show that the horizontal pressure and the power required per cubic inch of metal per minute decreased as the cutting speed increased. The vertical pressure between cutter and work remained constant. In other words, if we compare removing 5 cu. in. per min. at 150 ft. per min. cutting speed with removing 1 cu. in. at 30 ft. per min. from the same place with the same cutter, the pressure tending to tear the piece from the fixture and the horsepower required per cubic inch will both be less in the first case. The explanation of this may be that the friction between cutter and work plays a much more important part in milling than in lathe work and that the coefficient of friction decreases as the speed increases.

It would doubtless seem from the foregoing that the efficiency of

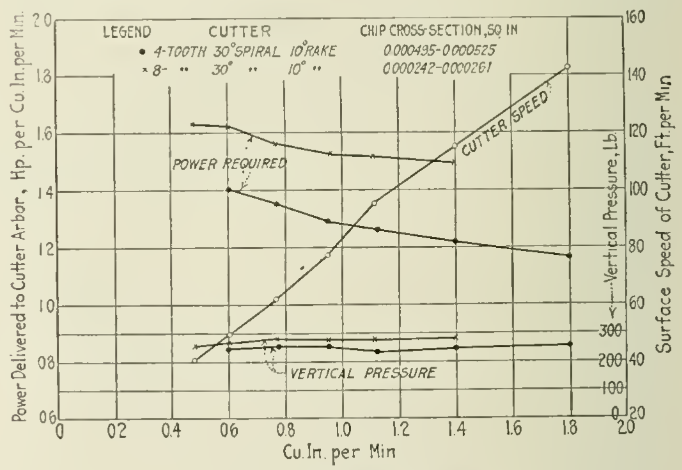

Fig. 10 Power and Vertical Pressure—Constant Chip per Tooth and Variable Load

(Material cut, mild steel; width of cut, 5.5 in.; depth of cut, 0.050 in.)

milling is increased by greater feeds per tooth. If these heavier chips are secured by using lower cutting speeds, the loss in the table becomes greater, the cutter itself requires more power per unit of metal than would be required for the same chip at higher speed, and the pressures between cutter and work become greater. The answer from the standpoint of power efficiency alone is then to use the cutter with the fewest possible teeth and to run it at higher speeds where the size of the chip is too great. The limitations to this practice are the danger of hammer or shock due to lack of continuity of cutting and the possibility of overheating the edges of the teeth due to the heavy pressures and high speeds. The structural strength of the tooth itself is not a limitation in well-designed cutters as this is practically always greater than the strength of the key or the arbor. The relation between the overheating of the edges of the teeth and the number of teeth in the cutter can only be settled by judgment, as no work has been done on the relative effect of cutting speed, volume and length of chip, ductility of the

(Continued on page 205)

The Elasticity of Pipe Bends

By Sabin Crocker[1] and S. S. Sanford,[2] Detroit, Mich.

In this paper the authors develop in detail mathematical formulas connecting the deflection of different types of pipe bends with the force producing deflection, and also expressing the stress set up as a function of the observed deflection and the constants of the bend. They describe experiments made to check force vs. displacement, and present charts for use in selecting the proper size and shape of bends to take care of a given expansion, and to determine the force exerted by a bend when in a given state of deflection. In general they recommend bends of larger dimensions than are ordinarily used, and their figures are said to be on the side of safety. In some cases the bends tested showed a greater flexibility than anticipated, due to minute folds formed on the compression side when bending pipe to short radius.

The use of expansion loops, offsets in the line, right-angled turns and similar devices to furnish flexibility for expansion and contraction in pipe lines resulting from temperature changes, has been general practice for years. Such bends, which utilize the elasticity of the pipe itself, are very commonly used for high-pressure work in preference to slip joints, corrugated expansion joints, or swivel offsets in which screwed elbows are arranged to turn on pipe threads. The use of pipe bends reduces internal friction in the piping by providing easy turns, eliminates unnecessary fittings and joints, and facilitates clearing other pipes and structural interferences.

Up to the present time the disposal of expansion and contraction in power-plant piping has been largely a matter of judgment rather than of rational calculation on the part of the designer. This has been due to a general lack of knowledge or interest regarding the principles and methods involved in calculating the forces and stresses resulting from the expansion of piping. However, if certain rather fundamental principles of engineering mechanics are brought into play, it is usually possible to determine numerical values with fair accuracy during the progress of design, and make use of this knowledge to improve the piping layout. As the drift toward higher steam pressures and temperatures in turbine practice continues, the problem becomes more and more important. Since there is also a tendency for the steam turbine to grow smaller relative to the size of the steam line to which it is connected, there is a danger that excessive stresses will be set up in the turbine casing as a result of expansion in the pipe line unless the piping designer knows how to calculate the forces involved.

The amount of expansion to be cared for in a pipe line can be accurately computed, provided the temperature range between extreme hot and cold conditions, the length of pipe, and the coefficient of expansion for the material are known. Having computed the amount of expansion or elongation of the pipe, the problem resolves itself into determining whether the piping arrangement under consideration has sufficient "spring" to absorb this elongation without producing either undue fiber stress in the material or excessive forces tending to tear the piping loose from its anchors. At the same time the proportions of the line must be economical and be adjusted to clear any structural interferences in the plant. Wall thickness and diameter of pipe, radius of curvature, and general layout all affect the flexibility which can be obtained with a given run of pipe.

The inadequacy of the usual methods of steam-pipe design has been brought forcibly to the attention of The Detroit Edison Company by several minor mishaps during the past few years. Fortunately, none of these were of a serious nature, but they did serve to show that piping laid out according to the best modern practice may be subject to forces of unexpected proportions. Thus in one instance unexpectedly large reactions caused a 14-in. high-pressure steam main to tear loose from what was supposed to be an adequate anchorage. This incident, and others of a somewhat similar nature, led those responsible for design and operation to ask themselves whether such failures could not be avoided by more intelligent design. Consequently, in undertaking the design of the company's Marysville power plant, where the elongation per hundred feet of steam pipe amounts to almost seven inches and the steam pressure is 300 lb. per sq. in., it was decided that pipe expansion must be cared for in a rational manner if such a thing were possible. Accordingly, the investigation here reported was undertaken to determine the fundamental relations between deflection, force resisting deflection, and stress set up in expansion pipe bends of various shapes. These relations were first determined mathematically, and later checked by physically testing bends of shapes which readily lent themselves to measurement of the quantities involved. The results thus obtained were then applied to the more complicated conditions in actual pipe lines. As a result it was possible to design the piping layout for the first section of the Marysville power plant, which has just been put in operation, so that the following results are obtained without allowance for cold springing:

Maximum fiber stress in pipe wall..... 6900 lb. per sq. in.
Maximum thrust against pipe anchorage 680 lb.
Maximum thrust against turbine flange 580 lb.

If credit is taken for cold springing, the maximum stress and forces given above are further reduced. These values have been obtained without making the expansion bends unnecessarily large.

Previous Work by Others

Before proceeding along independent lines an extensive search was made for existing literature, which disclosed that very little had been written on the subject. However, the following articles are of special interest:

(*A*) Formoenderung und Beanspruchung federnder Ausgleichroehren Strains and Stresses in Expansion Bends), by Prof. A. Bantlin, *Zeitschrift des Vereines deutscher Ingenieure*, Jan. 8, 1910, p. 43.

(*B*) Expansion of Pipes, by Ralph C. Taggart, *Trans.Am.Soc.C.E.*, paper No. 1167, Dec., 1910.

(*C*) Elasticity and Endurance of Steam Pipes, by C. E. Stromeyer, *Engineering*, June 19, 1914, p. 857 (from a paper read before the Institution of Naval Architects).

(*D*) Pipe Bends, Their Growing Use and Efficacy, *The Valve World*, Oct., 1915 (published by Crane Co.).

(*E*) The Design of Pipe Bends for Expansion in Pipe Lines, by J. G. Stewart, *Power*, May 10, 1921, p. 742.

Reference (*A*) deals with the comparison of physical tests and calculated results for bends similar to our double-offset expansion U-bends.

Reference (*B*) treats principally of the use of straight pipe and fittings in making up expansion loops. The results are in general similar to those of the present authors for straight lengths of pipe.

Reference (*C*) describes a series of failures of steam pipes in service, due to repeated strains beyond the elastic limit. A set of formulas similar to those presented in this paper was worked out to show what elongations could be cared for without eventually producing failure.

Reference (*D*) is a report of physical tests on pipe bends made by the Mechanical Experts Department of Crane Company, and published in their organization paper, *The Valve World*. A series of curves deduced from their experimental data and giving the amount of expansion required to produce a fiber stress of 15,000 lb. per sq. in. in different-shaped bends was included for the use of those interested in pipe design.

Reference (*E*) gives a method of computing fiber stress similar to that of Reference (*C*), and a chart for reading the elongation corresponding to 15,000 lb. per sq. in. stress for different bends.

It is worth comment that while the author's formulas were worked out independently of Reference (*C*) and before Reference (*E*) was published, all three sets are practically identical. The comparison of theoretical formulas with actual test results, and the rather complete design graphs worked out in this paper, take the subject a step beyond the point reached by earlier publications. The fact that none of the previous investigators has published all of the mathematical steps leading up to his final formulas, will make the derivations given in the complete paper by the authors of special interest to any one having occasion to work with the formulas.

[1] Piping Engineer, Detroit Edison Co., Assoc-Mem. Am.Soc.M.E.
[2] Research Department, Detroit Edison Co., Jun.Am.Soc.M.E.

Contributed by the Power Division and presented at the Annual Meeting, New York, December 4 to 7, 1922, of The American Society of Mechanical Engineers. Abridged. All papers are subject to revision.

Table 1 is a summary of such data published in the above references as were in shape to reduce to a common form for comparison with the work of the present authors. It will be noted that the formulas of References (*C*) and (*E*) agree very closely with those of this paper, while Reference (*D*), which has been widely quoted during the past seven years, differs considerably from the others except for the double-offset expansion U-bend. The following extract is quoted from Reference (*D*):

> A 180-deg. or U-bend has twice the expansive value of a 90-deg. or quarter-bend of the same size and radius, and an expansion U-bend, four times the expansive value of a quarter-bend or twice that of a U-bend. A double-offset expansion U-bend has five times the expansive value of a quarter-bend, two and one-half times that of a U-bend, and one and one-fourth times that of an expansion U-bend.

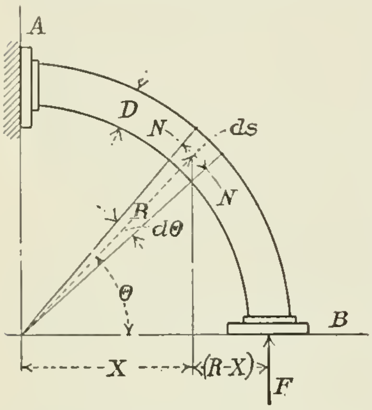

Fig. 1 Quarter-Bend, Force Axial

In other words, the relative ability of these particular bends to take up expansion without exceeding a safe stress is stated by Reference (*D*) to be in the ratio of 1 : 2 : 4 : 5, while the calculated ratio given by References (*C*) and (*E*), and checked by the present authors, is 1 : 4.4 : 13.2 : 32.9, assuming that the quarter-bend is connected to the pipe line so that the thrust of the line acts along the axis of the pipe in the bend at the joint, as shown in Fig. 1.

Referring to the stress index of Table 1, Reference (*D*) agrees quite closely with the others' results for double-offset expansion U-bends, but gives much higher values for the expansion cared for by quarter-bends, U-bends, and expansion U-bends than do the others. It will also be noted that the stress and flexibility indexes for the double-offset expansion U-bend given by reference (*E*) differ slightly from those given by the present authors. This is because the two bends considered are not of exactly the same shape.

A peculiarity of bends noted in Reference (*A*) was also observed in some of the bends tested by the authors, i.e., that the elasticity found by test exceeded the computed elasticity. Reference (*A*) describes tests on three kinds of bends formed to a shape which resembles a double-offset expansion U-bend, the first variety being bent from solid rod stock, the second from steel pipe, while the third was a hollow iron casting similar to a pipe bend. Tests of the first and third varieties checked very closely with calculated results, while the bend fabricated from a straight length of pipe was found to be much more elastic than the calculations indicated. The explanation given in Reference (*A*) is that the large deflections of the steel pipes must be attributed chiefly to waves or folds upon the compressed side of the pipe.

This conclusion is supported by the results presented here, all of the test bends formed to a radius of five pipe diameters or less having a flexibility in excess of calculated values, while, with one exception, those formed to a radius of six diameters or more gave results agreeing closely with those obtained by the formulas. This would seem to indicate that the excessive elasticity was due to puckers or folds in the pipe wall produced in the process of bending, the tendency being to thin the pipe wall at the outer circumfer-

Definitions of Symbols

- C = stress index (numerical values given in left half of table).
- K = flexibility index (numerical values given in right half of table).
- S = maximum bending stress in pipe wall, lb. per sq. in.
- D = outside diameter of pipe, in.
- R = mean radius to which bend is formed, in.
- E = modulus of elasticity (30,000,000 lb. per sq. in. for steel).
- I = moment of inertia of section, taken normal to center line of pipe of which bend is formed, in.[4]
- F = forc causing deflection of bend, lb.
- Δ = deflection of flange of bend = elongation of pipe line due to change in temperature, in = totel expansion to be absorbed by bend, i.e., total expansion calculated for a straight run of pipa with length equal to distance between anchors which occur nearest to bend under conesideration.

For shape of bends see Figs. 1, 2, 3, and 4.

ence of the bend and form minute crinkles or waves at the inner circumference. These conditions are more pronounced the shorter the radius of curvature, and in the case of the bend described in Reference (A), which was bent to a radius of only three to four pipe diameters, the waves were plainly visible. In American practice, where the minimum allowable radius of curvature is limited to five or six pipe diameters, these waves are not so visibly evident, nevertheless we may assume that they are present and have the effect of increasing the flexibility of bends formed to too short a radius.

Formulas and Design Graphs

A pipe bend may be considered as a beam of special form, one end of which is fixed and the other end of which is free to move in the direction of a force acting upon it. Since the bend is an elastic body, the movement of its free end will be proportional to the force acting, within the elastic limit of the material.

In the complete paper expressions are derived for the deflection Δ and the maximum bending stress S for the quarter-bend (Fig. 1), the U-bend (Fig. 2), the expansion U-bend (Fig. 3), and the double-offset expansion U-bend (Fig. 4), which are given in Table 1.

In each case, flange A has been considered as fixed. Such a condition would exist if the line to which A is connected where anchored at that point, or if A were a flange at the turbine. As a matter of fact, the entire analysis is really based on the movement of flange B with respect to A, and it makes no difference whether A is actually fixed or is permitted to move. F is the net force with which the pipe line pushes against the flange B when the line is hot. For design purposes the total expansion to be cared for between anchorages is determined from known or assumed temperatures, length of pipe, and coefficient of linear expansion. The length of pipe used is a nominal length equal to the actual linear distance between anchorages. In effect, it is as though a line of pipe such as that shown in Fig. 5 were assumed to be like that in Fig. 6, with the total movement due to the expansion of a straight pipe of length L applied at the flange B.

For the convenience of the power-plant designer, the formulas for several of the standard bends are represented graphically in Figs. 7, 8, and 9. The bends considered are the quarter-bend, U-bend, expansion U-bend, and the double-offset expansion U-bend with the forces applied as shown in the small figures on the graph and corresponding to Figs. 1, 2, 3, and 4. The forces and stresses set up in bends made up of pipe sizes up to and including 20 in., and bent to radii up to and including 120 in., may be read from these graphs without the necessity of solving the formulas.

Fig. 7 gives the maximum bending stress in the pipe wall of the bend for any expansion in the pipe line which must be cared for. Inasmuch as the stress is proportional to the outside diameter of the pipe for any given value of Δ, and is independent of its weight, this diagram serves for all weights of pipe. This diagram is drawn up for 8-in. pipe and values for that size may be read directly. For instance, an 8-in. expansion U-bend, formed to a radius of 60 in. and required to take up an expansion of 0.7 in. in the pipe line, would have a maximum bending stress set up in it of 5380 lb. per sq. in.

A sample problem will indicate the method to be used for other sizes of pipe. Since the stress is proportional to the diameter of the pipe, the value of the stress for any size of pipe may be obtained after finding the stress in an 8-in. pipe. The proportion between stresses can be made directly on the diagram by following the radial lines diverging from its lower right corner.

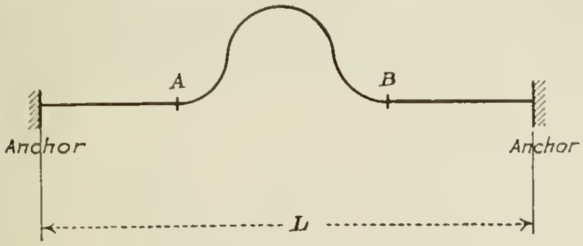

Fig. 5 Actual Piping Layout

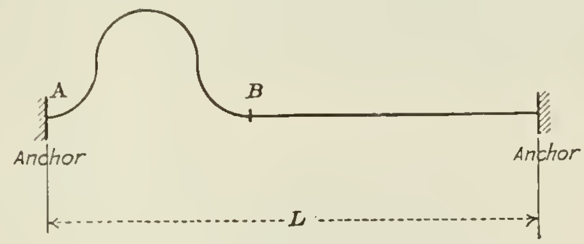

Fig. 6 Layout as Assumed for Calculation

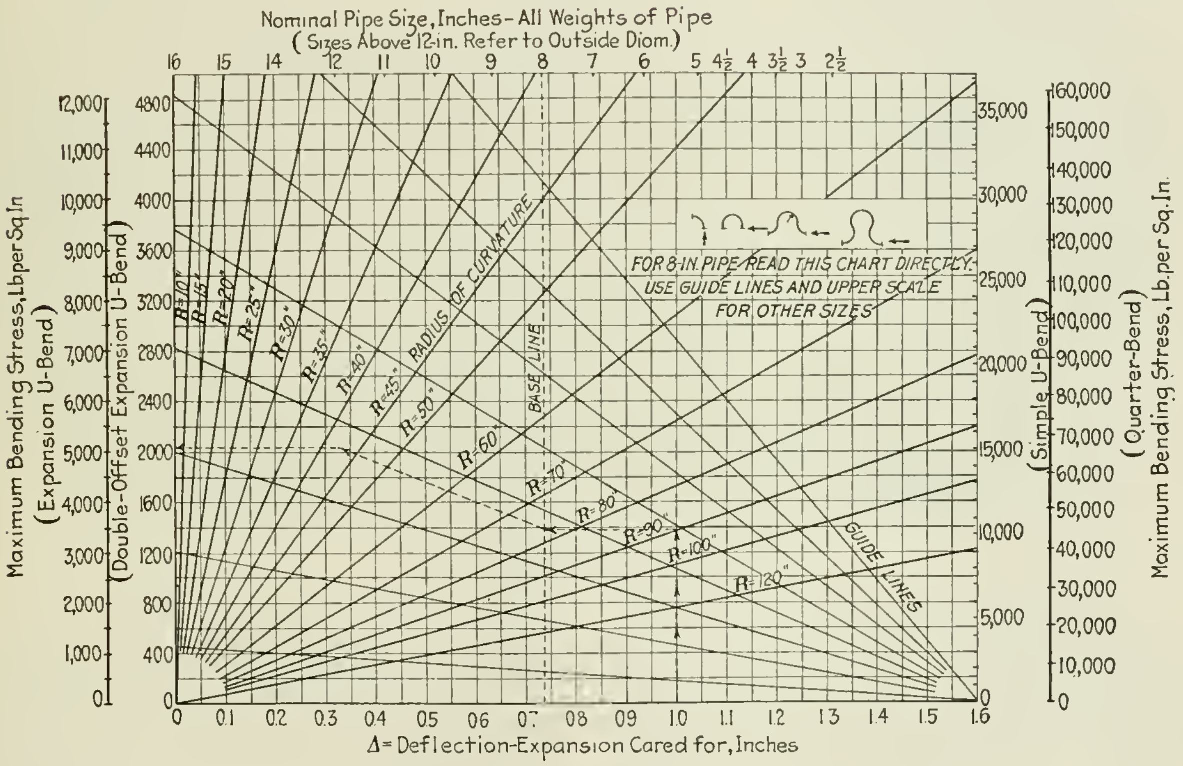

Fig. 7 Stress vs. Displacement for Various Shapes and Sizes of Pipe Bends

Sample Problem: A 12-in. double-offset expansion U-bend having a radius of 90 in. is to take up an expansion of 1 in. Required, the maximum bending stress in the bend.

From the intersection of $\Delta = 1$ in. and $R = 90$ in., extend horizontally to the vertical line under 8-in. pipe, which is referred to as the "base line," and the obliquely (with a line passing through lower right-hand corner) until under 12-in. pipe on the upper scale. The result is 2040 lb. per sq. in.

Since the stress is directly proportional to the displacement, this diagram may be used for values of Δ which fall beyond its range by multiplying both stress and displacement scales by the same factor. For instance, if a 5-in. expansion is to be considered, the stress for an expansion of 1 in. should be read on the graph and multiplied by 5.

Figs. 8 and 9 give the forces set up in the pipe line when pipe bends are used to take up the expansion. As these relations are functions of the moments of inertia of the pipe sections the internal diameters affect the results, and Fig. 8 has been drawn for "standard weight" and Fig. 9 for "extra heavy" pipe. These diagrams are for 16-in. pipe and values for this size may be read directly. The scale of pipe sizes at the top of diagram is laid off according to the moment of inertia of the pipe section, as the force to produce a given base line under 16-in. pipe, for making the proportion. The solution for a sample problem is indicated by the dash lines in Fig. 8. A double-offset expansion U-bend made of 14-in. O.D. pipe, $^3/_8$ in. thick, formed to a radius of 80 in., is required to take up the expansion of 1.1 in. in the pipe line. From the diagram, the force acting against the pipe anchorage is 610 lb.

Since the force is directly proportional to the displacement, these diagrams also may be used for values which fall beyond their range by considering both force and displacement scales as multiplied by the same factor. It should be noted that in using these diagrams the pipe size refers to the size of pipe used in the bend and has nothing to do with the size of pipe in the rest of the line.

Results of Tests

In all, eight separate expansion bends were tested. The methods employed in testing are described in the complete paper. The results are given in condensed form in Table 2.

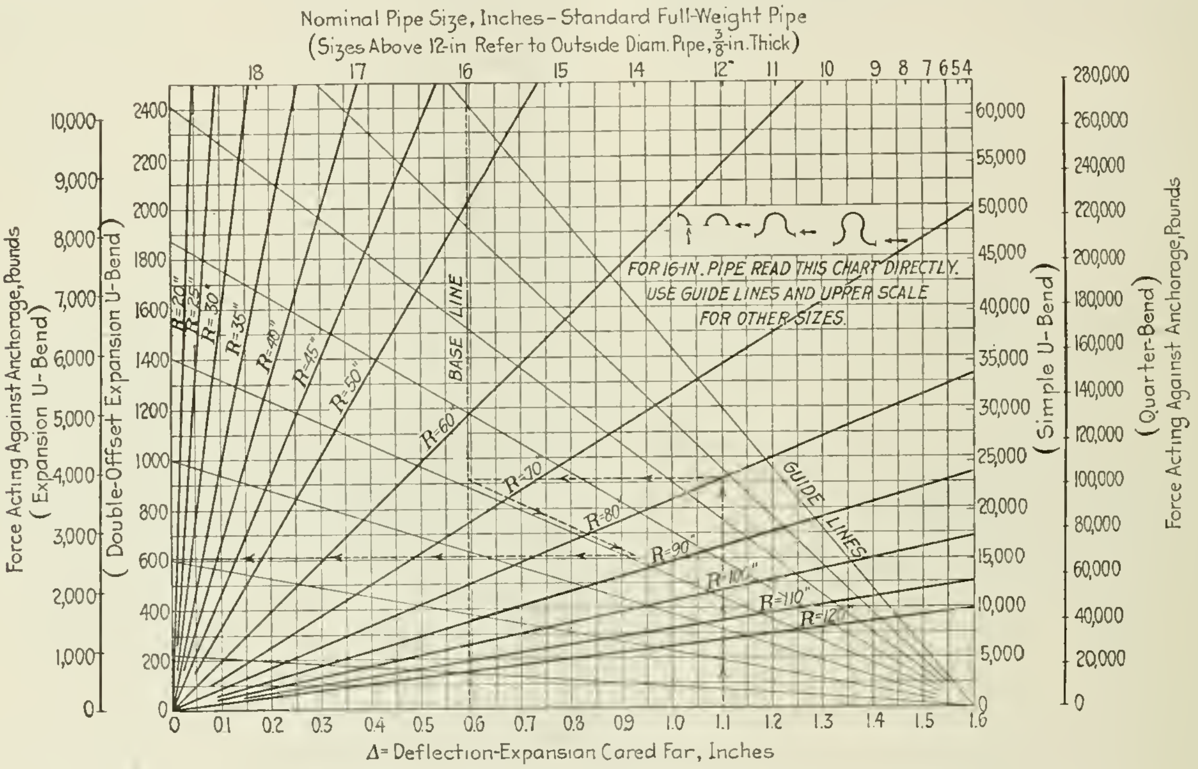

Fig. 8 Displacement vs. Force Exerted or Various Shapes and Sizes of Pipe Bends—Standard Pipe

deflection in the bend is proportional not to the diameter, but to the moment of inertia of the pipe.

After finding the force existing for a given deflection in the 16-in. pipe, the value for any other size of pipe may be obtained by using the radial lines diverging from the lower right corner, and the vertical

TABLE 2 RESULTS OF TESTS BY AUTHORS ON EXPANSION BENDS

Type of U-Bend	Nominal size of pipe, in.	Measured thickness of pipe, in	Radius of bend, in terms of nominal pipe diameter D	Flexibility index[1] K Calculated	Flexibility index[1] K Observed
Expansion U-bend	10	0.336	$6D$	9.42	29.8
Expansion U-bend	6	0.418	$6D$	9.42	9.42
Expansion U-bend	6	0.27	$5D$	9.42	14.08
Expansion U-bend	6	0.274	$5D$	9.42	16.88
Expansion U-bend	6	0.285	$5D$	9.42	12.02

Double-offset exp. U-bend	4	0.237	$7D$	39.88	40.7
Expansion U-bend	3-1/4-in. boiler tube	0.12	$8.31D$	9.42	9.42

[1] In formulas in Table 1

As noted before, the results from bends formed to a radius greater than 5 pipe diameters agree closely with those obtained from the formulas with one exception, this exception being the 10-in. expansion U-bend. The radius in this case was 6 diameters. The pipe in this bend was the largest size tested, all others being 6-in. or smaller. It is relatively more difficult to bend large pipe than small pipe, so as the pipe size increases the minimum allowable radius (expressed in pipe diameters) also has to be increased. One American manufacturer states that the shortest radius to which a 22-in. standard pipe can be bent is 6 diameters, while a 5-in. pipe can be bent to 4 diameters. In other words, there is relatively greater danger of the pipe buckling or having waves and folds in it in the larger sizes. It is entirely possible that these are responsible for the unexpected flexibility in this 10-in. bend. The bend was too large to be made from one length of pipe, so it was welded at the top of the loop. The bend was one purchased especially for test and had not seen service.

The first 6-in. expansion U-bend in Table 2 was one purchased especially for test and had not previously seen service. In this case there is a very satisfactory agreement between test and formula.

The remaining three 6-in. expansion U-bends were bought for the auxiliary superheated-steam line at the

Connors Creek power house and had not seen service at the time of the test. All were formed to a radius of 5 diameters and all had a flexibility in excess of the calculated value.

The two double-offset expansion U-bends were purchased especially for test and had a flexibility agreeing closely with the calculated values.

In order to eliminate as much as possible the formation of waves or folds in the pipe during the bending operation, a $3^1/_4$-in. expansion U-bend was made up from a straight boiler tube in a Babcock and Wilcox boiler-tube-bending machine. In this machine one end of the tube is clamped to one end of a quadrant having a grooved face and a radius of 27 in. This quadrant turns on its axis and is geared to a motor, the tube sliding against a stationary grooved wheel on the machine as the quadrant is turned. The length of the tangent from the grooved wheel to the circumference of the quadrant is relatively short. A second grooved wheel on the end of a lever which is pivoted near the axis of the quadrant assists in the bending. In this way compression on the inner side of the bend is minimized, reducing the danger of having waves or folds formed in the tube. The bend was formed cold in this machine, as nearly as possible to shape, and then removed and heated where necessary, and the bending operation completed. The test results show a very close agreement with calculated values. It should be noted that the radius of the bend with respect to the diameter of the pipe is greater than with any of the other bends tested. This tends to bear out the theory that those bends which are more flexible than the formula would indicate, owe their extra flexibility to waves formed on the compression side of the bend when a pipe is bent to a short radius.

Attention is called to the fact that in no case did the tests show a bend to be less flexible than the formulas would indicate, so if the formulas and the design graphs presented in this paper are used in practice, the designer will always be on the safe side. His bends may or may not be more flexible than his calculations would indicate, depending upon how the bends were made, but he need not fear that forces or stresses in excess of his calculated values will exist.

All the bends were tested while cold. Since the physical properties of mild steel are not altered appreciably up to 700 or 750 deg. fahr., which are about the maximum temperatures to be expected in a steam line with present practice, the relation between force and deflection should be the same whether the pipe is hot or cold.

The test method used was a rather crude one, yet in several cases the agreement between calculated and test values is remarkably close. It will be noted that in some cases there is a tendency for the force to become disproportionately larger as the displacement increases. This was doubtless due to the binding of the jack as the flange tended to swing to one side, and the flanges to assume positions at an angle to the pipe line. It should also be noted that in deriving the formulas no allowance was made for a change in shape of the bends as they take up expansion. Actually, the height of the bend, and therefore its flexibility, increases as the bend is deformed, so that for large deflections the actual force will be less than the calculated force. However, as the deflections are relatively small in actual practice, this will not affect the results seriously.

In checking a piping layout to determine if excessive fiber stresses exist anywhere in the pipe wall, the longitudinal bursting stress due to the pressure of the steam should be added to the bending stress given by the formulas. This is especially important when working with high steam pressures.

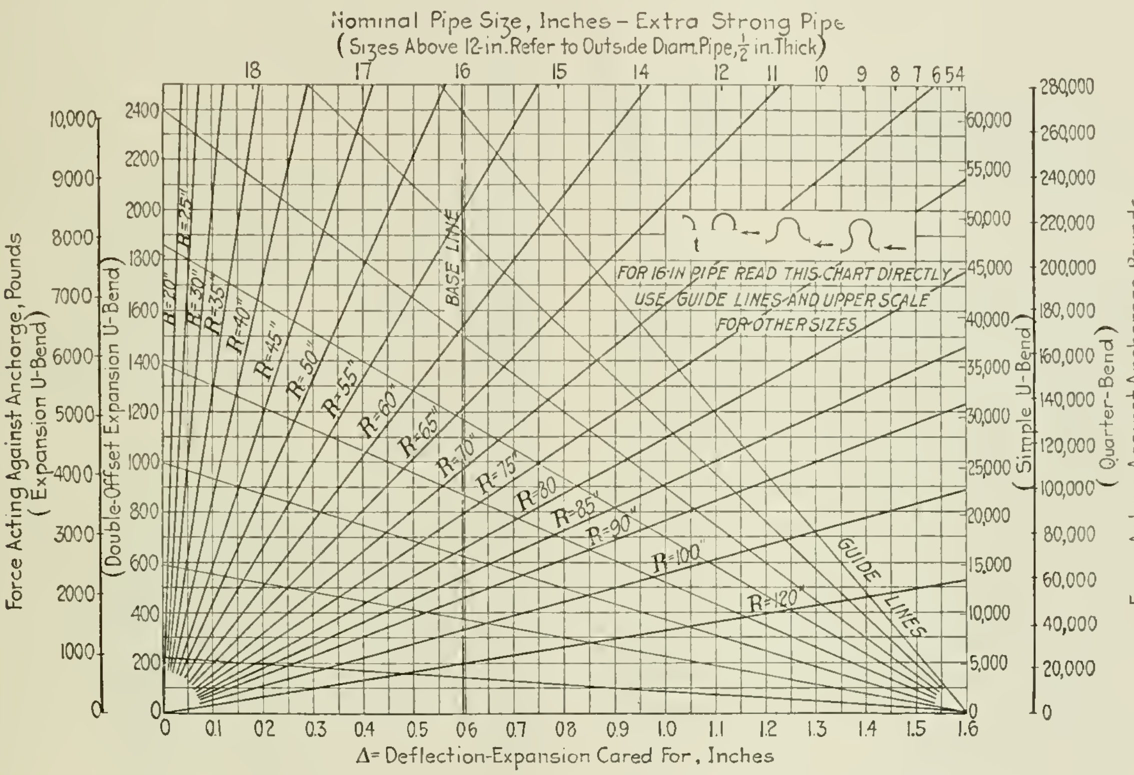

Fig. 9 Displacement vs. Force Exerted on Various Shapes and Sizes of Pipe Bends

Nothing has been said about the expansion which can be compressed back into the pipe by the forces set up at the anchorages. In each case it has been assumed that the expansion bend takes care of all of the expansion and that none of it is compressed back into the straight pipe. Actually, of course, a small part of the expansion is taken up by compression, the amount being directly proportional to the length of the pipe and to the force set up, and inversely proportional to the cross-sectional area of the metal in the pipe and to the modulus of elasticity for that metal. In the case of expansion U-bends and double-offset expansion U-bends, which are very flexible, the amount of expansion compressed back into the pipe is so small compared to the amount taken up by the bend that it can be neglected altogether. In the case of U-bends and quarter-bends, however, the forces are larger and consequently more of the expansion is taken up by compression. In actual practice the amount taken up by compression may be neglected, for in doing so the designer is making a small allowance on the side of safety.

Summary

To summarize in closing: This paper treats of expansion bends in pipe lines as if they were beams acted on by the forces set up by expansion of the piping. Upon this basis formulas have been derived for the forces and stresses in some of the more common types of bends. In the light of the material presented in this paper the

limits of safe expansion values for pipe bends set by Reference (*D*), and commonly quoted in engineering texts and handbooks, are apparently correct only for the double-offset expansion U-bend. For the other shapes the published values are much in excess of those given here. It is the authors' contention that these limits should be revised to agree with the formulas presented in this paper, for unless the published tables are used with large factors of safety, the forces and stresses existing in pipe lines will be excessive and dangerous.

Discussion

The discussion was opened by the reading of a contribution from William B. Campbell[1] who wrote that the right-hand half of the authors' Table 1 gave data for direct comparison of the calculated relations between force F acting on the bend and the deflection Δ produced, and the same relation from actual test. It would appear, however, that the left-hand portion was semi-experimental, in that the calculated values showed a relation deduced analytically between the observed deflection Δ and the maximum fiber stress S was manifestly not observed directly, but was inferred from the experimental value of F which accompanies a given Δ. This method of course reflected the observed relation between deflection and force acting, but it did not eliminate the effect of the method used for calculating S from F, which was based on ideal conditions in the shape and physical dimensions of the pipe. For this reason the "experimental" data in this section were not so conclusive as those in the right-hand section.

Robert Cramer[2] said that it was gratifying to learn that the authors had made an attempt to compare directly theoretical and experimental results. He noted in the paper, however, a point of theoretical nature which should be considered when test results were incorporated. In the diagram giving the basis of the theoretical investigation, the neutral axis of the cross-section of the bend was assumed to pass through the center of the circle, which was not true in the case of a pipe bend. It was a well-known fact, he said, that the neutral axis in curved beams did not pass through the center of gravity of the cross-section as it did in straight beams, and the peculiarity was more pronounced the shorter the radius of the beam compared with the magnitude of the cross-section.

For this reason, he said, it would pay the authors to pursue a line of more rigid theoretical investigation of the deviation of the experimental results from the theoretical results in the case of the shorter bends. He had noted in making comparison between the experimental and calculated results that in some cases the two checked closely, while in others the variation was very marked. It was not the slight variation to be expected from experimental or observational errors, but one which would suggest that the authors should look for some error in their calculations.

The authors considered the deflecting force always to be at right angles to the flange on which it was applied, with the exception of the case of the quarter-bend, in which they had distinguished between two cases, one with the force acting at right angles to the flange and the other with a force acting in the plane of the flange. In the actual case, he said, the problem was really more complicated than would appear from the authors' investigation, as it was frequently necessary to twist the flange in order to make a tight joint, and this involved another source of strain.

Francis Hodgkinson[3] said that the paper was extremely valuable because more and more attention must be given to the very important subject of the flexibility of the steam line. This was the first time, he thought, that reliable information had been presented. Generally speaking, he said, flexibility could be secured by laying out straight runs of pipe at right angles to each other. There was another kind of flexibility which the paper did not mention, and which was torsional flexibility of the pipe. With the decrease in size of turbines and the increase in capacity, the structure of the pipe line was becoming almost as strong as the structure of the turbine itself and it was necessary for the flange to have some angular freedom and that the pipe be arranged in such a way that its whole length would not have to be lifted up because of lack of alignment. It was frequently necessary, he said, to have some length of pipe with torsional flexibility.

J. A. Freiday,[1] speaking as a representative of Thomas E. Murray Inc., said that they considered the paper a valuable contribution, bearing as it did upon a subject which had not always been given proper consideration in the past. The subject was one which they had carefully considered in the numerous power stations they had designed. Up to two or three years ago they had made use of expansion loops made of pipe bends similar to those described in the paper. In a few cases, he said, they had experienced trouble with bends which evidently had not been properly annealed and which showed a tendency to straighten out and grow after being placed in service. In one case the growth of a 14-in. 90-deg. bend exceeded 2 in. in a few months, the increase being measured after the pipe had been taken out of the line.

In order to eliminate the possibility of such distortion and also to take care of the increasing steam temperatures in larger steam lines required by larger modern units, they had made an investigation some time ago to determine the best method of providing for expansion with the least reaction at the point of anchorage. The result of the investigation, he said, had shown that loops corresponding to the expansion U-bends but made up of straight pipe and fittings produced less reaction than an expansion U-bend requiring the same space.

This method of taking care of bends, he said, lent itself particularly to large pipe, for the use of large expansion U-bends was not practical due to fabrication difficulties. With the design of loop they had used in all recent installations no excessive pressure drop had been encountered due to this method of making bends.

He asked the authors if they had investigated any loops designed as he had described.

H. Leroy Whitney[2] said he had noticed many examples of square-bends and U-bends which did not take up the expansion they had been figured for and also, particularly in long transmission lines, he had noticed a double expansion U-bend which had taken over twice the expansion figured for it and that over a period of years marked deterioration in the pipe was shown. In regard to the buckling of pipe on the inside of the bend, he said that it was perfectly evident that if the pipe did buckle on the inside the fibers on the outside were not stressed nearly as much as if the pipe did not buckle. In large bends of comparatively small thickness it was almost impossible to make the U-bend without buckles on the inside. The buckles did no harm, he thought, they did not retard the flow of steam through the pipe to any appreciable extent but did take up expansion. If the pipe was subject to very high vibrations, he said, it was sometimes customary to pull or push them to the full extent that they would be distorted by expansion, so that when they were hot they would be in their normal state, relieving the thrust on steam apparatus.

George A. Orrok[3] said that he understood all the research had been made with cold pipe without pressure on the inside. He wondered if there was any difference between the action of a pipe bend with two or three hundred pounds pressure on the inside and one which was cold. He said that he thought many pipe bends had been designed so that the metal had been stressed beyond the elastic limit. It was a well-known fact that a pipe should not be stressed to 5500 or 6000 lb. This made it necessary to use heavy pipe if the pipes are large. Many times a pipe would rupture at bends when the weld had been placed in the neutral axis. He thought very heavy pipe should not be placed in bends and suggested the use of seamless tubing which was a common practice in our Navy and in the new stations of England and the continent. Such tubing could be stressed up to 12,000 lb.

John A. Stevens[4] asked what would be the thrust from pipe lines with a temperature of about 750 deg., at which the pipe itself would be red hot, and whether there would be a sufficient amount of deformation in the pipe line and the fittings so that the actual thrust would be smaller.

Progress in Steam Research

Harvard Investigation in Joule-Thomson Effect Shows First Results—Work Well Started at Massachusetts Institute of Technology and U. S. Bureau of Standards—A.S.M.E. Annual Meeting Session Devoted to Reports and Comments on Progress

On June 23, 1921 a group of scientists and engineers met in Cambridge, Mass., and discussed the available information regarding the properties of steam. As a result of this conference a project of research was planned; the A.S.M.E. was requested to sponsor the program, and the raising of funds commenced under a sub-committee of its Research Committee.

As originally planned, the Harvard Engineering School was to investigate the Joule-Thomson cooling effect in superheated steam at pressures up to 600 lb. and at temperatures up to 600 deg. fahr. The Massachusetts Institute of Technology was requested to determine, under the direction of Prof. Frederick G. Keyes, the pressure-temperature-volume relation of superheated steam at high pressures and over as wide a range of superheats as possible. The United States Bureau of Standards was asked to determine the specific heat of water for a more accurate determination of the mechanical equivalent of the mean heat unit.

At the Annual Meeting session held December 5, 1922, which was presided over by Prof. A. G. Christie, of Johns Hopkins University, reports were received from those in charge of the three investigations. Geo. A. Orrok, Chairman of the Executive Committee of the Steam Table Fund, presented a brief report of the finances. He was followed by Dr. R. V. Kleinschmidt, Research Fellow of Harvard University, and investigator of the Joule-Thomson effect under the supervision of Dr. Harvey N. Davis, who described the apparatus and methods and gave values for Joule-Thomson coefficients up to the pressures at which experiments had been conducted. The work to be carried on at Massachusetts Institute of Technology under the direction of Dr. Frederick G. Keyes was outlined in a paper read by Dr. Davis in the absence of Dr. Keyes, and N. S. Osborne, of the Bureau of Standards, related plans and progress in the work to be carried on at that institution.

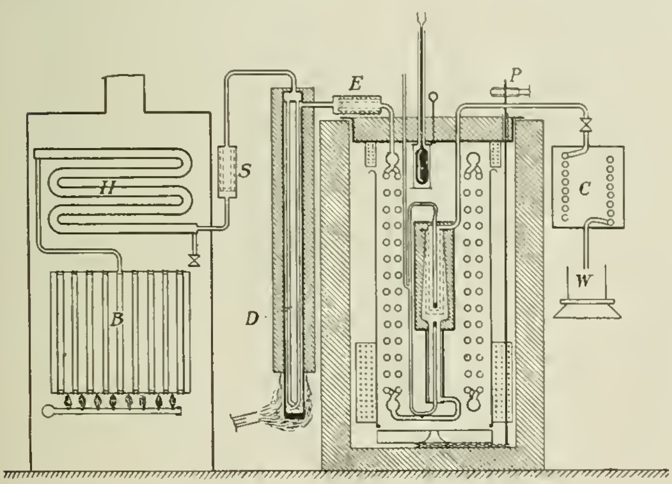

Fig. 1 General Arrangement of Apparatus

The report made by Mr. Orrok, and the remarks of Dr. Kleinschmidt, Dr. Keyes, and Mr. Osborne are given in abstract below.

Report of Executive Committee of Steam Table Fund

Your Committee charged with the raising of the Steam Table Fund has proceeded slowly with its work, the sum total of the subscriptions amounting to approximately $27,000. Of this $8,483 has been paid in and the second payments on the subscriptions are now due.

Your Committee has made two grants of funds and is considering three others in the near future. The first grant was made to Harvard University, to be expended under the direction of Dr. Davis on the investigation of the Joule-Thomson effect. Of this grant $5,333.50 has been expended, leaving a balance of $666.50. The second grant was made to the Massachusetts Institute of Technology, to be expended under the direction of Dr. Keyes on the investigation of the pressure-temperature-volume relations of steam. No money has been expended on this grant as yet.

Your Committee has also been considering a grant to the Bureau of Standards to cover the work which they are preparing to do, and we believe it is now time to finish the raising of the necessary money to carry all of these researches through to the end which we desire.

The Joule-Thomson Effect in Superheated Steam

By R. V. Kleinschmidt,[1] Cambridge, Mass.

Measurements of the Joule-Thomson or "throttling" coefficient, μ, in superheated steam are being made as part of the A.S.M.E. program for standardizing steam tables. Such measurements, supplemented by our present knowledge of specific heats at low pressures, furnish a convenient and accurate means of determining the total heat and the specific volume of superheated steam over any range of temperature and pressure at which the Joule-Thomson observations can be made.

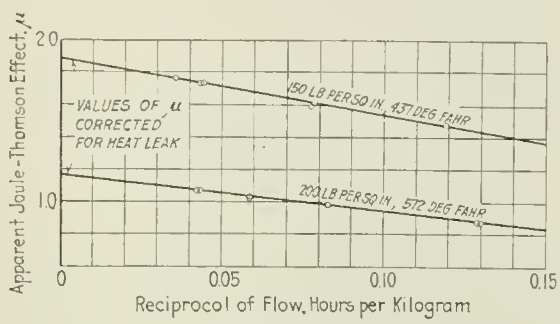

Fig. 2 Trueblood's Method of Correcting for Heat Leak

The experimental procedure consists in forcing steam—carefully dried and brought to the required temperature and pressure—through the walls of a porous tube or "plug" of alundum. The drop in pressure required to force the steam through the pores of the plug is measured on a differential mercury manometer, and the drop in temperature resulting from the throttling is measured by thermocouples read on a potentiometer.

The general arrangement of the apparatus is shown in Fig. 1. Steam is generated in a small gas-fired automobile boiler B, the pressure in which is closely regulated by an automatic control on the gas supply. It then passes through the first (gas-fired) superheater H, which acts also as a water separator. The steam then passed through a porous alundum strainer S, into a counter-current "drier" D, at the bottom of which it is heated far above the temperature at which measurements are to be made, to insure the evaporation of all drops of moisture. In passing up through the drier it is again cooled nearly to the temperature of the steam entering the drier, and it then passes through a second porous-plug strainer E, on which is wound an electric heating coil, by means of which the temperature of the steam can be very closely regulated. The steam then enters the main portion of the apparatus. This is immersed in a cylindrical tank 42 in. deep and 20 in. in diameter, heavily lagged and filled with heavy oil having the highest obtainable flash point. This oil bath is heated by electric heating coils, the current through one of them being controlled by a mercury-bulb thermostat which holds the temperature within $^1/_{100}$th of a degree or closer. The oil is circulated rapidly by a 15-in. centrifugal stirrer which sucks oil downward inside a cylindrical shield, and

[1] Research Fellow, Harvard University.

forces it up outside the shield through the heating coils. The oil bath has a tight-fitting cover from which all of the apparatus within is suspended, so that lifting the cover allows the apparatus to be removed for inspection, testing, and repair. The tight cover also makes it possible to heat the oil nearly to its flash point without great discomfort or danger from smoke and fumes.

The steam passes through a coil of eight $^1/_2$-in. seamless steel tubes, each 20 ft. long, immersed in the oil bath, and is thereby brought so close to the bath temperature that no difference can be

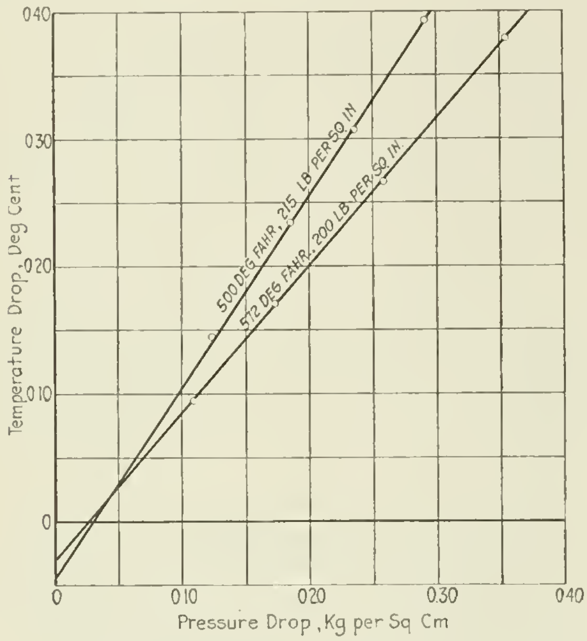

Fig. 3 Hoxton's Method of Correcting for Heat Leak

detected by a thermocouple. It then enters the "plug case" in which the measurements are taken. The plug itself is an alundum tube 1 in. in diameter, 8 in. long, with walls $^1/_8$ in. thick, closed at one end, and supported by the "plug case" at the other. The

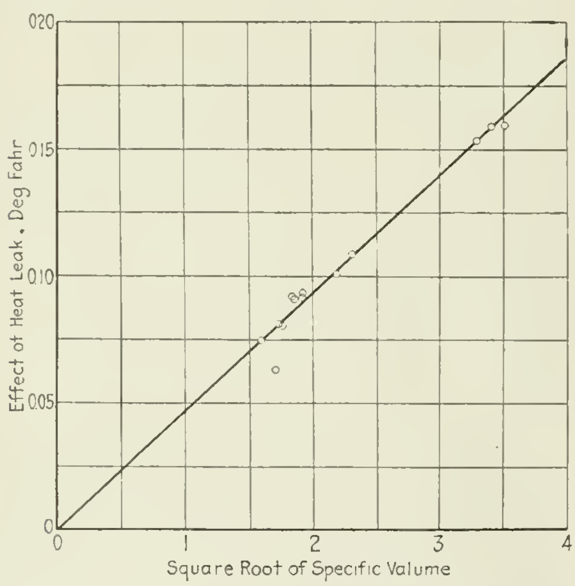

Fig. 4 Relation of Effect of Heat Leak to Specific Volume

steam, after passing the high-side pressure-gage connection and one junction of the differential thermocouple, passes around the plug and radially inward through the walls, over the other junction of thermocouple—which is placed inside the plug, near its closed end—out through the open end of the plug and out of the bath. Finally it passes through control valves into a condenser, and the condensate is weighed.

A 2-in. layer of asbestos wool provides lagging around the plug to prevent heat leak from the bath to the cooled low-pressure steam. This arrangement of the porous plug and lagging was carefully tested by Trueblood in order to get as small a heat leak as possible, and one that could be measured or allowed for, as will be shown later.

In taking measurements, readings are taken of the high-side pressure, the high-side temperature, the bath temperature, the pressure drop through the plug, the corresponding temperature drop, the rate of steam flow, and the room temperature (used in certain instrument corrections).

Observations are begun after the apparatus has been operating under steady conditions for from one to four hours, and readings

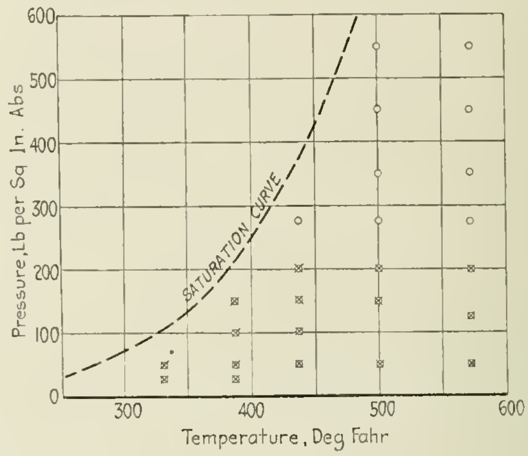

Fig. 5 Points at Which Measurements are to Be Made

of each quantity are taken as rapidly as possible over two periods of half an hour each, separated by at least half an hour. If these two sets agree closely the run is considered satisfactory and the flow is changed, keeping the high-side pressure and temperature the same as before. In this manner at least four runs are taken at different flows, with the same high-side pressure and temperature. From these runs a single value of the Joule-Thomson coefficient

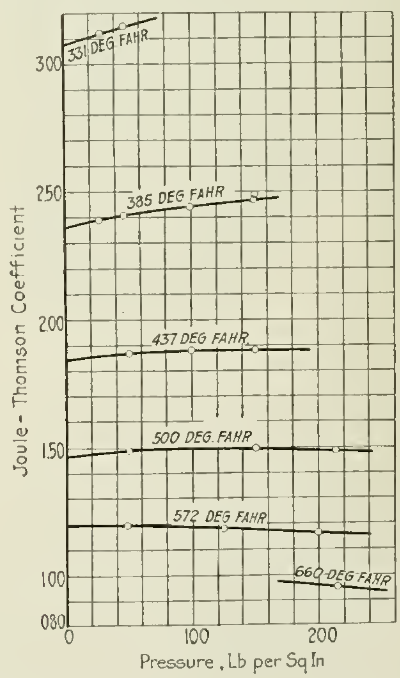

Fig. 6 Preliminary Results of Joule-Thomson Measurements

can be computed, corrected for heat leakage by one of the following methods:

1 *Trueblood's Method.* This is fully described in his paper. It consists in dividing the measured temperature drop by the measured pressure drop for each run, obtaining thereby a series of "apparent" μ's at various flows, and plotting these "apparent" μ's

against the reciprocals of the flows. These points lie on a straight line which is nearly horizontal if the flows are not too small, and the intersection of this straight line with the μ-axis (infinite flow), can be shown to be the true μ, corrected for heat leak. Fig. 2 is a sample plot of this kind.

2 *Hoxton's Method.* This method is a little easier to handle, though giving the same results as Trueblood's method. It consists in plotting the observed temperature difference against the observed pressure difference. The result, at high flows, is a straight line which, if extended, passes slightly below the origin. The slope of this line can be shown to be the true μ, corrected for heat leak, and the actual effect of heat leak is the distance below the origin at which the line cuts the temperature axis. Fig. 3 is a sample plot of this kind.

It can be proved that this intercept on the temperature axis should be nearly proportional to the square root of the specific volume of the steam passing through the plug. Fig. 4 shows that this law is closely followed by the experimental results. It is a delicate test of the consistency and accuracy of the results.

Fig. 5 shows the points at which measurements are to be made. The points indicated by crossed circles have been completed at the present writing. There are sixteen points finished and Fig. 6 shows these values plotted against pressure. On the basis of the work previously published the sign of the variation of μ with pressure is in doubt. Callendar's equation requires a rapid decrease in μ in going from zero pressure to saturation pressure. Goodenough and Heck predict an increase in μ followed by a decrease. The present work shows that the pressure coefficient is very small, whether it is slightly positive or slightly negative cannot be predicted with certainty from these results until all the corrections have been applied.

The more interesting portion of the work at high pressures remains to be done, and all the results given are subject to correction.

The Steam Investigation Program at the Research Laboratory of Physical Chemistry, M.I.T.

By F. G. Keyes,[1] Cambridge, Mass.

Before proceeding with the description of the plans for the new work on the pressure-temperature relation, the liquid and vapor saturation volumes as well as the superheated region, it may be well to refer to the earlier work carried out by Mr. R. D. Mailey of this laboratory. The preliminary work of Mr. Mailey was finished about 1912, after which the entire apparatus was redesigned on the basis of the experience gained in the preliminary measurements. The redesigned apparatus included improvements in the constant temperature baths such that temperatures to over 750 deg. fahr. could be maintained constant for long periods of time to within 0.02 deg. fahr. The bath was a prime requisite, since the purpose was to carry all the measurements to over the critical temperature, about 700 deg. fahr. During the time improvements had been made in the absolute piston type of pressure gage and experience acquired in its use.

The bomb or holder for the water or steam under measurement was retained. Steel was used by Holborn and Bauman, but for measurements wherein the greatest refinement is sought the known interaction of steam with steel at temperatures of 700 to 800 deg. makes its use undesirable. Platinum was chosen and a one-piece sphere spun over a hardwood form, leaving a neck about $^3/_8$ in. in diameter. The platinum sphere with its inclosed wooden form was heated and the wood burned out. A pair of hemispheres were now turned of steel such that when they were screwed together the spherical cavity formed therefrom made a good fit for the platinum sphere. The neck of the platinum sphere was spun out laterally and the cover, platinum-faced, locked on by means of a steel union piece, using a pure gold gasket. This bomb proved to be tight up to the highest pressure (3000 lb.) and to 800 deg. fahr. Water is of course without action on platinum and it would seem to have been ideal.

In the method employed for measuring the properties of substances whose critical temperature lies low enough one may confine the substance under measurement and at the same time transmit the pressure to the devices for measuring the pressure and volume by means of mercury. In the case of steam, however, the critical temperature lies at a point where the vapor pressure of mercury is considerable, and moreover the use of the platinum bomb with a gold gasket would prevent the use of mercury. The method actually employed consisted in confining the water with itself. A very fine copper tube of 0.01 in. bore connected the bomb with a steel cylinder contained in a constant-temperature bath maintained at about room temperature. The piston used in this cylinder was of mercury, whose level could be accurately advanced or withdrawn by the intermediary of a steel piston moving through a packing gland and advanced or withdrawn by means of a screw and nut. The total mass of water under measurement is known, but one portion is maintained always at room temperature and the other at temperatures up to the limit of the range desired. To obtain the amount of water under measurement in the bomb involves taking the difference between the total quantity and that in the cylinder with which the bomb is connected. In the superheated region where the specific volume of the steam is large, the mass of water, as steam, in the bomb will be small and comes out as the difference between two large quantities, which militates against accuracy.

The foregoing are some of the larger sources of error in the work of ten years ago. During the time that has elapsed many improvements have been made in the details of the methods used in the laboratory to measure volume, pressures, and temperatures accurately. In attacking the difficult problem of the measurement of the properties of steam the Research Laboratory portion of the task is receiving the benefit of all of the accumulated experience of these years.

The plans for the renewed work on steam include the substitution of pure nickel for platinum. Pure nickel was unobtainable in homogeneous forgings twelve years ago. This metal has been found to constitute a good choice for a number of reasons. It is unattacked by steam even at 900 deg. fahr. It is uniform in its expansivity with temperature and tough enough at higher temperatures to permit of sealing with absolute tightness. It does not alloy with mercury and hence mercury can be used to measure the stretch of the bomb with increase of pressure. The true volume of the bomb can likewise be determined at a number of temperatures by means of mercury and thus the volume of the actual bomb employed will always be known in terms of weight of mercury.

Any change in the future of the densities of mercury with temperature will thus permit a recomputation of the actual bomb volumes, although there is reason for confidence in the mercury densities as at present known.

The same general scheme of confining the steam with water will be employed, using, however, two different volumetric measuring pistons, one for the saturation dome and the other for the superheat where larger specific volumes come under measurement. The connecting capillary is of nickel swaged from larger tubing to about 0.01 in. bore.

The improvement in the volume-measuring technique is such that a volume change of about one part in forty thousand may be detected. The pressure-measuring gages are of the absolute piston type floated by oil. The constant of the gages is not determined by measuring the diameter of the piston but by direct comparison with a mercury column 31 ft. in length. The equilibrium of the piston is detected by an electrical contact device which has been continually improved during the past years. The checks at different heights of mercury column with the new gages are about one part in twenty thousand. Pressures of a fluid cannot of course be measured consistently to this precision because of the difficulties of securing equilibrium, but much has been learned concerning this latter problem so that very much greater precision can be expected than in the earlier work.

The superheated field is one of particular interest from a purely scientific point of view as well as from the engineer's viewpoint. Water is regarded by the man of science as a fluid different in its properties from substances sometimes called normal such as ether, ethyl chloride, or methane. It will therefore be of profound interest to learn whether at high superheats and high pressures water vapor is indeed different in its general properties from the so-called normal substances.

The Steam Research at the U. S. Bureau of Standards

By N. S. Osborne,[1] Washington, D. C.

The part of the experimental program which the Bureau of Standards undertook was a determination of the thermal-capacity of water as saturated liquid.

This problem came to us in two parts: First, the heat capacity of water, in the range from the normal freezing point to the normal boiling point, in terms of international units of energy, was wanted to establish with greater certainty the fundamental heat unit. That is to say, the mechanical equivalent of heat. This was wanted as a basis for steam-table construction. The second part, above the normal boiling point and as much higher as it was convenient to go, the thermal capacity of liquid water was desired as a further basis for steam-table construction.

This problem was analogous to one upon which the Bureau had been previously engaged, the results of which have just materialized in the form of complete tables of thermal properties of ammonia, which have just been presented at the annual meeting of the American Society of Refrigerating Engineers.

The problem of determining the thermal capacity of a saturated liquid, water, develops into a project by which, in a single apparatus, with the identical samples of the fluid, under similar conditions, with a constant degree of precision, and without dependence on other data, an entire group of thermodynamic properties, those for the saturation condition, may be determined; and it is this experimental project upon which we are at present engaged.

We have determined a general tentative design of apparatus appropriate to make these heat measurements which consists of a closed container for the fluid, made of a metal which will withstand the combined temperature and pressure without permanent deformation. The interior space is provided with an electric heater. The container in which this heater rests is also provided with an agitator, to distribute the heat so added, and promote equilibrium. The container is closed, except for outlets that provide it with valves, which may be opened or closed to permit the addition or withdrawal of portions of the fluid. If the necessary auxiliary instruments and devices are provided, we may observe the temperature of the container and its fluid content when in equilibrium, the pressure at any instant, the initial and final amount of fluid, the entire amount of heat added during any period of time, which will include that due to thermal leakage and to the energy dissipated in stirring.

The experimental processes which may occur, under the control of the operator, in connection with these observations, are three: First, by adding heat, keeping the mass of content in this calorimeter constant, its temperature can be changed; and, in addition to that, the fluid may be withdrawn from the calorimeter in two ways—either as vapor or as liquid, and, simultaneously, either by adding the necessary compensating amount of heat, the temperature may be kept approximately constant, or by adding no heat at all, the temperature may be changed.

The ones that we will use are the ones where we keep the temperature nearly constant and transfer fluid.

The experimental results of the three types of experiments can be expressed in terms of specific thermal properties of the saturated fluid, as three quantities, and the properties that come into these are the heat content of the liquid, the internal energy, plus the PV, and an expression including the latent heat, and the two specific volumes of liquid and vapor.

To the experimenter, the interesting thing about this is that all these results are obtained without the necessity of knowing either the heat capacity of our calorimeter or its volume. All that we require is that both of these things shall be definite; that is, that the heat capacity shall repeat itself at the same temperature and pressure, and the volume shall repeat itself.

In determining the design of the apparatus to accommodate this, a great many details developed, which had to do with the proper guarding against external influences on the interior part where occur the experimental processes to be observed. Other features are concerned with the control of the processes themselves, so as to make them conform to such specifications as the analysis requires. Two features illustrate the nature of the problems which arise.

In the first place, a vigorous circulation of the liquid in the calorimeter is desirable in order to attain equilibrium quickly, and so that the whole interior of the apparatus shall be bathed with the agitated liquid and its surfaces kept at a uniform temperature. Thus by controlling the temperature of the envelope, we may evaluate the outstanding thermal leakage that would otherwise exist. This circulating stream of water would be lifted to the top of the calorimeter, in order to bathe the entire interior surface. This leads to another important feature—that of locating in the top of the calorimeter, where it is continually bathed with the flowing stream, an evaporator, so that saturated steam may be manufactured and withdrawn from the calorimeter without disturbing the equilibrium within. It is proposed to furnish this circulation by a turbine pump, the duty of which will be about one three thousandth of a horsepower.

To provide means of assembling in the calorimeter parts such as these which I have mentioned, a metal shell has been developed which can be put together and made to stay tight, without resorting to any soldered joint. It is made out of a special alloy of copper and nickel—eighty per cent copper, and twenty per cent nickel. The two cup parts are threaded with a right- and left-hand thread, and one part has a groove one thirty-second of an inch in width in it; the other has a tongue which is made to nicely fit into that groove. The two are drawn together by means of a correspondingly threaded metal band, upon a ring of gold wire, one thirty-second of an inch in diameter. When we put on this double-threaded band with a powerful wrench, sufficient pressure is put on the gold washer to make it conform to the surfaces of this groove, and to make the shell tight, up to the pressure where the forces are balanced between the tension in this band, acting on the gold washer, and the forces of the hydrostatic pressure within, acting on the shell. We have found that the metal has properties to stand a pressure of 3000 pounds to the square inch. The joint held up to about 2400 pounds to the square inch, which gives us a very fair factor of safety.

The question of interaction of the water and the material in the calorimeter, can, with this device, be very well taken into account by gold plating the inside of the calorimeter and the other installation to go within.

The Development of Machine Tools

(Continued from page 154)

turret. This improvement made possible the modern automatic lathe and similar machines. It is a tribute to the genius of Spencer that his very first automatic machine was a great success. While he is known and remembered largely in connection with the invention and production of firearms, Spencer's greatest contribution to machine production is the universal cam wheel, a device which was never patented.

These, then, are the three great advances in transfer of skill in machine tools. Maudslay's slide rest and Stone's turret are used in the construction of semi-automatic machinery more frequently than any other machine elements, while the combination of these two with Spencer's universal cam wheel is the basis of practically all automatic machines.

The importance of these inventions and improvements cannot be overestimated. The period of their development from Maudslay to Spencer was a little over one hundred years. These inventions with others of the same period embody the results of the observation, experience, and effort of the greatest group of mechanics in the history of the human race. Their achievements made possible the work of such men as Hartness, Swasey, and other great builders and laid the foundation of modern industry and transportation. Selfishness, stupidity, and lack of knowledge have as yet stood in the path of the full realization of the benefits these inventions can bestow upon all humanity. It is to be hoped that a wiser generation will be able to solve the problem of distribution in such a manner as will permit the use of these modern productive methods to fill the land with plenty.

Means for Vocational Training for the Industries[1]

Industrial Education in Extension, Correspondence, Apprentice, Shop Training, and Various Other Schools—Report of A.S.M.E. Committee on Education and Training for the Industries

BY THIS report the A.S.M.E. Committee on Education and Training for the Industries seeks to disclose the present status of industrial education and training in order to secure expert attention and advice to the end that the average efficiency of the process may be raised. The Committee believes it not unreasonable to expect that careful consideration given to this report by all concerned in promoting industrial education will result in a coördination and simplification which may be suggestive of a standard code of procedure in vocational training. This may not pass beyond the statement of governing principles associated with a prescription of the steps in the process which the end requires. At any rate, the Committee is convinced that much good will result from the discussion which this report invites.

As will be seen from the papers constituting the report, industrial education and training of a vocational nature is susceptible of classification. The considerable task of collecting and arranging the information herein presented was performed under the individual supervision of three members of the Committee as indicated by the authorship of the several papers, and to these three members and Director Moyer, the Society is under a debt of gratitude.

In general, industrial education is conducted either inside or outside the works, and sometimes uses both plans coördinately. The distinction is recognized, therefore, between apprenticeship conducted within the works and vocational, trade, and evening schools outside of the works. Correspondence work and extension schools, strictly speaking, belong to the latter of the two classifications, although these are given separate treatment in the accompanying papers on account of their special character. In each paper typical courses are presented to illustrate what may be termed "standard practice" of its kind.

It has been estimated that an exhaustive survey of the whole field in the United States to be of value in pointing a conclusion would probably cost $100,000. With no funds available and convinced that the time is not yet opportune to warrant a procedure that calls for the solicitation of funds, the Committee presents the results of its studies with the belief that the picture thus afforded will appeal to the imagination and give a fairly definite idea of conditions so far as available statistics are concerned.

EXTENSION AND CORRESPONDENCE SCHOOLS

By JAMES A. MOYER,[2] BOSTON, MASS.

[The accompanying report by James A. Moyer, director of University Extension in Massachusetts, is made by request of the Committee on Training for the Industries of The American Society of Mechanical Engineers. The first thought in relation to this is to express no opinions as to the preëminence of any school or any state but simply to give the facts that will form the basis for a larger report on Correspondence and Extension Schools in the United States. A full report in detail would demand visits to every state in the Union, and several volumes. Consequently, no attempt has been made to cover more than a fair outline of what may be found.

On account of his wide experience with extension teaching, and also on account of his connection with the Massachusetts State Department of Education where records are kept of all correspondence schools and extension departments in the United States, Mr. Moyer is very well qualified for a study of this subject. There is a slight difference between a correspondence school and a course in extension work. The latter may include the former. Correspondence instruction lacks the contact among students that promotes discussion and supplies stimulus for study, but it makes up for that in the serious purpose of every student and in what must be confessed is superior instruction. A correspondence school can afford to employ the very best talent in the country for preparing the textbooks and can lend to the work a degree of technical skill that one cannot find in the average college. The extension schools are usually connected with universities. In Massachusetts the first conception of an extension department was the education of workingmen in the industries, and to that end the technical courses were those first established. But this was in an industrial state, dependent upon technical skill for a large part of its success in manufacture. There has been a steady growth, however, toward other subjects, and Mr. Moyer has under his charge what really amounts to a university of thirty or forty thousand students.

The question might be asked, have these schools reached the height of their usefulness? Will they progress by improvement into larger fields? Their work is extremely useful, as they open the way to an education for thousands of men and women who have no money to go to college and who can profit by this kind of absentee study.

I have suggested to Mr. Moyer that he go into some details with regard to his own work as typical of many extension departments of states. If his report stimulates active thought on this whole subject by members of the Society, it will have amply served its purpose.—IRA N. HOLLIS.[1]]

CORRESPONDENCE courses in industrial subjects have been an important part of adult education for more than thirty years, and many of the courses have received wide publicity. During this thirty-year period one well-known correspondence school has enrolled nearly three million students, mostly in industrial subjects, and this same school, during the last year, sent out more than one million lesson assignments.

Besides the privately organized correspondence schools, nearly every state now has a correspondence-school system supported by taxation. These state-supported institutions are usually organized as a department of the state university, where there is one. In states like Massachusetts and New York, however, where there are no state universities, the correspondence instruction is organized in the state departments of education. Most of the state-supported institutions giving instruction by correspondence, and also some of the privately supported institutions, have given this kind of teaching the name "University Extension," which usually includes also class instruction for adults, as organized in large centers of population to take the place of correspondence instruction.

All correspondence instruction is conducted through the mails. By this method the student is sent a supply of specially prepared texts. At the end of each text a series of questions are asked which the student is requested to answer, after having carefully studied the subject-matter of the texts. These answers are sent to the correspondence school for correction. When these have been carefully corrected and graded by instructors, the percentage given is marked on the corrected paper and returned to the student so that he may see just where he has made errors.

It should be emphasized that a correspondence course comprises material organized as a basis for the instruction of a student at a long distance. It is therefore a system of instruction in which the assignment material is common to all students, but considerable variation is possible on account of the flexibility and adaptability inherent in this system of instruction. In the informational courses the differences in maturity, native ability, prerequisite preparation, etc., can all be taken care of readily and the course fitted to the need of the individual. The resultant body of papers

worked out coöperatively between teacher and student makes a volume peculiarly fitted to the individual needs of each person. This statement is important because in the minds of many people a correspondence course is incorrectly conceived of as a series of tests and examinations and a grading of the papers written in such tests. Work that does not rise above this procedure is not correspondence instruction. Where it follows correct procedure, the correspondence method supplies one of the most effective means by which adults may keep abreast in any informational field. Correspondence students may include those who have had little more than a common-school education, as well as those who have taken their advanced degrees from the eminent universities of the country, numbering men and women conspicuous in many professions.

Extension Classes

Extension classes are locally organized. The instructors are either members of the faculty of the university or school conducting the classes, or persons living in the vicinity in which the class is conducted, provided, of course—in the latter case—that qualified persons are available. This instruction is conducted by ordinary educational procedure. An effort is always made in extension teaching to adjust the instruction as much as practicable to the individual needs of the individual student.

Extension classes differ from residence classes in that membership in them is open to all who can give reasonable evidence of their ability to profit by such instruction; and in that these classes afford, so far as is possible in classroom work, individual attention to individual needs.

The courses offered by either of these plans range in price ordinarily from \$3 to \$150, depending largely on the cost of the text materials furnished, and whether or not the institution giving the course is supported by taxation.

The instructional material consists, as a rule, of lesson pamphlets prepared and published by the university or school. Each pamphlet includes from one or two to as many as twenty-five pages of explanatory or "lecture" material, one or more pages of questions which the student is to answer and submit for correction, and whatever directions the student may need as to the way in which lessons are to be prepared. Usually each course is so arranged that it may be used with equal facility either for class or for correspondence instruction.

The rapid expansion of this work has been favored from the first by the type and range of subjects in which courses are offered. For the demand for education of this kind is concerned not with particular, closely defined groups, but with the whole adult population. To be sure, in some quarters the demand is more pressing as the lack of essential education is greater; but everywhere, among men and women of every class and occupation, there is evident the desire for further opportunities to study. The bulletins describing the courses offered by the largest correspondence and university extension institutions contain upward of one hundred and fifty courses, including such section headings among the industrial courses as mathematics; drawing; steam engineering; electricity; structural engineering; textiles; natural science; commerce and management; history and government; and business economics. Within each group are comprised, as far as possible, courses ranging from the most elementary to those of college grade. The breadth of such programs, when offered by state institutions, has resulted in making every man and woman in the state a prospective student. In that case the state is offering something for everybody, and consequently the idea of continuation education has penetrated into every industry or business. The mechanic, the fireman, the engineer, the business man, the clerk—from the unlettered immigrant on the one extreme to the college graduate on the other—all are represented in the enrollments.

The problem of making these courses widely available to classes is one of reaching fairly compact, well-centralized groups, and the method of approach is accordingly direct. Agents of the university or schools consult with industrial executives, the representatives of business and social organizations, and school superintendents, and through them discover for what subjects each community has a genuine need. Instructors are then appointed, according to the nature of the courses, from college faculties or from among commercial and industrial specialists. And it is significant of the whole university-extension scheme that an instructor's formal connections and affiliations count less toward his appointment than his ability to give vital, effective instruction.

Usually study rooms and lecture halls in local school buildings, provided by the courtesy of the school departments, serve as class meeting places; and in some instances as many as half a dozen university-extension classes meet in a building on a single evening. When a class is of special interest to the employees of a certain industrial plant, it is frequently arranged to meet in the plant itself. Public-library halls and clubrooms are also used on occasion, but always with the understanding that every university-extension class, whether held in a public or a private building, is open to any resident of the state. The chief consideration in the choice of the meeting place is this: that it enables the institution to reach the people where they are.

As a tangible evidence of achievement, each student who successfully finishes a course either by class or by mail is awarded by many institutions a certificate giving the name and grade of the course, and the number of lessons completed. On certificates for all college-grade courses, the work done is usually stated also in terms of equivalent semester hours.

Advantages of Correspondence and Extension Courses

A result of correspondence courses and university extension classes less easy to estimate in formal values is the unexpected spirit of democracy to which they have given rise. Social groups which ordinarily acknowledge no common interests have learned to know of each other through the common interest in correspondence lessons; and those brought together in classes, having profited by the same instruction, have been led through class discussion to compare their views with the utmost cordiality and freedom. A non-technical course in the care and operation of gasoline automobiles, for example, has provided a common ground of interest for men and women of every occupation and walk of life. But perhaps the most effectively democratic are those classes for the training of foremen and executives in oral English, for in these particularly the students not only meet together but discuss with each other matters of general interest. There is something peculiarly personal and cordial about these classes, where each member at some time during the course addresses his fellow students on a subject of his own choosing. And the method as well as the membership of these classes is democratic, for the students both recite and criticise recitations, while the instructor, acting as a sort of moderator, takes the platform only for brief intervals, to make suggestions. From these recitations all the restraint of formal address is lacking; if other members of the class disagree with the speaker's opinions, they are at liberty to offer their own in opposition. Incidental debates are frequent; and in the interest of discussion, every shadow of social distinction vanishes.

The correspondence courses, while affording no such opportunity for student-to-student contact, are no less large in their appeal. As may be supposed, there was at first, among persons familiar only with the methods of high schools and colleges, some little tendency to regard correspondence instruction as a second-rate substitute for class work. But seldom did that tendency amount to prejudice. When class instruction in a desired industrial subject was clearly not available in a community, even the skeptical preferred to give the correspondence method a trial rather than to forego the chance of any instruction whatever. And the first experiment was usually convincing.

The student quickly came to recognize that correspondence study has its own peculiar advantages—that it is available to him at any place and at any time; that each paper he submits gets the individual and undivided attention of an instructor; that "bluffing" is out of the question—he must prepare himself on every part of the lesson; and finally, that he may set his own pace, unhurried by more brilliant students and unhampered by sluggards.

By artisans and mechanics, correspondence courses are usually accepted without question. Perhaps because the advertising of correspondence schools has long been directed chiefly at them and because many of them have already had experience in the "learn by mail" method, they have evidently had the start of their neighbors in appreciating its advantages. Most of them willingly accept

it as a substitute for class instruction, and not a few declare that they actually prefer it.

Recognizing that the common fault found with correspondence is that it lacks "personal contact," correspondence schools have set before themselves the ideal of making and maintaining between instructor and student a genuinely personal relation. That ideal is freely expressed; and every correspondence instructor is trained to respect it. With the first assignment of each course, the student is asked to submit an information sheet on which he has recorded such matters as name, address, age, occupation, and the extent of his previous schooling. This information the instructor enters on his personal records and reviews from time to time, so that he keeps in mind a rough mental sketch of the student with whom he is dealing. Some instructors who handle the papers of from one hundred to one hundred and fifty students yet maintain so intimate an acquaintance with each as to recognize his handwriting and to remember what have been his individual difficulties. This system has proved to have the double advantages of keeping the instructor constantly in touch with the student's progress so that he may more effectively prescribe and advise, and of making the student realize that his instructor knows him personally and is in a position to understand his peculiar difficulties.

But the ideal of personal helpfulness does not stop with the instructor; it is written into every course. On whatever subject, the material of the lesson pamphlet must be human, wholesome, and practical. Hypothetical problems, so far as possible, are avoided, and their places taken by problems based on fact. A certain course in textile mathematics, for example, says not, "Suppose that there are 580 looms in the ——Mill at Lawrence," but, "There are 580 looms in the —— Mill." And there are. The student gets not only a problem in mathematics, but along with it reliable facts about the textile industry.

So it is with the other courses: the instruction is concrete and tangible. The aim is to make the language of each assignment unmistakably clear; and the lesson requirements are such that the student shall be capable, under ordinary circumstances, of carrying them out. If, in spite of careful editing and supervision, faults appear after a course has been put into circulation, the instructor is on the watch for them. When his experience with students leads him to believe that a course might be improved, he makes a detailed report, in which he states what is wrong, and how, in his judgment, the fault may be corrected. If his criticism is found to be just, the course is revised.

The personal touch with students is also maintained in another way. Each month a news letter, so-called, is sent out to every person enrolled in the correspondence list. Sometimes it is merely a friendly letter of encouragement. Sometimes the letter is editorial in nature, touching, perhaps, upon the qualities of good citizenship. Sometimes it is a page of suggestions as to methods of study. Intrinsically, the news letter is a small affair, hardly to be counted in comparison with the actual work of instruction, but it seems to remind many students that in the staff of instructors, whom they may never see, there is a cordial personal interest for their success; in short, they are not dealing with a "soulless" organization.

Results of University-Extension Work in Massachusetts

The results to which these methods have led are encouraging. We have mentioned already how general has been the appeal of the courses, and how democratic has been their influence. Taking Massachusetts as a typical case, and not at all by way of expressing a superiority, but rather in order that the members of the Society may get a clearer understanding as to how this kind of instruction has grown—the advance has been almost in geometrical progression: At the end of the first year from its establishment, the Division had only a few more than 3000 students; today the total enrollment is well above 100,000, and it is significant of growth that more than a third of that number represents enrollments for the past year alone.

But numbers by themselves are less important than the geographical distribution of students and classes. It would have been comparatively simple to secure heavy enrollment by concentrating effort in a dozen or less large cities and towns, neglecting meanwhile the more remote corners of the state. This, however, has not been done. Each year active effort is directed toward filling in the gaps—toward carrying instruction into towns where university extension has not before been well represented. In consequence, there is hardly a town in the state where classes have not been held, and the post offices are few which do not handle the mail of university extension correspondence students.

Not only among students but also among many organizations and many individuals generally interested in education, the university-extension idea has spread. In certain cases these have been reached by special services such as the distribution of visual-instruction material and the publishing annually of a list of university-extension lectures for the use of women's clubs, parent-teachers' associations, and like organizations. But of even greater importance is the contact which has been established with the employers of men and women studying correspondence and extension courses. Whenever a student completes a course, unless he objects, his employer is notified and asked that, if possible, the student be given a word of commendation. The response has been admirable. Every mail brings letters from employers in which they express their appreciation for this educational work, and, frequently, report that they have personally talked with the student and have arranged for his advancement at the first opportunity. And in almost equal volume come letters in which the students themselves tell of promotion made possible through university-extension study. The student is thus encouraged to continue the work of self-improvement, which he sees has won for him favorable notice from his employer; and the employer himself is often led to ask that university-extension classes be established in his city or town for the training of his other employees.

And so, at the conclusion of its seventh year, the Division can look back with some satisfaction at the training of more than a hundred thousand students, and forward to new opportunities for services that are daily opening before it. The work of the past, by establishing contacts, has blazed a trail for the work of the future; and the time seems not far distant when every community in Massachusetts shall make its annual demand upon university extension.

Extension Work in Wisconsin

In the University of Wisconsin the University Extension Division was organized on its present basis as an extramural college with a dean and separate faculty in 1906. Some forms of extension teaching have been conducted by this Wisconsin institution since 1892. Much of the present development by correspondence study courses and extension teaching in classes has been due to the pioneer work of this university. Louis E. Reber, Dean of the University Extension Division and a member of The American Society of Mechanical Engineers, has been in responsible charge of this institution and deserves a great deal of credit for present accomplishments in this form of education, not only in Wisconsin but in all other states as well. His contributions to this subject deserve special mention. In this connection, it is interesting to note that the International Correspondence School was organized within a year of the time that extension teaching was first established in Wisconsin.

Summary of University-Extension Service in Various Institutions

Replies to a questionnaire sent to various institutions giving correspondence or "extension" class instruction have been carefully studied and grouped in Table 1. Most of the questions asked were more detailed than the headings of the columns, and therefore more explanation is necessary. The heading of column (1) means the number of years since the establishment of correspondence or "extension" class instruction in the institution. Columns (2) and (3) refer to the kind of instruction offered by the institution, that is, whether the teaching is exclusively by mail, which is called correspondence instruction, or whether it is given in classes which are not regularly organized to take the standard residence courses of the institution. These classes differ from residence classes in that the enrollment is usually permitted of adults who can be expected to profit by the instruction without, however, the educational tests of college entrance examinations, and the class is usually organized at a considerable distance from the city or town in which

[1] No examinations or certificates.
[2] Necessary textbooks extra.

the parent institution is located. In column (4) are tabulated the number of students who received instruction in the school year 1921–1922; and, on the other hand, in column (5) are recorded the total number of students who have received instruction in the institution since its organization or establishment. Columns (4) and (5) include, therefore, the total enrollments of both correspondence and class students for the times specified. "Student completions" as referred to in columns (6) and (7) means the number of enrolled students who have satisfactorily completed their courses either by correspondence or in classes from the time of the organization of this form of instruction to the date of these reports (about July, 1922). There is considerable variation of practice in the institutions included in the tabulation as to the kind of record for "completions." Some institutions give certificates and others give only "credits" on the records of the institution. Some courses are also much longer than others; even the same institutions will offer some short courses and some long courses so that a high record for completions obviously means more when referring to long, rather than short, courses of study. Column (8) does not mean the cost to the institution for instruction, but is the amount charged students for enrollment, and although there may be exceptions, includes as a rule the text materials that the student actually requires. In some cases where the necessary text material is obviously extra, this has been noted by reference to a footnote. Column (9) refers to the percentage of the total number of persons enrolled in the institution for both correspondence and "extension" class instruction who are taking industrial (engineering or industrial trade) subjects. Column (10) is under the heading "Positions Graduates Enter" and the replies were not satisfactory for tabulation because of the great variety. The reply of one institution was, "Practically all are in industries;" and three others replied, "Various." The tabulation of this column, therefore, gives very little useful information. Column (11), headed "Results of Training," is an abbreviated statement for the following question: "What effect have these schools (meaning those giving correspondence and extension-class instruction) upon the education of foremen?" Some replies were received which could not be stated briefly enough for tabulation. For example, the University Extension Division of

the University of Wisconsin reports as follows: "It has a wholesome and stimulating effect. Where the instruction has been specifically organized as foreman training instruction, the result has been to increase their efficiency as a direct applied result. Where the courses have been general or avocational the instruction has added to the resources of the student in ways that are equally valuable as compared with its having only the vocational bearing." The correspondence school which has reported the largest enrollment has sent an explanation of this question in the following interesting paragraph: "As explained in our preceding answers, most of our students are already engaged in occupations of various sorts at the time they enroll for our courses. For this reason, we feel safe in saying that practically every journeyman in any trade enrolls for a course with a view to bettering his position. A machinist, for example, usually enrolls for a course in mechanical engineering or a closely allied course with a view to becoming a shop foreman. Furthermore, we have a course for foremen. This course deals mainly with the employing and handling of labor, safety fundamentals, and ten lessons which are entitled 'Training the Executive.' A man enrolling for this course is supposed to have mastered the technical end of his trade, or else he would not occupy the position of foreman. To sum up the answer, we feel that our school plays a very important part in the education of foremen." Column (13) refers to methods of instruction and is more interesting to educators than to persons engaged in industry.

SCHOOLS FOR APPRENTICES AND SHOP TRAINING

By R. L. Sackett,[1] State College, Pa

The object of apprentice training is to train a sufficient supply of young men to meet the need for skilled employees, including foremen and superintendents. It is believed that thorough training stabilizes employment, reduces turnover, gives a better understanding of elementary economics as applied to industry, and tends to "create a greater interest in and loyalty to the concern."

A number of developments have occurred within the past year indicating an appreciation of the need for apprentice training. The Industrial Association of San Francisco, for instance, an organization of employers, because of the difficulty in obtaining sufficient skilled labor and the high wages demanded, has been led to establish schools for plasterers and plumbers. They plan to open other schools for bricklayers, steam fitters, carpenters, electricians, and others. Out of 75 who responded to the first call for plasterer apprentices, 25 passed the preliminary tests. During the training period of 12 weeks, the trainees are paid $2.50 per day of eight hours and are taught by skilled workmen. At the close of the course they are put on regular work at good pay, and at the end of a year are to be rated as journeymen.

In training plumbers the plan is somewhat different. The apprentice has two weeks of schooling, then goes as a helper for four weeks on real jobs and then returns to the school.

The report says that the association believes that it can train men to be master craftsmen in 12 to 18 months, whereas three to four years have been demanded in the past.

The New York Building Congress Apprentice System

The most extensive program of apprentice training that has been recently developed is one prepared by the New York Building Congress, which is an organization composed of representatives of the architects, builders, and trade unions. A committee on apprenticeship was organized in January, 1922, "in response to a demand on the part of the building industry to develop men better trained in their craft and in citizenship than present-day trade conditions provide or permit."

The Committee states the purpose of the movement as follows:

> The Committee was established for the purpose of fostering the development of the apprenticeship in the building trades, not by dictation, but by acting in an advisory capacity with similar committees from the various interests represented in the Congress.
>
> The Committee proposes to coöperate with all other committees, organizations, and movements of trade, labor or educational interest, by bringing their activities together and overcoming the difference or inertia that has existed and which has done so much to handicap, if not to frustrate, the best interests of training in the building trades.

The policy and the general plan have been adopted by both the New York Building Trades Employers Association and by the Building Trades Labor Council, representing the unions. The joint plan is in operation and was first applied to woodworking apprentices after the carpenters unions had approved the idea. The general plan of the apprenticeship is for the apprentice to learn his trade on the job and receive his instruction in related technical studies during part-time attendance at school. The intention is to utilize the public continuation and evening schools so far as practicable but where such coöperation cannot be obtained the Congress will open its own schools.

There is sufficient evidence of an adequate supply of apprentices ready for training, and plans are being made for the organization of training for plasterers, bricklayers and other trades as soon as practicable.

This movement by the New York Building Congress has the support of financiers, contractors, and union labor and it has aroused widespread interest in the problem of supplying an adequate number of skilled mechanics and artisans. There is an encouraging sign in the announcement by the Committee that—

> The employers see the need of a constructive and sound system for recruiting skilled help and the unions realize that the trades should be dignified with a true educational merit and background.
>
> It is proposed to proceed carefully and to develop along other occupational divisions in the Building Trades until the entire field is covered, our purpose being to expand gradually so as to build up a system of good sound training that will not only meet the needs of the business but also provide an educational opportunity for our young men.

Building-trades magazines and a wide variety of associations in other cities have expressed their interest in and have endorsed the plan. It is the most conspicuous development of the year in its line. It marks the confession by employer and unions of a recognized need; it is an outstanding evidence of possible and desirable coöperation and it is an acknowledgment that there are educational methods which will expedite the preparation of skilled men.

Railroad Apprenticeships

The railroads have been from the first strong advocates of an apprentice system. They have two classes, namely, those having a common-school education, and those who have been graduated from a technical college.

Those with a common-school education are given class work in mathematics, mechanical drawing, physics, and elementary mechanics along with their shop work.

Those who have a technical education are put on more advanced repair, maintenance, design and construction—principally in the motive-power departments.

The pay of apprentices on railroads has been increased until it represents a fair wage.

Industrial Apprenticeship

In 1918 the Westinghouse Electric and Manufacturing Company, of Pittsburgh, added an apprentice drafting course to its educational work.[1] The course consists of two years of eight terms of three months each. The class periods are two hours in length and classes meet three periods per week. The following information was received, which will make clear the object and methods employed by a company which has conducted shop and apprentice training for many years.

The entrance requirements specify high-school graduates or the equivalent.

The apprentices spend the first few weeks in the Educational Department where they are given a very intensive course in tracing. They are then transferred to one of the Drafting Divisions where they remain for the first year, after which they are transferred to the shop and scheduled through the Pattern, Foundry, Forging, Machining, and Assembling Departments for the next six months. This enables them to acquire the actual shop experience so essential to designing. After completing their shop experience they are

[1] Dean of Engineering, Pennsylvania State College. Mem. Am.Soc. M.E.

[1] The details of this curriculum may be obtained on request from the Westinghouse Electric & Manufacturing Co., East Pittsburgh, Pa.

brought back to the Drafting Division for the remainder of the course.

The terms in general cover Objects of Drawing, Drawing System, Hand and Machine Tools, Patternmaking and Molding, Shop Practice, Materials and their Application in Manufacture, Development and Sections, and Clearances and Allowances. The mathematics in the course range from the fundamentals of arithmetic to the strength of materials in concrete problems. It might be well to mention the fact that the aim is first to make men, and that the various processes are accordingly used to instruct the boys, rather than to teach the processes.

When the course is completed, the graduates are transferred to the Engineering Department as regular employees.

Fifty-two apprentices have been enrolled in the course at this writing. Twenty of this number are still with the company, making the total turnover from the very beginning of the course, four years ago, only 61.5 per cent. Eleven have been graduated and three of their number have entered college. The remaining eight are still in the Drafting Office. Ten left the course on account of remuneration and three of them have returned. Of the twenty remaining with the company, six have been there over three years; five others have been there over two years; and the remaining nine have been there over one year. Only one of the total number was discharged.

This company also has apprentice courses for machinists, toolmakers, foundrymen, patternmakers, electricians, and junior engineers.

The applicant for trades training is interviewed by at least two different individuals and is given a simple test in mathematics. Those accepted are placed on probation for a period of three months. Their record is checked monthly by a trades apprentice committee and at the end of three months a definite decision is made as to whether an agreement shall be entered into between the young man and the company. If the young man and the company desire, a contract is entered into at this time outlining the obligations and duties of both parties. The apprentice is then placed in a special department in the factory where he receives preliminary instruction by specially qualified instructors. Supplementing the shop work each apprentice reports to the trades apprentice school four hours each week, two hours of instruction being devoted to blueprint reading and mechanical drawing, including tool design; and the remaining two hours divided between shop problems, economics, science, and manufacturing operations.

The National Metal Trades Association

This association also has an apprentice-training system which has been in operation for several years at different plants. It maintains an educational director who devotes his time to the study of apprentice training and shop instruction.

The Committee on Industrial Education of this Association says:

> Investigation in the metal-trades industry has shown that while in normal times there is a fair supply of semi-skilled specialists, there is always a dearth of skilled, all-around craftsmen. These highly skilled men are not only indispensable in the shop, but it is to this group that industry must look for its future foremen, superintendents and managers, and for practical designers and engineers.
>
> So pressing has this need become, that serious thought must be given to methods of adequate training of young men for this purpose if we would stimulate and not stifle the fullest development of American industry.
>
> Mindful of its urgency and realizing the consequences which must follow continued indifference toward this important question the National Metal Trades Association, after an exhaustive survey of the situation, has prepared a plan of apprentice training which, with slight modifications, will adapt itself to a shop of any size.

The association has adopted a standard form of indenture, setting forth in full and clearly all the details of compensation, service and training. Provision is made for a probationary period of three to six months, and by examination an apprentice who has had additional schooling may reduce the period of apprenticeship. Wages paid vary with the progress of the trainee, ranging from $33^1/_2$ per cent to 85 per cent of a journeyman's wages.

An interesting provision is made by which a highly specialized plant may send its apprentices to another plant for part of their training. This is a new type of "coöperative training;" in this manner they obtain the best instruction available in a group of industries.

Careful records are kept of each apprentice and his progress in learning each process. Each instructor grades each man on such qualities as speed, accuracy, etc., as well as on his skill on the particular process. The final record card shows the details of the four-year course, the time used, grade and instructors' estimate of personal qualities. The entire scheme is carefully planned and recognizes the rights and duties of the apprentice and of the company.

To a questionnaire sent out by the National Metal Trades Association, 572 replies were received. Of these 146 stated that some method of apprenticeship was being used, 72 train their operators, and 68 conduct foreman training classes. Of those training apprentices, 81 use the method of casual training by foremen, workmen, or by observation and practice, and 49 have definitely planned systems of instruction either in the production department or in an independently organized training division.

Shop Training

During the world war, various quick methods were adopted for training men for jobs with which they were more or less unfamiliar. Most of the methods had been used in industry for some years, but neither so extensively nor so intensively as in war work. Out of the experience of peace and war have come certain well-defined methods of training men for new jobs. These may be classed as:

1 Vestibule schools, where the training is in an independent organization and not in the production department.

2 The shop school conducted within the production department. This instruction may be by classes, by groups, or by special instruction for works clerks, routing clerks, and others of whom there are only a few in any plant even though it be large.

Vestibule Schools. There is no uniformity in the use of this term. It will be used here to define that type of training conducted in a separate shop where the trainees are segregated from those on production. Here it is proposed to give the "one best way" of doing a certain operation under good conditions. Learners are not distracted by the comments of other workmen. They do not learn the wrong way. They do not take the time of a foreman from production. They do not waste so much material.

On the other hand, a separate training department is not justified in the average small plant, but only where the demand for new, trained men is fairly constant and considerable. The separate school depends on the production department to absorb its output and if there is not close coöperation between the two, the separate school will be unsatisfactory.

The instruction often consists of one or two periods per day of classroom work and the remainder is spent on the process or operation to be learned.

The instructors should be chosen from the skilled men in the production department who have the ability to transmit what they know and tact in doing it. The production department will naturally object to losing one or more of its most valuable men for this purpose.

Shop Schools when conducted in the production department have the advantage of a certain elasticity. Instructors not required at the time can be put back on production. The majority of plants employ this method, and the foreman is most frequently the teacher. The modern demands on the foreman are much more severe and exacting than they used to be. To ask him to be a teacher also is a questionable expedient except where the number of trainees at one time is small. Where the plant expects foremen to be teachers, it seems reasonable to instruct them in methods of teaching.

The instruction is usually for the sole purpose of increasing the immediate productivity of new employees, saving waste of materials, and reducing wear and tear on machines. The training of apprentices is much broader and includes more of the industrial and economic background of production. The Federal Board for Vocational Education, in Bulletin No. 48, urges the importance of teaching in shop schools, the character of and sources of the materials used, the general processes of manufacture, the purpose and principles of planning and routing, the definition of terms frequently used, reading blueprints, job tickets, safety, welfare, hygiene, and the elimination of waste.

Wages During Training Period

In a plant where piece rates prevail a beginner will often become

discouraged and quit before he has learned the process and become sufficiently skilled to make a reasonable wage. It is usual to provide a special day rate during the period of training so that the trainee will be assured of a certain minimum income until he has the skill necessary to earn a higher wage on a piece-rate basis of payment.

Another method is to give the trainee a bonus, during the learning period, on the regular piece rate, depending on the production reached. If he does not accomplish the minimum production set he has the fixed day rate, and if he reaches or exceeds the minimum production he receives a bonus on the piece rate.

Where contracts are let to a group to construct or erect parts or the whole of a complicated machine, the cost of instructing a new man is sometimes borne by the group as a part of the total cost or contract price.

Where a group of workmen in a particular shop are held responsible for the instruction of new men, a leader is appointed who sees to the supply of tools, materials and the set-up of machines. The earnings of the leader may be charged to overhead, but enter into the cost of the job in that shop. In this manner the earnings of the group and of the individual are affected only by the time given by each man to instruction and not by the loss due to the reduced production of the leader.

A record card is kept of each learner, giving the time required to master each machine or process, the production output, and comments of the instructor or foreman on the progress of the learner. The time card also gives valuable information as to the capacity of different men to teach—or their indifference.

Difficulties in Shop Training

The old method of having the foreman "break in" the new men presumed some knowledge of the job by the employee and was in vogue when the foreman's job was much simpler than now. Because of this custom and the desire of some foremen to continue this duty, it is difficult to convince the management of the desirability of having trained teachers, i.e., men of skill who have been instructed how to teach. Too frequently a man is chosen to teach just because he knows the subject. Very often one who is not an expert becomes a better teacher because he has the gift or has been trained in the process of teaching.

Experience has demonstrated that assigning to the teaching an assistant foreman who has been trained to teach, or a selected workman who has the qualities of a teacher, is economy. In other words, the organization of teaching is important, and is increasingly important as the number of trainees increases.

Unfortunately there are very few books on teaching which are written for and adapted to this particular condition. However, a stimulus to the training of industrial teachers has been given by the Smith-Hughes Act—a federal law which provides funds with which to train industrial teachers for service in shops and in continuation and trade schools. Each state has an organization for this purpose operating under the joint supervision of the state department of education or public instruction and the Federal Board for Vocational Education.

The expense of maintaining trained instructors who are non-productive is frequently an objection in the eyes of the management. It is difficult to show by figures the reduced time and materials used in learning, the saving in wear and tear on machines, the saving in the foremen's time, the reduced turnover during the training period, the lessened interference with production, and the greater satisfaction to piece workers when they are not asked to break in new men.

Good instruction insists on doing the thing in the right way, and then learning to do it as fast as possible by correct methods. Production insists on doing the work as fast as possible, though the methods pursued may not be the best and ultimately may not lead to the greatest possible production commensurate with the effort made. There is a natural conflict between good instruction and the purposes of the production department which is not given due weight. It has been found that those who have received a thorough apprentice training often make good teachers because they have been thoroughly trained and have learned in the logical order, i.e., they have been given the simplest jobs first, then the more complex, while the desire to obtain early production may lead to an illogical order in the instruction of a new man and a waste of time.

Selection of Men

Another difficulty arises from the fact that in many plants there is little attempt to select men who are adapted to the job. An increasing number, especially of the larger plants, select both apprentices and skilled workmen (or those who are to be trained in some process requiring skill) with care. Educational tests of a simple character are given applicants for apprenticeships and systematic questions tending to establish fitness or unfitness are being applied to mature applicants. Trade and psychological tests were applied during the war and a valuable body of information and experience was gathered. There is much that is sound, and when turnover costs from one hundred dollars per man to twice that, it seems the part of wisdom and economy to apply discriminatory tests to all applicants, keep a simple record, and test the efficacy of such tests by experience. There are numerous sources of information on this subject such as the bulletin of the National Personnel Association, The Instructor, the Man and the Job, by Charles R. Allen,[1] and various journals on applied psychology, management, etc.

In conclusion, it is safe to say that whether the shop training should be done in a separate department or on the production floor depends on the size of the plant, normal turnover, complexity of the job to be learned, and other factors. In any case more attention should be given to organizing the instruction, selecting those to be trained with more discrimination, selecting instructors because of their skill as workers and as teachers, and so arranging the instruction as to give the new employee the best information available about his job, the methods, materials, and machines used. Some day we shall realize the importance of giving him a reflection of company ideals, methods of recognizing ability, faithful service, and loyalty. Perhaps industry will see the wisdom, even economy, of teaching its younger men the fundamental principles upon which a sound future industrial policy must rest. Up to the present time industry has had very few ideals, with marked individual exceptions, and such ideals as it may have had have been carefully locked in the safe rather than spread among the employees.

Industrial management in the United States, speaking broadly, has never used educational methods for its own salvation and for the upbuilding of industry. However, some have appreciated the value of teaching and have found such methods distinctly effective.

INDUSTRIAL EDUCATION AS REPRESENTED IN SCHOOLS

By C. R. RICHARDS,[2] NEW YORK, N. Y.

THIRTY years ago, the demand was often voiced on the part of employers for trade schools to train mechanics competently in place of the disappearing apprenticeship system. During these thirty years a number of attempts to meet this demand in schools both under private and public control have been made but the results and experience gained have not demonstrated that this function is one that can be served effectively in a large way by a school.

Outside of a number of schools run on a business basis for profit there are at present in the United States some fifteen or more schools that, strictly speaking, may be called trade schools, that is, schools admitting applicants sixteen years of age or over and aiming to train manual workers for a trade. The first of these, the New York Trade School, was founded by Richard T. Auchmuty in 1881. The development of schools aiming to take the place of apprenticeship in whole or in part after this date was very gradual—the Williamson Free School of Mechanical Trades was founded in 1889 and the Baron de Hirsch Trade School in 1891.

In 1907 the trade school entered upon the stage of public administration. In that year the Milwaukee School of Trades previously established was taken over by the city under the terms of the Industrial Education law passed by the Wisconsin legislature. Since that date public trade schools have been opened in Philadelphia, Pa., Portland, Ore., Bridgeport, New Britain and other places in

[1] Staff Federal Board for Vocational Education, Washington, D. C.
[2] Director, Cooper Union. Mem. Am.Soc.M.E.

Connecticut, Worcester, Mass., Yonkers, N. Y., Indianapolis, Ind., and Scranton, Pa., together with several institutions on private foundations such as the David Ranken, Jr., School of Mechanical Trades at St. Louis, the Arthur Hill School of Trades at Saginaw, Mich., and certain departments of the Dunwoody Institute, Minn.

Certain of these schools—the New York Trade School and the Baron de Hirsch—represent the short-course type; the others offer courses of two or three years in which practical trade training is supplemented by instruction in drawing and technical practice and in some cases by science and mathematics.

One reason why schools of this type have not further increased in number is because of the severe economic difficulties under which they labor. First of these difficulties is the problem of support presented to the student worker during the period of instruction. Trade school training of the type under discussion is in common practice restricted to the period above sixteen years of age, and as the great bulk of the youth who will form the mechanical and industrial workers of the country must of necessity enter upon remunerative work at sixteen or shortly after, the sacrifices necessary to permit attendance at a trade school can be expected only from a comparative few. The second aspect of the economic problem in relation to such schools is found in the large expense of administration, instruction, materials, and physical maintenance in proportion to the number of students that can be instructed. To be successful the trade school must demonstrate not only that it can give a better training than that obtainable under practical commercial conditions but that it can give training so much better as to compensate for the loss of wages during the learning period. At the best it is only in a few high-grade trades, the full command of which involves extensive subject matter and breadth of experience, that trade-school training can claim sufficient advantages over training under commercial conditions to repay its expense. It is, consequently, only in cities representing exceptional concentration of such industries that trade schools, at least of the long-course type, can expect support, and it is not yet entirely clear even in these cases whether the results obtained are proportionate to their expense.

It is in other fields that the large place of the school as a factor in industrial training has become evident—in the fields of preparatory and supplementary education. Here the schools have demonstrated their great value.

To properly estimate the place of the school in this whole connection it is essential not only that some knowledge be had as to what is being done in schools at the present time, but that an understanding be developed as to what forms of instruction can be most effectively consummated outside of the industries—that is, in schools; and what phases can be developed effectively only inside the industries. Both types of training are essential in a comprehensive system of industrial education—one is complementary to the other—and both need to be encouraged with intelligent discrimination in order that they may be developed as parts of an effective whole.

Evening Schools

The largest development of supplementary instruction has been in the evening school. This type is the earliest development of industrial education in our country and today reaches the largest numbers. Cooper Union and Mechanics Institute of New York; Franklin Institute and Spring Garden Institute of Philadelphia; The Ohio Mechanics Institute of Cincinnati; and the Virginia Mechanics Institute of Richmond all opened their classes about the middle of the nineteenth century. These schools were all due to private initiative and it was only slowly that schools under public administration entered this field.

The early work of the evening industrial and technical classes consisted of various lines of drawing, to which were gradually added courses in science, mathematics and technical subjects. Beginning about 1890 certain of these institutions established practical shop courses in a few of the high-grade mechanical trades intended to broaden the experience obtained by the student during the day.

The concern of public evening schools was formerly almost entirely with general studies and it is only of late years that differentiated and specialized courses related to industrial practice have been introduced in the schools of the more important cities. The expansion of such work, however, is now going on rapidly. In New York State in the year 1920–21 there were enrolled 22,984 men and 4,222 women in evening industrial extension classes under public administration, admission to which required actual employment in a related trade. The law in this connection states:

> Evening vocational schools (may be established in cities) in which instruction shall be given in the trades and in industrial . . . . subjects which shall be open to pupils over sixteen years of age, who are regularly and lawfully employed during the day and which shall provide instruction in subjects related to the practical work carried on in such employment.

A list of the evening industrial courses for men given during the year 1921–22 in New York State is as follows:

- Auto mechanics
  - Auto-block testing
  - Chassis repairing
  - Engine repairing
  - Gas-engine theory
  - Lighting and starting
  - Storage batteries
  - Vulcanizing and tire repairing
- Architectural drafting
- Blacksmithing
- Book illustrating
- Clay modeling
- Commercial photography
- Cooking and catering
- Dental trade (mechanical dentistry)
- Electricity
  - Alternating-current theory
  - Direct-current theory
  - Electric installation (house wiring)
  - Plan reading and estimating for electricians
  - Principles of artificial lighting
  - Radio
  - Railway signal work
  - Telegraphy
  - Telephony
  - Underwriter rules and regulations
- Foreman training
- Hydraulics
- Industrial chemistry
- Interior decorating
- Jewelry design
- Life drawing
- Machine shop
  - Advanced machine-shop practice
  - Elementary machine-shop practice
  - Blueprint reading for machinists
  - Mechanical drawing for machinists
  - Free-hand sketching for machinists
  - Shop mathematics for machinists
  - Theory of materials and processes
  - Tool designing
  - Tool making
- Mechanical drafting
  - Advanced mechanical drafting
  - Elementary mechanical drafting
- Mill wrighting
- Motion-picture operating
- Mural designing
- Player-piano mechanics
- Plumbing and heating
  - Leadwork
  - Plan reading and estimating
  - Principles of heating and ventilation
  - Hot-air system
  - Hot-water system
  - Steam heating
- Poster designing
- Printing
  - Advance hand composition
  - Cost estimating
- Elementary hand composition
  - Job and cylinder presswork
  - Kelly press operating
  - Monotype operating
  - Offset presswork
  - Photo lithographing
  - Proof reading
  - Typographical design
- Sheet metal work
  - Plan reading and estimating
  - Sheet-metal drafting
- Shop mathematics
- Ship drafting
- Ship fitting
- Shoe finishing
  - Cobbling
- Sign painting
- Steam engineering
- Textiles
  - Garment-machine operating
  - Knitted fabrics
  - Lace designing
  - Loom repairing
  - Men's tailoring
  - Ribbon manufacturing
  - Textile chemistry
  - Textile design
  - Women's tailoring
- Woodworking
  - Advanced cabinet making
    - Elementary cabinet making
    - Drawing for cabinet makers
    - Blueprint reading for carpenters
  - Framing
    - Millwork
    - Inside finishing
    - Plan reading and estimating
    - Stair building
    - Use of steel square
    - Patternmaking
- Terra-cotta work
- Upholstering
- Welding
  - Electric
  - Oxyacetylene

The attendance in these trade extension courses in New York City during the year 1920–1921 was 13,538 men and 3,969 women.

Part-Time Classes

Part-time classes are a development of comparatively recent years. Laws making it permissive for municipalities to develop part-time classes in place of evening classes for employed boys and girls who had not finished the elementary school began to appear as early as thirty years ago. The first law making attendance compulsory in such classes was that of the state of Wisconsin in 1911.

This action was followed by other states until the number that have enacted such laws now reaches twenty-one. As long as these compulsory school laws referred only to boys and girls up to the age of 16 years they had limited significance from the standpoint of industrial education as the instruction given was necessarily largely of a general nature. In 1917 Wisconsin passed a law making attendance in a part-time school compulsory for all employed boys and girls up to 18 years of age. Since that time such laws have been passed in 10 states with the result that opportunities for imparting valuable instruction in matters related to the needs of the vocation in which the boy or girl is employed have developed. The opportunities for rounding out and broadening the education of the young workers in the industries thus presented are very important although the extent to which such instruction can function on the industrial side is largely dependent upon the size of the community in which such classes are maintained or upon a degree of industrial concentration in the community which will allow classes from single or related industries to be segregated so that specialized class instruction can be given.

The large opportunities for related vocational instruction in this field lie in connection with the high-grade trades involving considerable content of trade or technical knowledge depending on an understanding of elementary mathematics and science. In the case of low-grade factory industries where neither processes or materials present need for technical knowledge the school instruction must necessarily assume other directions.

The results of such instruction, however, whether dealing with pupils from skilled trades or factory industries, have been found of much assistance to foremen and superintendents in determining promotional opportunities inside the plant.

The numbers in part-time classes in New York state in the year 1921–1922 were 26,678 boys and 21,760 girls. The New York state law requires that part-time schools shall be established in cities and school districts having a population of five thousand or more inhabitants and that each minor under age of 18 years who is not in regular attendance upon some public, private or parochial school or who is regularly employed in some occupation, unless he has completed a four-year secondary course of instruction, shall attend a part-time school. Such attendance shall be for not less than four hours a week and not more than eight hours a week. These hours should be between the hours of 8 o'clock forenoon and 5 o'clock afternoon. This law was put in operation September, 1920, and municipalities are given until September, 1925, to put the law into full operation.

At the present time practically all cities outside of New York City require the attendance at such schools of all employed minors 14, 15, and 16 years of age. New York City requires the attendance of those 14, 15, and 16 years of age when they are not elementary school graduates. Schools or classes are now in operation in 103 communities in the state.

Part-time instruction is apparently destined to increase throughout our country until it reaches all employed youth up to 18 years of age. Under these conditions the study of just what elements of instruction can be given best in these classes is a matter of much importance and one requiring thoughtful consideration. The subject is receiving considerable attention and the elements of the problem have been very well analyzed in a bulletin recently put forth by the Federal Board for Vocational Education called "Part-Time Schools."

Vocational, Industrial, or Unit-Trade Schools

Preparatory industrial training or pre-employment trade training is represented in its most important phase by schools under public control called, variously, vocational schools, industrial schools, or unit-trade schools. These schools have arisen largely from the discovery of the fact first brought out by the report of the Massachusetts Committee on Industrial and Technical Education in 1906 that in the case of the large number of boys entering employment at 14 years of age, the two years following are largely wasted as far as progress toward a skilled trade is concerned.

The first school of this type to be established was at Rochester, N. Y., in 1908. Since then a considerable number of schools providing practical work in one or more of the large trade groups, together with related instruction in drawing, elementary science, history, English, shop calculations, accounting, and business forms have been organized in several eastern states. Such schools do not aim to impart a trade training but to develop some amount of industrial intelligence and knowledge of shop methods and materials in the boy or girl 14 or 15 years of age that they may be better prepared at 16 to enter upon industrial employment.

The causes that have brought the preparatory trade school into being in the United States are not alone the economic advantage to the industries in preparing better material for entrance therein, an advantage that employers would be quick to perceive yet slow to bring about; but rather the recognition on the part of the public of a social obligation to better the opportunities for great numbers of young persons to enter upon more substantial careers.

The development of these schools has been largely confined to the eastern Atlantic states, particularly Massachusetts, New York, New Jersey and Pennsylvania. In New York state there were twenty-four such schools in 1920–1921, scattered throughout the different cities of the state. There were five in New York City, four in Buffalo, three in Rochester and lesser numbers in the smaller cities. Table 1 gives the unit trade courses maintained in these schools and the enrollment for 1921–1922.

Table 1 Enrollment by Trade Courses in Unit Trade Schools of New York for 1921–1922

Name of Trade Course	Enrollment			Number of Schools Offering Courses
	Boys	Girls	Totals	
Electrical work	1636	0	1636	13
Machine shop	1299	0	1299	19
Auto repairing	1111	0	1111	8
Cabinetmaking-carpentry	689	0	689	15
Printing	477	0	477	12
Machine drafting	422	0	422	8
Patternmaking	304	0	304	9
Sheetmetal	226	0	226	8
Architectural drafting	159	0	159	2
Plumbing	146	0	146	4
Commercial design	115	0	115	2
Sign painting	72	0	72	1
Bookbinding	44	0	44	1
Painting and decorating	27	0	27	1
Forging	20	0	20	1
Industrial chemistry	16	0	16	1
Power-plant operating	16	0	16	1
Shoemaking	12	0	12	1
Dressmaking	0	1250	1250	1
Millinery	0	466	466	1
Garment-machine operating	0	190	190	1
Novelty, lamp shades, sample mounting	0	59	59	1
Garment design	0	29	29	1
Straw-machine operating	0	28	28	1
Flowers and feathers	0	27	27	1
Manicuring and shampooing	0	24	24	1
Embroidery-machine operating	0	18	18	1
Cooking	0	13	13	1
Totals	6791	2104	8895	

This type of school would appear to have become a stable element in the educational system and may be expected to assist materially in equipping a considerable number of boys and girls entering the industries with greater industrial intelligence, greater understanding of industrial processes, and greater interest in industrial careers.

Secondary Technical Institutes

A group of schools, small in number but performing most important work in mechanical and electrical fields, have been developed in various parts of the country in the last thirty years. These schools offer a technical training above that of the trade school and below that of the engineering school, aiming, in other words, to equip the technical expert, designer, inspector, tester, overseer, shop superintendent and power-plant superintendent, in short, the non-commissioned officers of industry. Prominent among these schools are Pratt Institute, certain departments of the Carnegie Institute, the Ohio Mechanics Institute, the Rochester Mechanics Institute, the Lewis Institute, the Wentworth Institute, and the Dunwoody Institute. Such schools comprehend courses in machine construction, electrical construction, industrial electricity, steam and electrical power-plant practice, foundry management and operation, machine design, industrial chemistry and courses called industrial mechanical engineering and industrial electrical engineering. The courses generally extend two years in length although in certain schools they carry beyond this time. It is to be hoped that this type of school will develop considerably further in our country. It has a task to perform purely its own and one of extreme value to industry and engineering.

Technical High Schools

A number of schools aiming to fulfil the office of secondary

technical schools have been organized under public administration in the last 20 years. The manual training schools which developed rapidly in the United States between 1880 and 1900 did not contribute, as they were expected, trained workers to the industries, and attempts have been made to convert some of these schools into technical high schools having the distinct purpose of preparing pupils for industrial leadership, that is, for positions in industrial life requiring skill and technical knowledge and of greater importance and responsibility than those of skilled mechanics. The weakness of such schools, considered from the standpoint of the productive or operating industries, lies mainly in the fact that they neither require practical experience before entrance nor provide parallel experience as in the case of coöperative schools. As a result their graduates have mainly entered drawing rooms and other white-shirt occupations in industry or else, to a considerable extent, gone on to engineering schools. One of the functions for which these schools seem relatively well fitted is that of preparing young persons for entrance into the field of industrial chemistry.

Cooperative Schools

The coöperative plan by which the students spend half their time at work in industrial establishments and half in school, and which was first highly developed in the engineering department of the University of Cincinnati, has since been applied to students of high-school grade. This plan differs from the part-time plan in some important respects. In the first place the student body consists of enrolled high-school students and not of young workers already employed in commercial establishments. In the second place the larger amount of time spent in school allows both general and technical education to be carried much further. This type of school is maintained in some 47 cities in our country at the present time but its exact place in the scheme of industrial education is not yet clearly defined. Whether, on the one hand, any considerable number of those aiming at and fitted for regular mechanics' work in trades will be drawn to such schools, or whether, on the other hand, such schools will develop capacity for training leaders of the foreman and expert type still remains to be seen.

It is to be doubted that many high school students can be counted upon to enter manual occupations in the industries. We must recognize that the ideals of the homes from which come the large body of high-school students are directed distinctly away from such occupations for the sons and daughters and it would seem clear that the contributions of the high school to the field of industry must be found in supplying young men with the basis of a good education who are fitted after a further period of practical experience to attain positions of at least subordinate leadership.

From this point of view it is evident that coöperative industrial classes in the high schools cannot be expected to reach large numbers, but on the other hand it is also evident that such classes give promise of developing a type of young man well fitted to find an important place in the industrial order.

Foreman Training

Considerable development has been made in the past two years in the very important field of foreman training. A valuable contribution was made to the subject by a report published in 1920 by the Federal Board for Vocational Education by Charles R. Allen.[1] The work has been forwarded both by the Federal Board and by state authorities. In the former case the work has been promoted in three principal ways:

First, by national conferences of four weeks in length held during the last two summers at Minneapolis, attended by state representatives and representatives of industrial concerns, in which courses for the training of conference leaders were developed.

Second, demonstration courses or conferences conducted by agents of industrial education service in industrial plants. A large number of these conferences have been held in various parts of the country in the last two years. The programs have almost uniformly covered a period of two weeks and foremen have been in attendance at the conference either five or six hours a day during working hours.

Third, through publishing the results of research and experimental work and distributing this material to persons in the states and industries who are concerned with the problem of foreman training.

Programs of foreman training have also been developed by the states of New York, Missouri, Pennsylvania, Nebraska, Virginia, Georgia, and Ohio. This work is generally conducted by some educational institution of recognized standing under the supervision of the special state agent in charge of this type of work. Most state work is conducted in industrial plants during the regular working hours.

The development of this work promises to be one of the most important as yet undertaken by the schools. It has been dealt with not on the conventional basis of school instruction but largely through conferences in which the chairman or leader seeks to make his points by drawing out the experiences of the foremen present. Assistance in this field has been eagerly sought for by employers and if the work is carried out with the same judgment and care that have marked its beginnings it may well prove of invaluable service to industry.

Results of Federal Vocational Education Act

The passage of the vocational education bill, commonly called the Smith-Hughes Act, by Congress in February, 1917, placed the the whole matter of vocational training in schools upon a new basis. By the provisions of this act, which went into effect July 1, 1917, one-half the cost of the salaries of teachers of trade and home economics subjects and of teachers and supervisors of trade and agricultural subjects is paid by the Federal Government up to the limit set by the government appropriation and one-half is paid by the state or local community. The state or local community or both must meet all the other expenses of the schools including site, plant, equipment and other expenses together with the salaries of teachers of academic subjects.

To take advantage of its provisions the act requires the state through its authority to accept the provisions of the federal bill, designate or create a state board of control and designate the state treasurer as custodian of the funds. All moneys disbursed by the board are paid by the state treasurer to approved schools as reimbursement for expenditures already incurrred. Federal money is paid to local communities only after their work has been approved by the state board on the basis of the federal act.

Schools entitled to the benefit of the federal grant are: (*a*) all day schools in which half the time must be given to actual practice of a vocation on a useful or productive basis; (*b*) part-time schools or classes for workers over fourteen years of age; (*c*) evening schools or classes for workers over sixteen years of age.

In order that states may receive federal aid, teachers, supervisors, and directors must have the minimum qualifications, the plant and equipment must meet the minimum requirements, and efficiency of instruction must meet the minimum standards as set up by the state board and approved by the federal board.

The Federal Board for Vocational Education is composed of the Secretary of Agriculture, the Secretary of Commerce, the Secretary of Labor, the United States Commissioner of Education and three citizens appointed by the President by and with the consent of the Senate, one to be a representative of manufacturing and commercial interests, one a representative of agricultural interests, and one a representative of labor.

The effect of the Federal Vocational Education Act upon the development of vocational education since its enactment has been very marked. Prior to the passage of the act only seven states in the union had enacted laws recognizing vocational education as a part of the public school program and appropriated funds to assist local communities in developing this type of work. Before January 1, 1918, every state in the union, through official action by the legislature or by the governor, had accepted the provisions of the Federal Vocational Education Act. Every state during the same period submitted plans for accepting the provisions of the federal act and the rulings of the Federal Board for Vocational Education as regards standards and methods. Every state also set up a definite State Board for Vocational Education and organized itself for the discharge of its duties under a responsible staff. The number of states employing supervisors of trade and industrial education in 1916 was seven, in 1921 was forty-five.

[1] Staff Federal Board for Vocational Education, Washington, D. C.

In 1916 the total appropriations by states for vocational education was $1,300,510.15 and expenditures by local communities was $2,118,208.96, making a total of $3,418,719.11. In 1921 the total state appropriations were $5,595,956.78, those by local communities $9,489,809.01, and federal appropriations in the same year were $2,949,850.57, making a total of $18,035,616.36. The most significant element in these figures is the increase of local appropriations largely brought about by the stimulus of federal grants. Enrollment in federally aided vocational schools increased from 164,186 in 1917 to 323,028 in 1921.

The publications prepared by the Federal Board for Vocational Education upon various problems of vocational education and administration have been extremely helpful to those engaged in the field.

The value represented by the great expansion of vocational education under public control undoubtedly should not be entirely measured by figures of enrollment or by money expended. During the rapid development of the last few years, some of this work unquestionably has not been entirely effective or well done, as it has not always had the benefit of thoroughly competent instructors or supervisors. Like other educational work under public control its character is largely dependent upon the quality of personnel that is represented in the state departments of administration and by the local supervisory officers. It would seem to be a fact, however, that in most of the states the men occupying these positons represent a new type of educator, a type practically minded, generally possessed of some measure of practical experience and characterized by energy, initiative, and forward-looking vision.

Machinery has been set up and a large personnel developed for a vastly important work and if the results of this work, the policies pursued, and the quality of organization represented can receive both criticism when deserved and encouragement when merited from practical men and in particular from men of engineering status, the possibilities of sound and competent development of this phase of industrial education will be greatly increased.

The foregoing review of the present status of the many types of industrial education proves that such education has already advanced in a truly remarkable way and promises much for the future. An attendance in trade extension courses in New York alone of over 100,000, with approximately 325,000 studying in federally aided vocational schools supported by appropriations of over $18,000,000, together with a record of over 4,000,000 students in the United States having completed correspondence courses, will suggest much to the lay mind.

Director Moyer gives a clear and valuable survey of existing facilities for correspondence instruction and shows how employees of the industries may best secure the advantages thereof. That these advantages may be the greatest, each industry should coöperate with the university-extension agency in its state and secure for its employees the additional personal instruction furnished when correspondence instruction is applied for by groups, and the consequent formation of what are called extension classes.

Dean Sackett's description of existing apprentice and shop schools will prove of value to every industry which has under consideration the starting of such a school in its own establishments. The associated analysis by Dean Sackett of the difficulties to be overcome is not the least important part of his contribution.

Director Richards deals with the organized trade schools and vocational education of industrial nature in the public schools. Evening schools, part-time schools, unit trade schools, secondary schools and high schools for technical training, and coöperative schools of vocational nature are all included within his theme aud receive his illuminating analysis. A very important part of the paper is his summary of the results of the Federal Vocational Education Act.

The Committee is of the opinion that not only are these papers which it puts forward as its report of much value in themselves, but that a full discussion of the subjects treated therein by the members of this Society who are directly connected with manufacturing will result in an additional improvement in the practice.

W. W. Nichols, *Chairman,*
Committee on Education and Training for the Industries.

Discussion

The previous reports were presented at the A.S.M.E. Annual Meeting Session held December 5, 1922, with W. W. Nichols, Chairman of the Committee on Education and Training for the Industries, in the chair.

In discussing the section devoted to extension and correspondence schools, Dane A. Carpenter pointed out that, while instruction by correspondence is as old as written language, the large field for this work is evident from the fact that only 13.9 per cent of the pupils entering grammar school graduate from high school and only 2.3 per cent graduate from colleges or universities. Even though colleges increase their registration at the present rate they will be able to handle only a small fraction of the high-school graduates. Mr. Carpenter expressed the belief that the disadvantage commonly mentioned in connection with correspondence teaching, namely, lack of personal intercourse between teacher and pupil, and pupils in schools, had been greatly overstressed. He emphasized the fact that the merit of any correspondence institution depends upon inspirational effort, adequate textbooks, and educational service. He agreed thoroughly with Dr. Hollis, who, in his introduction to Dr. Moyer's paper, stated that the strength of the correspondence school was its ability to employ the very best talent in the preparation of the textbooks. D. B. Preston told of the work being carried on by the Extension Division of the United Y.M.C.A. schools. The standard course which is being carried on by the Y.M.C.A. schools in class rooms of various manufacturing institutions throughout the country is also being conducted by the Extension Division by correspondence. The Executive Division instructors who direct the lessons and check and compare results have found that in almost every case the work of the Extension Schools is superior to that of the class-room students.

In closing his discussion, Dr. Moyer stated his belief that our high-school education should be changed so that the students would be encouraged to take a smaller part of the high-school work and finish their education by night-school study, in extension schools, or by correspondence schools.

In his discussion on the second subdivision of the report, that devoted to school for apprentices and shop training, George M. Basford stressed the importance of convincing the higher executives of the organization that men can be trained and can be used after training. Only when executives look inside their own organization for the man they want and for the man they themselves have made, can training in the industries and by the industries be successful.

J. C. Wright emphasized the words of the previous speaker and assigned to the engineers of the country the responsibility for leadership in securing a greater understanding of the need for industrial training. He asked for the moral support and active assistance of the engineering profession for the Federal Board for Vocational Education. Frank B. Gilbreth also supported the remarks of Mr. Basford as to the importance of securing understanding by executives of the need for industrial training, especially that type which recorded "the one best way."

J. P. Brown, F. P. Anderson, James A. Moyer, W. H. Sawtell, and F. E. Matthewson discussed the merits of the high school and its place in preparing for industry. In closing the discussion Dean Sackett reëmphasized the marked change in the attitude of management toward education as exemplified by the period preceding the war in comparison with the war period and since the war. He stated it was his belief that one of the best contributions of shop training is the bringing together of the management and the men into closer relationship, and if this relationship permits the discussion of the fundamental principles of sound industry, a great deal has been accomplished. Arthur L. Williston stressed the importance of grouping in the preparation and training of the workers of industry. He suggested that each member of the Society attempt to induce the organization with which he is connected to record the facts regarding the extent to which workers were devoting themselves to self-improvement in correspondence schools or part-time schools. Dr. Hollis stated that all education must tend toward fitting young men to make a living that they might not become public charges and to use intelligently the spare time that they can gain by reduction of hours of labor.

New Factors Influencing the Design of Woodworking Machinery

By SERN MADSEN,[1] CLINTON, IOWA

Such factors as the adoption of high-speed steel, demands of greater economy, power and speed, the use of ball bearings, and the direct application of the electric drive, necessitate new standards for woodworking machinery. The author discusses these factors, summarizes the problems of driving and fitting cutter heads, and tells how ball bearings and electric motors overcome many of them. The savings in power resulting from the use of ball-bearing motor-driven arbors are pointed out, and the paper includes tables of synchronous-motor speeds and motor speeds available with two and three frequencies.

WOODWORKING machinery, which has been considered standard for many years, is now passing through a period of revolutionary design. Among the many factors which are causing this change may be mentioned: (1) Adoption of high-speed steel and improved cutter-head design; (2) the demands for greater speed and more economical production; (3) the use of ball bearings for high-speed arbors; and (4) the direct application of the electric drive, first to individual machines, and now to each individual head.

It is the purpose of this paper to show how these factors are greatly influencing and determining the type of woodworking machinery of the future. The machines considered, for the most part, will be those used in the sash, door, and millwork industries,

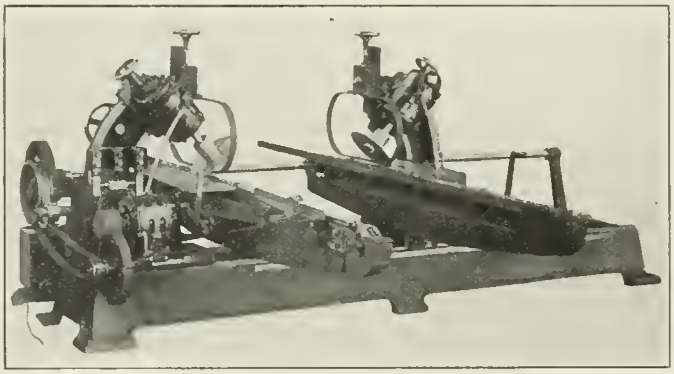

Fig. 1 Double Cut-Off Saw

(The motor applications to this machine illustrate how well motors can be used to apply power to arbors adjustable to various angles. These motors are built to carry the entire bearing load in the end plates of the motor itself. The bearings are of the single-row deep-groove type with about 18 or 20 $^5/_{16}$-in. balls. Grease lubrication is used.)

and these represent quite completely all the machinery used in the remanufacture of lumber into finished products.

Practically all woodworking machines perform their work by a process of milling, abrading, boring, or pressing. By far the greater number perform shaping operations and use milling or cutter heads of various shapes and forms. Discussion of this class of machines, alone will be fairly representative of the entire line.

Cutter Heads

In the early days of the development of the woodworking industry only the very choicest lumber was used. Preferably softer woods and the straighter-grained materials went into articles requiring much shaping and fine finishes. With such materials the old-style square cutter head did remarkably well. Having a hook with an angle of 45 deg. it cut and planed well with a minimum of power required. The growing scarcity of softer wood resulted in the necessity of working up not only the harder woods but the crooked-grained materials as well. Coupled with this came the demands for greater speed. The square head, though still used to some extent, had a tendency to tear due to its great hook. The remedy was to back bevel or reduce the cutting angle of the bits. Two difficulties were encountered: carbon steel would not stand up, and the power required to drive the heads increased. The adoption of high-speed steel remedied the one difficulty but did not reduce the power.

The improved work and absence of tearing resulting from more of a scraping cut has so influenced cutter-head design that now it is not unusual to find cutter heads with as little as 5 or 10 deg. rake instead of the original 45 deg. With cutters having so little angle the shavings are broken up and come off more curly. In some cases the power required may be reduced by setting the cutters at a sufficient angle to produce a side-shearing cut.

More Power and Speed

When it was found that high-speed steel would stand the scraping cut it became almost universal practice to apply more power and turn out more work. Milled-to-pattern bits and round heads with their high-speed-steel bits were developed; as all of these could withstand greater centrifugal stress, higher speeds could be used in an endeavor to obtain more knife cuts.

Here again it was found that more power and more speed meant wider belts, larger pulleys, and excessive belt speeds. At somewhere around 4000 r.p.m. we begin to experience more or less trouble in transmitting power to the cutter heads by means of belts. Centrifugal force tends to reduce both the grip of the belt and the arc of contact on the cutter-arbor pulley. The high belt speed tends to whip it to pieces and necessity for greater tension strains the belt. Heating up of the pulleys tends to increase belt slippage and further aggravates the trouble.

Whether influenced by these considerations or not, belt-driven machines have not generally been designed to operate at more than from 3600 to 4000 r.p.m. The use of two driving belts, one at each end of the cutter-head arbor, has enabled some machines to operate at the higher speeds.

Since designers were limited in the direction of increased cutter-head speeds and since it is practically impossible to set two or more knives or bits to cut exactly the same, it was necessary to find some means of securing a greater number of uniform-depth knife cuts per revolution of the cutter heads. Larger-diameter cutter heads were adopted and more bits inserted, but no matter how carefully set up, generally but one bit actually does the finish cutting and leaves "revolution marks" on the work. The axis of rotation of a cutter head at high or operating speed is never the same as at rest. Slight unbalance causes a corresponding "throw" at high speed which may be sufficient to cause one bit to cut deeper than the rest. We may be able to make all bits cut, but seldom will they "finish" the same depth. A difference of 0.001 in. or less is very apparent on feeds greater than 1 in. for each 15 revolutions of the cutter head.

The problem of getting all bits to cut has practically been solved by jointing or dressing them to even length with a stone while the head runs at cutting speed. High-speed steel is much more satisfactory where jointing is necessary. If the "heel" produced by jointing varies too much on the successive bits or cutters the effect is as bad as though one were longer than the others. In spite of all these improvements there are still cutter heads that cannot be jointed and we must depend on higher rotative speeds.

Having summed up the various problems of driving and fitting cutter heads, it is interesting to note how admirably ball bearings and electric motors overcome many of them. The belt drive, at its best, subjects the bearings to more or less pounding and vibration and also causes a tremendous amount of side pull and friction owing to belt tension.

A motor direct-coupled to the arbor overcomes some of these

[1] Superintendent of plant equipment, Curtis Companies, Inc. Mem. Am.Soc.M.E.

Contributed by the Forest Products Division and presented at the Annual Meeting, New York, December 4 to 7, 1922, of The American Society of Mechanical Engineers. Slightly abridged. All papers are subject to revision.

objections, but still involves difficulties with couplings, alignment, etc., besides requiring considerable space.

A practice which is constantly growing in favor is to "build the motor in" so as to make the motor shaft and cutter arbor identical. While such an arrangement is ideal in providing high speeds, even, steady torque, and an abundance of power, it still involves some problems in bearing design. On this one point there is still no approach toward standard construction. Some machine builders mount the motor entirely outside the main arbor bearings and let the rotor run on an overhung shaft with no bearings in the stator whatsoever. This construction works very well on lower speeds up to possibly 1800 r.p.m., but its use is questionable on speeds of 3600 r.p.m. and higher.

Attempts have been made to improve this construction by use of an outer bearing in the motor, but best practice greatly favors the use of only two bearings on any high-speed arbor wherever possible.

Another method which appears to meet with more approval is to build the motor frames exceedingly strong, with heavy bearings and as great overall length as practical.

One machine builder has adopted a construction involving a heavy yoke with heavy bearings at each end and mounting the stator on the yoke. While this is an exceedingly heavy construction, it does remove nearly all mechanical stress from the motor frame itself.

Still another method of construction used by a prominent machine builder consists of mounting the arbor in the usual bearings at the ends of a heavy yoke. The motor complete is located on the arbor between these bearings, and ball bearings in the end plates maintain clearance between rotor and stator.

These varied types of construction show that no definite best plan has yet been decided upon. The essential problem is to provide for:

1 Rigid bearings without end play for the cutter-head arbor
2 Bearings that will maintain, or are adjustable for, clearance between stator and rotor
3 Bearings that will stand up at the higher speeds of 5000 to 7000 r.p.m.

Ball Bearings

In nearly all of the designs ball bearings are used and are meeting with very good results. Types of bearings vary from the double-row self-aligning type to the deep-groove single-row. The latter has the preference where end play is to be prevented, but the former is much preferred where radial load is predominant. It is quite important that end thrust be cared for at only one bearing and that all other bearings be free to move longitudinally with the shaft as it may expand or contract. One manufacturer uses a well-lubricated bronze thrust bearing to resist end play in one direction, while one of the ball bearings meets it in the opposite direction.

In the usual construction the inner ball race is locked to the arbor while the outer race is free to creep or turn gradually. Bearing manufacturers claim this is desirable in order to distribute gradually the wear to different surfaces of the outer race. Instances are known, however, where this has gradually worn the retaining case to the point of objectionable looseness. Proper lubrication also seems, to be a problem worthy of further study. Ordinarily hard-grease cups are used but better, more nearly fool-proof devices, are needed. Automatic circulating-oil lubrication seems most desirable for high speeds. Prevention of oil leakage into the motor windings is a difficult problem to solve successfully.

The life of ball bearings at high speed is something not yet well determined. It is generally agreed that they do not need replacing so often as babbitted bearings. Very few properly designed bearings fail short of what is considered satisfactory service.

Even with the possibility of an occasional bearing failure, there nevertheless seems to be a general feeling among users that it is far cheaper, both in time and money, to replace an occasional ball bearing, than to replace babbitted bearings giving a like service. A prominent designer advances the belief that the average life of bearings operating at 3000 to 7200 r.p.m. will be about three years, and that at speeds slower than this they will last indefinitely.

Power Requirements

The savings in power resulting from the use of ball-bearing motor-driven arbors is little short of amazing. Tests of motorized and belt-driven equipment seem to indicate that we may hope to save nearly 50 per cent of the power now used for driving such machines as molders, stickers, planers, sanders, etc. This is cheering news in the face of the facts brought out earlier in this paper that the later types of heads designed to do better work do require more power to drive them. By this happy coincidence it may be possible for woodworking plants to keep their power requirements from continually mounting higher.

While it is encouraging to know that the total power requirements of a woodworking plant can be reduced by the substitution of ball-bearing motor-driven machinery, there nevertheless are other new problems that must be considered. In order to motorize a machine completely it is necessary to make the aggregate horsepower of all the individual motors much greater than the average power consumption of the machine. Each motor must be enough oversize to care for extreme or overload conditions. Oversize or underloaded motors operate at a lower power factor. It is therefore necessary to provide either oversize generators or to install syn-

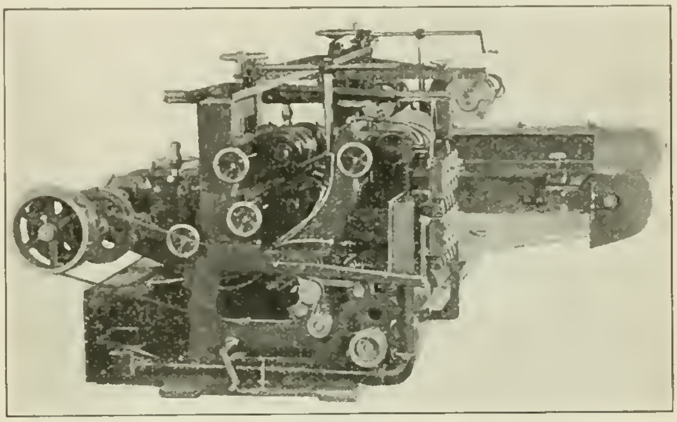

Fig. 2 Double-End Cut-Off Saw

(This machine uses nine motors and illustrates well how belt and gear drives are being eliminated. To meet the limitations of small space even the motors have to be built with small diameters and increased in length. Motor controls on this class of machines provide that the motor driving the feed will stop automatically if for any reason any one of the cutter-head motors should stop. Push-button control is being adopted almost exclusively.)

chronous condensers. In a new layout perhaps the larger generator is preferable, while for equipment already installed the synchronous motor offers the best solution.

Higher Frequencies

In general, 3-phase 60-cycle current is standard for woodworking plants. This limits motor speeds not only to 3600 r.p.m. maximum but also to comparatively few other speeds. Frequency changers are now standard equipment with many electrical manufacturers, and they are generally installed as individual units to care for each new high-speed motor-driven machine as installed. This practice soon requires an undesirable number of extra units.

A problem which is already becoming acute is to determine the better practice of providing higher-frequency current, whether by frequency changers or by direct generation in the power plant; also how many frequencies should be available and which will give the most desirable range of motor speeds. Table 1 gives the available synchronous speeds for a wide range of frequencies. From this we can choose such combinations as are desired.

Assuming that 60 cycles will always be standard and that one other frequency is desired, Table 2 gives the additional motor speeds for 80 and 85 cycles. Of the two, 80 cycles gives the better range, but the maximum speed available may not be considered high enough. If the highest speed must govern, then 85 cycles is preferable.

If we wish to have three frequencies available we find that 60, 75, and 90 cycles or 60, 80, and 100 cycles give the best ranges of speeds with the most uniform steps. The combination shown in the left-hand half of Table 3 gives a most desirable range above 1080 r.p.m. and is probably preferable for direct connection of motor to cutter head arbors.

The right-hand half of Table 3 shows a combination of speeds that has fairly even steps all through and is especially even in steps

for speeds below 1000 r.p.m. This makes this combination especially desirable for direct connection of motors to exhauster fans where quite definite speeds are needed and which are not obtainable with the 60-cycle current alone. Everything considered, 60, 80, and 100-cycle currents seem to be the most desirable. This permits a start with 60 and 80 cycles as in Table 2 and later adding the 100-cycle current.

Another use of two or three frequencies for is driving feed motors. It also makes available a proper cutter-head speed to suit the work being done, a practice which is still quite unknown to the woodworking industry. One machine-building company already cares for this by using a multi-speed motor for driving the frequency changer, which indicates that variable cutter-head speeds may even now be on the way. It seems logical that different woods and different cutter heads should operate at different speeds for best results.

Power Generation

There are many ways of generating or converting power of different frequencies, such as:

1 Main generator, 60-cycle; others through frequency changes

2 Two or more independent units operating at different frequencies

3 One large prime mover with two or three generators on the same shaft.

In small plants the first method is undoubtedly to be preferred. Where only two frequencies are desired two separate units might be preferable, especially for larger plants. When three frequencies are desired it seems best to use at least two units and possibly to put two generators on one shaft.

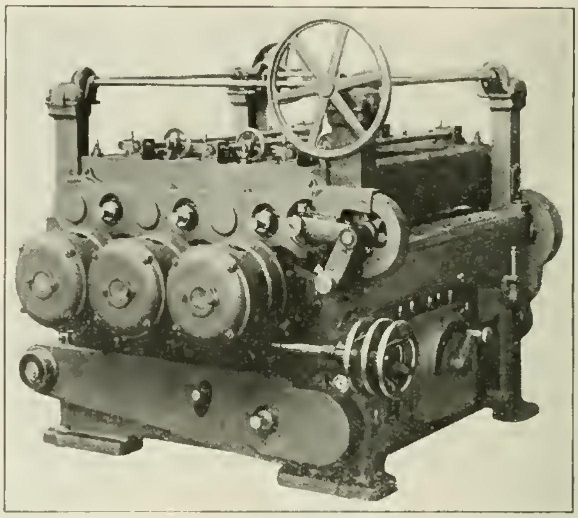

Fig. 3 Three-Drum Direct Motor-Driven Sander with Overhung Motor

(This design illustrates perhaps one of the most successful designs of motor application in which the motor is overhung. The stator is attached securely to a yoke which connects to two drum bearings, while the rotor is mounted directly on the projecting end of the drum shaft. This construction insures perfect alignment at all times, since all parts move as a unit. End oscillation of the drum is provided for by use of a rotor of slightly greater length. The usual drum speed, 1200 to 1800 r.p.m., is low enough to permit use of the overhung motor without an outside bearing.)

Another solution may be in specially built generators with multiple windings. These are problems that are worthy of some thought. Each plant will have its own problems as to how large the capacity for current of each frequency must be. It would be desirable to have the higher frequency units arranged to operate at 60 cycles in emergencies. Nearly all woodworking machines can be operated with considerable variation in speed if necessary, in case of breakdown or emergency. Other considerations will be extra switchboards and power lines, but this part of the multiple system is not complicated.

This discussion has thus far dealt but briefly with these new factors in woodworking-machinery design, but it is hoped that it may point out the opportunity for standardization among machine builders in getting out this new line of electric machines. Among the items that may well be standardized may be mentioned the following:

1 Use of 3-phase 60-cycle 220-volt alternating current as the basic standard for power in woodworking plants

2 Adoption of either 40- or 50-deg. rating for motors; 40-deg. motors are decidedly to be preferred in woodworking plants

3 A definite choice of certain higher frequencies. The adoption of 60, 80 and 100 cycles is suggested

4 An attempt at standard design for motor mounting, arbor bearings, and motor-control apparatus.

The reason for such standardization is to simplify the amount of apparatus with which the woodworking-machine operators must be familiar. Simplicity and standardization will be greatly appreciated by the users and will contribute greatly to the development of this type of machinery.

Pulverized-Coal-Burning Central Station, Bruay Mines, France

By JACQUES BOYER

DESCRIPTION of an installation said to be one of the largest pulverized-coal-burning plants in Europe and which embodies several improvements as compared with general European practice.

Fig. 1 shows the pulverizing plant with a capacity of 180 tons of coal per day of 16 hr. It comprises two concrete coal bins located under a standard-gage track and intended to receive from the cars the coal as it comes from the mines. Two belt conveyors with a capacity of 25 tons per hour deliver the coal from these bins to two elevators which lift it to another bin over the grate of a rotating drying furnace. (This drying furnace is shown in the original article by a halftone not suitable for reproduction.) After drying, the coal passes through a magnetic separator which removes any particles of iron it may contain, and then is carried by two elevators to a screw conveyor (Fig. 2) which distributes it among three hoppers. From these it flows by gravity into three Simon-Carves ball crushers. The pulverized coal is then lifted by air suction and delivered by a blower into two storage bins, whence it can be fed by gravity as desired on to weighing platforms so as to check the amount employed each day by each furnace. From the weighing platform the coal is delivered to the proper furnaces by piping with an inside diameter of 100 mm. (3.9 in.).

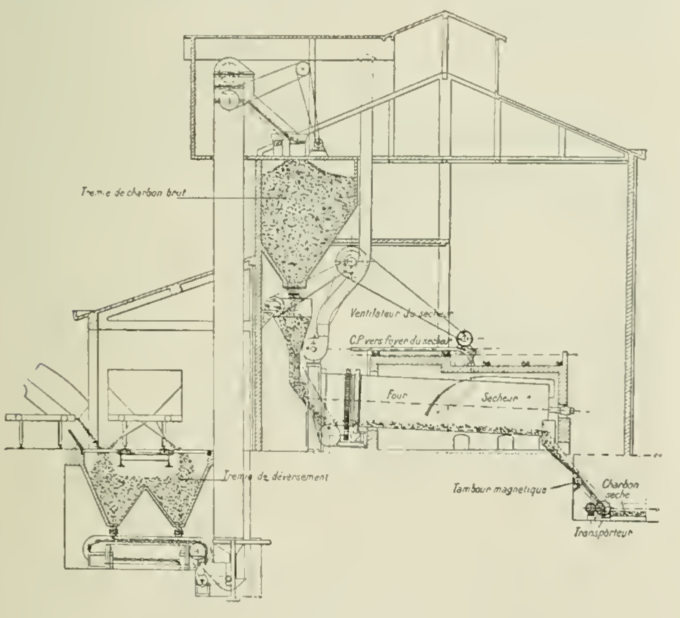

Fig. 1 Diagrammatic View of the Pulverizing Plant at the Bruay Central Station

(*Trémie de charbon brut* = raw-coal bin; *trémie de déversement* = discharge bin; *ventilateur du sécheur* = drier blower; *C.P. vers foyer du sécheur* = conveyor belt delivering pulverized coal to the drier furnace; *four sécheur* = drier furnace; *tambour magnétique* = magnetic separator; *charbon séché transporteur* = dry-coal conveyor.)

As has been shown by Michel Sohm, chief engineer of the surface plant of the Bruay mines, the condition of the pulverized coal has an important bearing on its combustion. In order to carry the degree of fineness to which the coal is broken up as far as possible the crusher is equipped with a horizontal shaft provided with four sets of articulated handlike members working as hammers. This machine pulverizes coal in sizes 0.10 to 0.15 mm. (0.0039 to 0.0059 in.) both by friction and by percussion.

Furthermore, the dimensions of the combustion chamber of the furnace must be properly proportioned for a given fineness of coal. As a matter of fact it is easy to see that coarsely granulated coal will require a greater excess of air than an impalpable coal powder. Likewise, the length of time that the powder has to remain in the furnace in order to achieve complete combustion also depends on the size of its grains. Thus slaty coals, which are the hardest to pulverize, come out from the machine with a coarser grain and their velocity of ignition is clearly inferior to that of pure coal; they ignite at a greater distance from the tip of the burner, soften, and

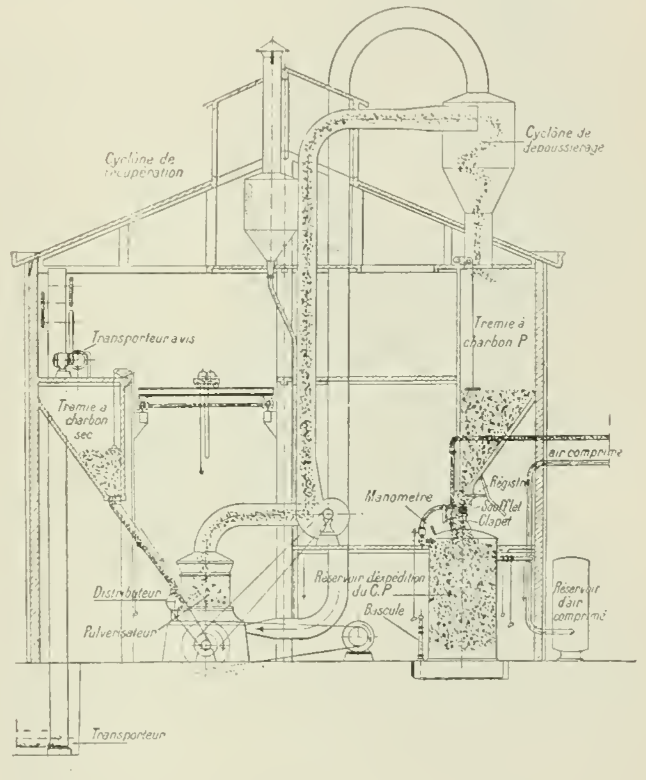

Fig. 2 Diagrammatic View of the Plant for the Storage and Delivery of Pulverized Coal to the Furnaces

(*Cylone de récupération* = recuperator blower; *cylone de depoussiérage* = dust-elimination blower; *transporteur a vis* = screw conveyor; *tremie à charbon sec.* = dry-coal bin; *tremie a charbon P.* = pulverized-coal bin; *air comprimé* = compressed air; *régistre* = damper; *soufflet* = bellows; *clapet* = valve; *réservoir d'air comprimé* = compressed-air reservoir; *réservoir d'expédition du C.P.* = delivery bin of pulverized coal; *bascule* = weighing bridge; *distributeur* = distributor; *pulvérisarteur* = pulverizer; *transporteur* = conveyor; *manométre* = manometer.)

clinker whenever the grains come in contact with each other, and in order to insure their complete combustion it becomes necessary to provide longer paths for their travel.

The above considerations explain why it is that as the hammers of the crushers wear away, the walls of the combustion chamber, the bottom parts of the lower passages, and the orifice of the injector become covered with slag. The reason is that unless the crusher hammers are renewed from time to time, the degree of fineness, which was fully efficient initially, ceases to be capable of providing for complete combustion. Moreover, variations in the degree of humidity have a notable influence on the output of the pulverizing equipment and on the regularity of flow of the pulverized coal either at its exit from the storage bin or through the distributor passages or burners. Hence the necessity of preliminary drying, which makes it possible to use all kinds of coal.

At the Bruay central station (Fig. 3) only dry coal ground to an impalpable powder is used. This coal is delivered by distributor fans into bins located in front of the furnaces. At the bottoms of these bins there are two controllers per boiler which distribute the fuel to the furnaces, while a low-pressure blower supplies each furnace with the air necessary for combustion. The air is mixed with the coal just before they enter the furnace. Various precautions have been taken to prevent the penetration of the pulverized coal into the crusher or engine rooms. It is said that these precautions have been of such a nature that the total loss in weight of coal from the time it is discharged from the cars to the time it is delivered to the furnace is less than 0.6 per cent. The controller distributors of the pulverized coal are equipped with a simple regulating device involving the use of a flywheel driven by a variable-speed motor, and this insures a regular supply of fuel to the furnaces.

As shown in Fig. 3, each furnace consists of a combustion chamber,

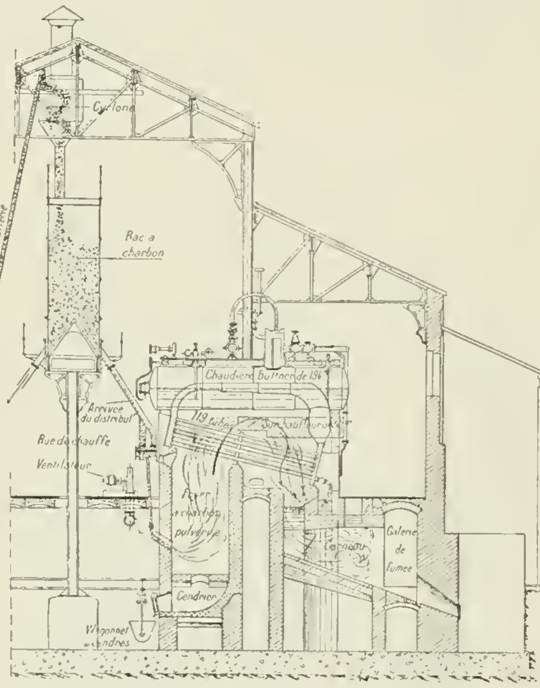

Fig. 3 Diagrammatic View of the Buttner Boiler Equipped for Burning Pulverized Coal

(*Cyclone* = fan; *transport de C.P. vers chaufferie* = conveyor delivering pulverized coal to furnace; *bac à charbon* = coal bin; *ventilateur* = blower; *arrivée du distribut* = distributor delivery line; *chaudière Buttner de 194m²* = Buttner boiler with 194 sq.m. heating surface; *surchauffeur de 50m²* = superheater with 50 sq.m. heating surface; *carneau* = flue; *foyer a charbon pulvérisé* = pulverized-coal furnace; *cendrier* = ashpit; *wagonnet a cendres* = ash car.)

separated by an arch from the slag pit, which latter is provided with a door that closes automatically. This arrangement facilitates the flow of the powdery or molten slags and also makes it possible for them to be raked into the monorail ash car shown in the drawing. The boilers with which the plant is equipped are of the Buttner make, each with 194 sq.m. (2087 sq.ft.) of heating surface, 119 tubes and a superheater of 50 sq.m. (538 sq.ft.) which give an evaporation of 3600 kg. (7935 lb.) per hour at a temperature of 275 to 300 deg. cent. (527 to 572 deg. fahr.).

The damper arrangement is such that the gases are forced to flow parallel to the walls—in other words, to pass over the entire width of the set of tubes. With the aid of a lever controlled from the front of the boiler the fireman can operate this damper which is made as a balanced butterfly valve. He can also communicate at any time by electrical means with the pulverizing plant, this arrangement being described in detail in the original article. One of the safety measures provided is a special device in front of the boiler which simultaneously and automatically stops both the pulverized-coal delivery and the fan blast, so as to extinguish the fire instantly when necessary under any of the furnaces. The purpose of this device is to prevent damage due to excessive pressure. The apparatus is electrical and consists of a current interrupter controlling both the pulverized coal delivery and the combustion air fans. (*La Nature*, no. 2543, Dec. 30, 1922, pp. 422–426, 6 figs., *dA*)

Short Abstracts of the Month

AERONAUTICS

Loening Flying Control. Description of a type of transverse airplane control which has recently been tested in flight. This control, called a lateral pressure equalizer, is mounted on the extreme tip of each wing.

A small section of the leading edge of the wing is extended out beyond the tip, to which is hinged a pressure-equalizer flap which is controlled through cables and levers by the pilot. It is claimed that with the new device the use of the trailing-edge aileron may be eliminated entirely.

Notwithstanding the fact that the pressure equalizer was tested under bad winter conditions, the ship was found responsive in overcoming wind puffs. (*Aviation*, vol. 14, no. 1, Jan. 1, 1923, p. 13, 1 fig., *d*)

AIR MACHINERY

Determination of Initial Pressure of Centrifugal Ventilators

Tests of Centrifugal Ventilators with Special Reference to Initial Water Gage, Henry C. Harris. It is claimed that very little progress has been made toward the discovery of the most suitable means of determining the initial water gage produced by the running of a ventilator. As a basis for calculation and experiment, the author took the practical example of a fan of large capacity installed to ventilate a mine of small capacity, namely, a Capell fan of the double-drum type 20 ft. in diameter and 6 ft. wide, with a single inlet 11 ft. in diameter and running at 90 r.p.m. The area of the shaft was 70 sq. ft., the area of the fan drift 72 sq. ft., and the area of fan inlet 95 sq. ft. Another series of tests were carried out on a Sirocco fan.

These tests, the results of which are given in the original paper

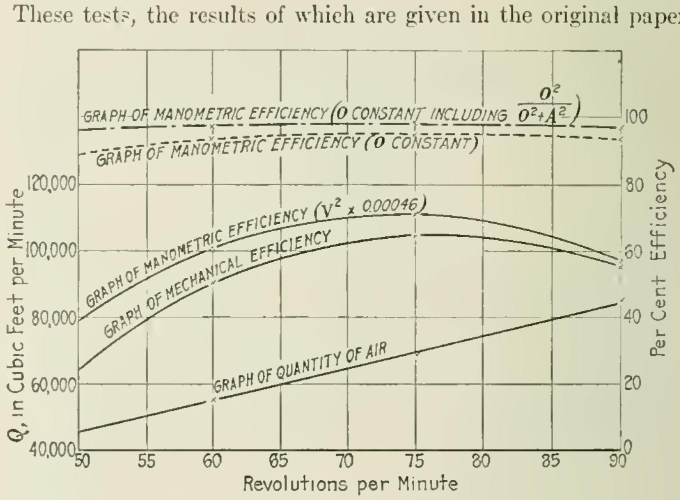

Fig. 1 Graphs of Results of Capell Fan Test

(Full lines for graph of manometric efficiency derived by conventional method; broken lines for those derived by the author's method.)

in the form of tables and curves, of which Fig. 1, for the Capell fan test, is reproduced, have led the writer to ask himself the following questions: (*a*) Why is the manometric efficiency of the ventilator so variable and so low? (*b*) Why does the fan give maximum results at 75 r.p.m. instead of at 90 revolutions as intended, etc.?

In trying to answer these questions the author found that a more consistent method than the conventional one of determining the initial water gage is necessary before any results of tests can be considered reliable, this being due to the fact that in most cases the velocity of the air on leaving the fan chamber which is used in determining the initial water gage, is not identical with the speed of the tips of the fan blades. The author therefore suggests a different method for determining the water gage, and by means of this method he derives the graph shown in Fig. 1 which appears to give results of a more uniform order. It is also claimed that on the basis of the manometric efficiency derived by this method the

maximum results at 70 revolutions instead of at 90 revolutions are consistent for a fan of large capacity ventilating a mine of small capacity. (Paper read December 9, 1922 before the Mining Institute of Scotland, abstracted through *The Iron and Coal Trades Review*, vol. 105, no. 2859, Dec. 15, 1922, pp. 884–885, 2 figs., *ep*)

ENGINEERING MATERIALS

Research Work on Aluminum, Iron, and Electron. Dr. of Engrg. Hanszel. Before the war aluminum alloys usually had a comparatively high tin content, namely, 6 per cent, and, in addition, 2 per cent of copper. Since these metals were scarce during the war, it became necessary to substitute other materials for them, zinc at first being preferred. It was, however, desired that the substitution of the alloying elements should not interfere with the machinability of the alloy and its compressibility. An alloy was therefore produced having an even higher tensile value than the previous standard alloys. It contained 7 per cent zinc, 0.8 per cent magnesium, and the remainder aluminum. Other similar alloys contained 10 per cent zinc and 0.7 to 1 per cent magnesium. These alloys when tested gave rupture strengths as high as 27,000 to 29,000 lb. per sq. in. For one of them (10 per cent zinc and 1 per cent magnesium) it is stated that the elongation was zero. The machinability of the alloys was poor. It was found, however, that the addition of 1 to $1^1/_2$ per cent of tin made them freely machinable. Pressed aluminum rods gave a metal of higher strength, though its machinability appears to have been poor.

The original article gives, among other things, curves showing the influence of adding manganese to aluminum as affecting the strength, elongation, and hardness of pressed round bars. (First of a series in *Canadian Foundryman*, vol. 14, no. 1, Jan., 1923, pp. 26–27, 1 fig., *g*)

Duralumin

An Investigation of Duralumin, Seibei Konno. Data of an investigation carried out at the Tohoku Imperial University, Sendai, Japan. The following conclusions have been reached:

1 In quenched duralumin, the softer the quenching the more the immediate effect of hardening increases, and its aging affect, as well as its final hardness, decreases. In a quenching in oil at 100 deg. or at higher temperatures the aging effect vanishes. On the other hand, the harder the quenching the more the immediate effect decreases, and the aging effect and the final hardness increase, their maximum values being obtained by quenching the alloy from 500 deg. in water.

2 The above effect of quenching is due to the dissolution of Cu and Mg compounds in Al, the process of dissolution or separation being very slow. Thus duralumin is in a somewhat hardened state, even if it is cooled very slowly from 500 deg.; perfect annealing is only obtained by heating the alloy at 350 deg. for one hour or more.

3 The quenching effects on the specific electric resistance of duralumin are very great and exactly similar to those on the hardness. Hence the specific resistance measurement is the most suitable method for the investigation of the hardening of duralumin.

4 The alloys of Al-Cu show by quenching an immediate effect of hardening, but the effect of aging only very slightly. Hence, the immediate effect is partly due to the dissolution of Al_2Cu in aluminum, but the principal cause of the aging effect of duralumin is not attributable to that compound.

5 In the alloys of Al-Mg which contain about one per cent of magnesium, the immediate effect of quenching is always very small, but the aging effect is as great as that of duralumin.

6 The aging effect, as well as the immediate effect of quenching the above alloys, is attributable to the dissolution of Mg_2Si in Al, but not of metallic magnesium; because, if magnesium increases beyond 1 per cent, the above two effects begin to diminish, and with an increase of above 3 per cent of magnesium, almost vanish; but an addition of both magnesium and silicon in the proportion of the compound Mg_2Si increases the same effects. A small quantity of silicon is always present in aluminum as an impurity.

7 The further addition of about 4 per cent of copper and a small quantity of manganese (up to about 0.5 per cent) to the alloys of Al-Mg increases the hardness, but not the aging effect. This alloy, usually called duralumin, has thus nearly the same aging effect as the alloys of Al-Mg.

8 From the specific resistance-temperature curves for quenched duralumin, we conclude that a quenched alloy is tempered at two steps, beginning at 210 deg. and 280 deg., respectively. The first step in the curves is due to the partial separation of Al_2Cu, and the second to that of Mg_2Si.

9 The quenched duralumin expands at room temperature as the aging proceeds, as in quenched low-carbon steels.

10 The above effect of quenching and the accompanying change in the physical properties of duralumin are exactly similar to those in severely quenched carbon steels. Hence we can easily explain the hardening of duralumin by Prof. K. Honda's theory of the hardening of steels.

The paper is accompanied by numerous curves and photomicrographs. (*Science Reports of the Tohoku Imperial University*, First Series, vol. 11, no. 4, Sept., 1922, pp. 269–294, 6 figs., 9 plates, *eA*)

FUELS AND FIRING (See Motor-Car Engineering)

HYDRAULIC MACHINERY

Chain-Type Water Elevators—Tests

Tests of Caruelle Water Elevators. These water elevators, also called "Chaine-Helice," have been described in *Engineering*, vol. 98, 1914, p. 40, and are used mainly for raising water from open wells to the ground level.

The device consists of belts made up of strips of sheet aluminum alloy bent so as to form a series of triangular cells, the cells being riveted to a flexible supporting element, which, in the case of the smaller sizes, is a band of aluminum bronze. In the larger sizes balata belting is used to support the aluminum cells, a number of which are placed side by side. Large driving and jockey pulleys are used with these belts in order to reduce the bending to a minimum and grooves are turned in both pulleys to clear the rivet heads so that the latter are not worn away. A feature of this device which is particularly useful in the case of hand-driven installations is that they remain filled with water when stationary and if a ratchet is provided to prevent the belt from running back, due to the weight of the entrained water, delivery will commence as soon as the belt is set in motion. This is important with deep wells pumped intermittently at frequent intervals.

The tests were carried out by Sir Alfred Chatterton of the Indian Public Works Department and Arthur S. Collins, City Engineer of Norwich. In these tests two belts were used, the lifting elements of one measuring $^7/_8$ in. wide and $^5/_8$ in. deep, and those of the second $1^5/_{16}$ in. wide and 1 in. deep. The aluminum-bronze bands to which the elements were riveted were 1 in. and $1^3/_8$ in. wide, respectively, and in both cases the pitch of the triangular cells was $^1/_2$ in. The drive was by means of a leather belt from an electric motor, so arranged that the torque exerted could be measured. The lift in all cases was 152 ft. 6 in.

The results are given in diagrams in the original article. With the smaller belt a maximum net efficiency of 95 per cent was obtained with a linear speed of about 7 ft. per sec., but the efficiency fell off rather rapidly as the speed increased. In the case of the larger belt the maximum efficiency reached was practically the same, but was maintained over a wider range of speeds, only falling to 85 per cent at 13.4 ft. per sec. The maximum overall efficiency with the larger band was much higher than that obtained with the smaller band, the former reaching over 74 per cent and the latter about 58 per cent. Owing to the short distance between the centers of the driving and driven pulleys, rendered unavoidable by the existence of buildings close to the wall, a very tight belt had to be employed. This absorbed an undue amount of power and materially reduced the overall efficiency in both cases.

The tests have also shown that the larger belt gives a much wider range of deliveries with good efficiency, the maximum efficiency being reached at about 950 gal. per hr.

Another series of tests was made by the same authorities with the water-elevating belt made up of four sets of cells of the larger size of the two above described, riveted on to a balata belt. Here it was found that to obtain the highest efficiency with water elevators of this type, it is important that the immersion of the jockey pulley should be only sufficient to allow the belt to fill completely, a condition which would not always be complied with in practice.

It is claimed, however, that the advantages of simplicity, reliability, and general good efficiency are more than sufficient to compensate for this drawback. (*Engineering*, vol. 114, no. 2973, Dec. 22, 1922, pp. 770–771, 5 figs., *e*)

INTERNAL-COMBUSTION ENGINEERING (See also Motor-Car Engineering)

Ripert Motor with Steam Chamber in Head

The Ripert Motor, M. Grison. It is claimed that the following conditions, if satisfied, would improve the Diesel engine when operating on heavy oils and, in particular, would make it more flexible.

First, introduction of the oil into pure air not only at the dead center but ahead of it, namely, toward the end of the compression, in order to obtain a vaporization and diffusion of the oil through

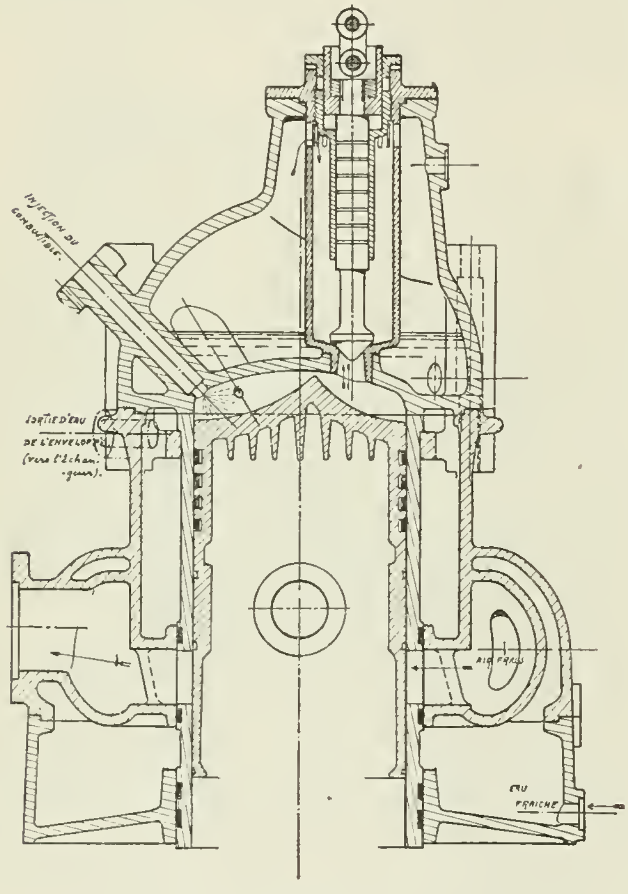

Fig. 2 Ripert Oil Engine

(*Injection du combustible* = fuel injection; *sortie d'eau de l'enveloppe* = exit of water from jacket; *air frais* = fresh air; *eau fraiche* = fresh water.)

the air during the heating of the latter. The fuel being introduced during compression, the atomizer meets with only a relatively low pressure in the cylinder. It therefore works more efficiently. The fuel injection takes place without air injection, which eliminates the unfavorable refrigerating action of the latter. This of course makes the high-pressure compressor together with its appurtenances unnecessary.

The second condition is that the compression should continue up to the dead center, and hence a temperature should be attained close to that necessary for spontaneous ignition. As the fuel has already been distributed through the entire mass of the air and heated with it at the same time, the ignition can take place at the dead center throughout the whole charge simultaneously and have all the characteristics of an explosion.

During combustion a certain amount of water vapor should be introduced into the cylinder both because of its influence on the gas and on account of the well-known catalytic effect which assists the combustion of the heavier particles of tar oils. The steam helps to prevent the formation of coke deposits and improves the lubrication of the cylinder and hence the mechanical efficiency. With accelerated combustion and assured cooling it would not be necessary any longer to induct into the cylinder as great an excess of air as in the Diesel engine (thirty times the weight of the oil), which would increase the volumetric efficiency. Finally, the possible increase in the revolutions would tend to reduce the weight and first cost of the machine.

It is said that the Ripert motor (Fig. 2) was designed with the view of realizing as completely as possible the foregoing theoretical considerations. The drawing shows a two-stroke-cycle motor. The construction differs from that of the Diesel engine solely in the cylinder-head arrangement, which, in the Ripert motor, forms a kind of boiler. It is supplied with water in such a manner as to maintain automatically its internal temperature at about 250 deg. cent. (482 deg. fahr.) and the steam pressure at 30 kg. (428 lb. per sq. in.) approximately, although in both cases higher values may be employed.

Water feeding is effected by means of a small pump whose output is automatically controlled by a thermostat. This pump is independent of the speed of the motor. The water may be taken from the cylinder jacket and preheated by exhaust gases before being fed into the cylinder head, where it is superheated to the necessary extent. This plan is used, however, only with large motors. There is no trouble in maintaining a certain level of water in the cylinder head. The boiler in the head communicates with the combustion chamber in the cylinder by means of a valve.

The Ripert motor may operate with or without steam admission. If it is operated without steam admission when the piston is at its lower dead center, air is supplied to the cylinder either by crankcase compression or by a special pump. About the middle of the compression stroke or somewhat later heavy oil is introduced by solid injection. The temperature is then sufficient to vaporize the atomized oil and prevent its precipitation. The piston then proceeds to complete its upward stroke. At the same time the compression is regulated in such a manner as to develop the highest possible temperature, which would not, however, reach that of auto-ignition.

A few degrees before the dead center is reached, the valve communicating with the cylinder head is opened and the clearance space placed in communication with the head into which compressed air has been forced before starting the motor. This is done only once in the course of operating an engine. The compressed air at a pressure of about 30 kg. (428 lb. per sq. in.) penetrates with its excessive pressure into the clearance space and suddenly forces the mixture back toward one of the sides of the deflector of the piston, producing a strong mixing effect, this being assisted also by the shape of the top of the piston and the compression chamber. Ignition then takes place spontaneously on account of excessive pressure. The explosion forces back into the head the air which came out of it along with some of the gaseous products of combustion. When at the beginning of the expansion stroke the pressure in the head has become equal to what it was at the beginning of the cycle the communicating valve is closed, the expansion in the cylinder itself continuing. With this arrangement it is not necessary to renew the compressed-air charge in the cylinder head as it renews itself automatically, though after some time the air is replaced by gases of combustion.

It is important to note that this cycle is not really the one on which the Ripert motor works, although it is not impossible. The true cycle of the Ripert motor is one in which steam is introduced into the cylinder. This steam, at a pressure of 30 kg. (428 lb. per sq. in.) or more, is contained in the cylinder head and suddenly forces back the cylinder mixture.

The position of the valve with respect to the deflector at the top of the piston is such that during the mixing period a relative stratification of the two fluids, steam and gas, is maintained. At the end of the period of steam injection one part of the chamber is still filled with steam, while in the other the gases (air and oil vapor) are collected.

The ignition occurs throughout the entire mixture at exactly the predetermined moment, either spontaneously as a result of excessive compression, or in the case of semi-Diesel engines, by sudden forcing of the mixture into a preheated chamber or electrical ignition tube. The combustion takes place throughout the entire charge in the form of an explosion. During this explosion while the pressure in the cylinder becomes greater than the pressure

of the steam introduced into it, the steam flows back into the cylinder-head chamber through the valve as long as it remains open. Eventually a certain amount of gas penetrates into the cylinder head chamber in accordance with the point to which it is desired to limit the maximum pressure of the explosion. In multi-cylinder engines the cylinder heads communicate and form a single boiler which insures the uniformity of pressures resulting from the explosions in each cylinder, notwithstanding the unavoidable variations in fuel feeding.

As soon as the downward movement of the piston reduces the internal pressure the gases from the cylinder-head chamber flow back into the cylinder, passing through the valve which is still open in the opposite direction and along with these gases a certain amount of steam enters the cylinder and stays there. When the pressure falls sufficiently low the valve closes. The expansion and exhaust portions of the cycle do not differ from those in conventional engines. The theoretical calculation of the original cycle is given in the original article.

No data of tests are adduced. Some diagrams are given containing "practical" figures, but it is not stated how they are obtained. (*Bulletin Technique du Bureau Veritas*, vol. 4, no. 10, Oct., 1922, pp. 245–247, 2 figs., *gt*)

High-Compression Gasoline Engines

Internal-Combustion-Engine Characteristics Under High Compression, J. H. Holloway, H. A. Huebotter and G. A. Young, Mem. Am.Soc.M.E. This paper is a report of a series of tests conducted during the summer of 1922 by the authors at the Engineering Experiment Station of Purdue University. The work consisted of research into the operation of internal-combustion engines under comparatively high compression on ordinary gasoline without detonation. The compression ratio of the engine was 6.75 and the compression pressure 122 lb. per sq. in. gage. The ingoing charge was passed through a hot-spot vaporizer and thence through a cooler between the carburetor and the valves. Jacket-water temperatures between 150 and 170 deg. fahr. were carried at the outlet port of the jacket.

The theory held by the authors as to the causes of detonation of combustible charge is presented briefly. The source of the two phases of detonation encountered in this work is believed to be overheated areas in the combustion chamber. The methods of combating these hot spots are given in detail, and the special equipment applied to the engine to accomplish the desired result is described. The effects of load, speed, compression ratio and mixture ratio are studied, and curves showing the variation in the engine characteristics due to each factor are submitted. All tests were run without a trace of detonation.

From these tests, which are represented as covering only a narrow range in the field of gasoline-engine operation, the following conclusions are drawn:

1 Under laboratory conditions a compression pressure of 120 lb. per sq. in. gage is perfectly feasible when the engine is designed with a full regard for the elimination of the factors that induce detonation.

2 Under service conditions the same attention to these factors will permit the use of much higher pressures than those common at present.

3 An increase in the compression ratio results in a marked improvement in the thermal efficiency and the general performance of the engine at all loads and in the maximum power at all speeds.

4 The sources of detonation are the spark plug, the exhaust valve, the piston head, and any other portions of the combustion-chamber walls that become overheated.

5 The maximum economy is obtained with the leanest fuel-air mixture giving reliable combustion. Such a mixture varies from 0.060 lb. of fuel per lb. of dry air at 25 per cent load, to 0.057 lb. at 75 per cent load; or, from 16.6 to 17.5 lb. of dry air per lb. of fuel. Hence, for this range of load the leanest possible mixture is desirable, provided good vaporization is secured. At a full throttle opening the maximum power is usually sought at the expanse of economy. An 0.075 mixture, or 13.3 lb. of air per lb. of fuel, is rich enough to insure the greatest output.

6 The water-jacket heat loss reaches its maximum value at approximately the mixture giving the highest power with a fixed throttle opening, or a 0.075 ratio.

7 Exhaust temperature is highest with a 0.065 ratio.

8 The power of an engine can be increased 25 per cent by a change in the compression ratio from 4.45 to 6.75, provided detonation is absent.

9 With the same change in the compression ratio the thermal efficiency is raised 7 to 12 per cent through a load range of 25 to100 per cent of the engine power.

10 At full load a mixture temperature of 125 deg. fahr. at the hot spot is high enough to give good distribution in a four-cylinder engine with a properly designed hot spot. If the mixture is cooled below this temperature between the hot spot and the valves, the performance of the engine is improved. A low limit of 100 deg. fahr. at the valves can be allowed safely.

11 At partial throttle opening, a hot-spot temperature of 175 deg. fahr. is not excessive and assists in the use of very lean mixtures for high economy. (*Journal of the Society of Automotive Engineers*, vol. 12, no. 1, Jan., 1923, pp. 111–117, 11 figs., *e*)

Hammer-Spray Injection System. Details of a device for enabling gasoline engines to use kerosene and light fuel oils such as oil of about 34 and 36 deg. B. (Development of the Hasbrouck patents.)

The system consists of a spray of fuel injected into the combustion chamber of each cylinder of the engine by a pump by means of a sudden blow of a hammer on the plunger of the pump. The fuel is injected into the cylinder through a spray nozzle to which flexible tubing is led from a pump; the plunger of this pump is actuated at the proper moment for injection of fuel by a hammer operated by a spring under moderate tension and by a trip cam mounted on a shaft driven by means of a belt, chain or the like.

It is said that when the plunger of the pump is driven down by the blow of the hammer the correct amount of fuel is forced through the tubing past a ball check and injected in a very finely pulverized spray between the seat of the valve and the spherical surface of the valve head against the tension of the spring. One pump plunger and one spray nozzle are required for each cylinder.

Tests of this device have been made by Prof. E. H. Lockwood, Mem. A.S.M.E., of Mason Laboratory of Sheffield Scientific School, Yale University, and two installations have been in service on boats at New Haven for many months. Of the tests made, one was in connection with a single-cylinder four-cycle stationary engine of $4^5/_8$ in. bore and 5 in. stroke, which operated on 36-deg. B. oil and with 25 lb. cylinder compression, starting cold with relieved compression on the second turn of the flywheel after standing idle for over six months. This engine also operated on alcohol and kerosene with this device installed. A single-cylinder two-cycle marine engine of similar bore and stroke was tested by Professor Lockwood, and is now driving a 23-ft. by 9 ft. 6-in. converted catboat about $5^1/_2$ m.p.h. This engine starts cold directly on kerosene or fuel oil on 35 lb. compression, and the consumption is moderate, one gallon sufficing for two hours and twenty minutes' running. (*Motorship*, vol. 8, no. 2, Feb., 1923, p. 118, 3 figs., *d*)

MACHINE PARTS AND DESIGN

Belt Transmission, D. Genkin. An extensive, largely mathematical analysis of belt transmission. As a rule, in computing the efficiency of belt transmissions only losses on pulleys are considered. In the present instance the author, after reviewing the known formulas, endeavors to determine the magnitude of all the other losses. Among other things, he calls attention to the undesirability of using belts in power transmission from an electric motor.

The conclusions at which he arrives are that no matter how carefully belt transmission may be designed and worked out, the power losses inherent in this type of transmission can rarely be brought below the five per cent level. As regards less carefully designed belt transmissions, the losses involved therein may not only be in excess of all reasonable limits but may cause a rapid wear of the bearings and frequent stoppages of work due to the wear on the belt itself.

The article itself, after a brief introduction, proceeds to a mathematical study of the operation of a belt transmission, which, among other things, investigates the relation between the initial tensions on the tight and loose sides of the belt, the variation of tension

along the portion of the belt in contact with the rim of the pulley, the effect of elongation of the belt in running, and the calculation of the suction of the belt.

The selection of the best tension in the belt is discussed, after which an extensive abstract is quoted from Taylor's work on Shop Management.

The losses due to periodic elongation and contraction of the belt are mathematically discussed, likewise the losses due to the resistance of the belt bending around the pulley. (*Revue Générale de L'Electricite*, vol. 12, no. 25, Dec. 23, 1922, pp. 975–988, 5 figs., *mtA*)

MACHINE TOOLS

Pull or Push Cutting Strokes, F. H. B. One of the problems in the use of certain types of machine tools is whether the cut shall be taken on the pulling or the pushing stroke. This consideration applies to such machines as possess holders or rams carrying the tool out from the end. In such a category come shapers, broaching, keyway-cutting and filing machines, hacksaws and some of the gear shapers. The primal difference in cutting on the pull or the push stroke is that of change from tension to compression, a change which may affect all the elements: the tool, the ram, its slides and the means of propulsion. In discussing the advantages or disadvantages of either method the author cites the ordinary pillar shaper where the presumed advantage of the pulling stroke, namely, consolidating the slides of the table and saddle by the cutting pressure, is discounted by the fact that substantial table supports are now employed in most of the ordinary shapers to withstand the downward and outward thrusts.

The author discusses in detail keyseating machines, broaches, hacksaws and gear shapers. In keyseaters a draw cut may be usefully employed if long hubs require it for keyways cut in their bores.

In case of gear shapers both the push stroke and the draw stroke may be used, the latter being employed in the Fellows shaper which possesses a vertical ram. There are, however, shapes that cannot be cut on the pulling stroke, for example, gear clusters, where owing to the contiguity of another tooth ring, the cutter cannot start up from below. However, the design of the spindle end of the Fellows machine permits of fixing on the cutters for either the push or the pull stroke without trouble. (*Mechanical World*, vol. 73, no. 1879, Jan. 5, 1923, pp. 2–3, 3 figs., *p*)

MARINE ENGINEERING (See Special Processes)

MEASUREMENTS

Passing of the Quarter. On January 1, 1923, by an amendment to the Corn Sales Act the hundredweight has become the sole legal standard for sales of dry products in Great Britain and Ulster, thus eliminating the quarter as the legal measure.

The bushel or small box was the ancient unit of Saxon dry measure. The quarter was eight bushels and the system was to buy by measure, quality being roughly appraised by weight. For more than a century, however, there has been a tendency on the part of buyers to insist on sales by uniform weight, in addition to which the measure "quarter" was uniform throughout the country. (*The Times Trade and Engineering Supplement*, vol. 11, no. 237, Jan. 20, 1923, p. 429, *g*)

METALLURGY (See Engineering Materials)

MOTOR-CAR ENGINEERING

Alcohol as Fuel. One of the main difficulties in the use of alcohol in engines is that of starting. This has, however, been solved by the so-called bi-fuel scheme in which starting is done on gasoline and running on alcohol.

In this connection, the original article describes the gasoline-alcohol Claudel-Hobson carburetor and the so-called Hobson non-pinker, a device to prevent "pinking" (detonation knock) in high-compression engines, of importance because with alcohol the higher compression is needed than with gasoline.

The device consists of a diaphragm-control needle valve in a small auxiliary carburetor so connected to the main carburetor that at periods when the depression in the main carburetor is low the device comes into operation and allows alcohol to feed to the cylinders. The depression is low when the throttle is open and high when it is closed. Therefore the alcohol is fed to the cylinders and cut off again exactly at the required moment. (*The Autocar*, vol. 49, no. 1419, Dec. 29, 1922, pp. 1310–1311, 2 figs., *dg*)

A Six-Wheel Motor Omnibus

Six-Wheel Motor Omnibus in Paris. Description of a new type of motor omnibus being placed in operation in Paris. One of the obstacles in the way of more efficient utilization of motor omnibuses is their limited seating capacity. Thus, while the ordinary trolley car can carry up to 100 passengers and more in rush hours, a motor omnibus in Paris has only 38 seats. To increase the seating capacity, seats would have to be provided on top, an arrangement which has not proved popular in Paris although extentensively used elsewhere, as, for example, in England. One way to meet this situation was to increase the overall wheelbase by

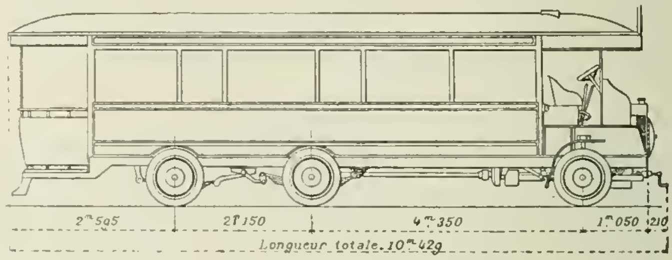

Fig 3 Six-Wheel Motor Omnibus in Paris
(*Longueur totale* = total length.

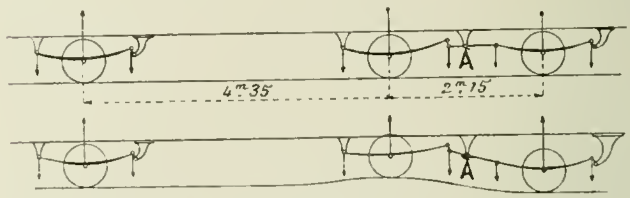

Fig. 4 Balanced Suspension Arrangement of the Paris Six-Wheel Motor Bus

providing an intermediary axle, which meant a six-wheel arrangement and raising the seating capacity to 48 seats. Fifty such buses are already under construction.

The new bus has a total length of 10.43 m. (34.4 ft.) and a width of 2.25 m. (7.25 ft.). The axles are spaced unequally, the front axle being 4.35 m. (14.4 ft.) and the rear axle 2.15 m. (6.90 ft.) from the middle axle, the total wheel base being therefore 6.50 m. (21.30 ft.). The steering is on the front and rear axles only. All the wheels have the same diameter 0.95 m. (37.4 in.). The front and rear set are equipped with single solid tires, the middle wheels with double tires of the same section.

The chassis is equipped with a special device for maintaining constant the distribution of load on the wheels. In a vehicle carried on two axles this distribution does not change materially notwithstanding variations in level of the road, but this would not be the case in a vehicle carried on six wheels, unless special means were taken to accomplish it (in this case a balancing gear joining the extreme tips of the rear and middle springs). This balancer *A* (Fig. 4) oscillates about a shaft carried in a support rigidly held on the chassis. This being so, the system of forces acting on the chassis is of a statically determinate nature and the reactions on the wheels are independent of the relative position of the latter. The loads on the steerable wheels may be equalized by suitably locating the middle axle, which is also very useful from the point of view of stabilization of direction. Another advantage of a balanced suspension is that it decreases the vertical movements of the carriage, which reduces the jarring and the wear both on the omnibus and the road.

The vehicle is provided with a mechanism brake, a wheel brake and an auxiliary braking device acting on the middle wheels and operable from the rear platform.

The omnibus (Fig. 3) has an interesting steering system which cannot be described here on account of lack of space. It is pointed out in this article, however, that a six-wheel car has less tendency to skidding than one running on four wheels. (*Le Génie Civil*, vol. 81, no. 27, Dec. 30, 1922, pp. 605–607, 11 figs., *d*)

Aster Engine Valve Gear

The "Eighteen Six" Aster. Description of the Aster automobile, built by a British company which for 22 years has manufactured engines for automobiles.

One of the interesting features of this engine is its valve-operating gear (Fig. 5). The valves are directly overhead and in line. They are operated by rocker levers, the ends of which are pushed up by push rods from the tappet gear above the camshaft. The latter is silent-chain driven and is located in the crankcase. The two features of this gear are the absence of working bearings in the rockers and the provision of silent oil cushioning to the tappets and push-rod gears.

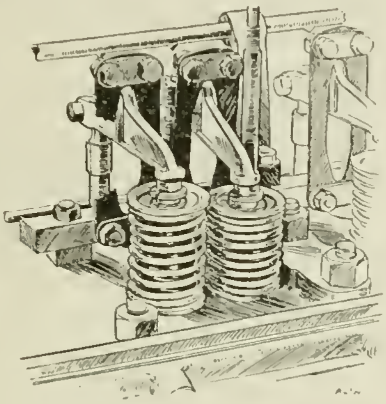

Fig. 5 Valve-Operating Gear of the Aster Engine

The rockers instead of being pivotally mounted on trunnion bearings as is the conventional practice, are rigidly bolted to upstanding steel spring pillars which curve to allow the outer ends of the levers to depress the valves. The push rods are provided with ground spherical seatings, carefully constructed so that there will always be a film of oil between the opposed surfaces. This is said to insure silence. The measure of the accuracy of the fit here is important, and the spherical surfaces are very carefully machined and ground in order that an oil film shall always be present between them.

The fan is provided with a telescopic adjustment for height in order to allow of the adjustment of the belt. The adjustment is fixed by a small hand lever and can be made without the use of tools.

One of the minor features is that the water outlet pipe from the cylinder head to the top of the radiator is stayed by a couple of stay rods at the side, which have the effect of staying the radiator to the engine. Another point about the engine design is the use of a small air pump driven by a cam on the camshaft and providing air pressure for the rear-tank fuel supply to the carburetor. This pump is fitted with a release valve which is in an accessible position, is easily adjustable from the outside, and may be readily dismantled should occasion arise for any adjustment or examination.

The transmission of the power from the gear is carried out by means of an enclosed propeller shaft which runs in a long tapered torque tube forming the forward extension of the live axle The function of this tube is to take the torque and the propulsion loads. (*The Auto-Motor Journal*, vol. 28, no. 2/1149, Jan. 11, 1923, pp. 27–30, 11 figs., *d*)

POWER-PLANT ENGINEERING (See also Special Processes)

The Design of Structural Supports for Turbo-Generators, Edward H. Cameron. Discussion of the relative merits of the three common types of pedestals for turbo-generators, namely, reinforced concrete, structural steel, and composite. The author believes that the tendency of the steel pedestal to vibrate with the machine constitutes its one disadvantage when compared with the concrete pedestal, and the design of a steel pedestal so proportioned as to avoid this vibration is a difficult problem.

The pedestal must have mass enough to absorb all vibrations and be rigid enough to prevent swaying. The most practical means of arriving at the requisite mass for a turbo-generator pedestal is by a study of existing designs in satisfactory operation both as to total mass and its distribution. To facilitate this the author gives weight-ratio curves and cost curves.

The original article gives a series of practical suggestions as to the best method of proceeding in designing pedestals for turbo-generators, the general advice being that utility or fitness rather than relative cost should be made the sole basis of comparison in deciding on the type of pedestal to adopt for a turbo-generator installation. As regards costs it is stated that for ordinary designs the cost of the pedestal should not exceed about 5 per cent that of the turbo-generator, and that in general any saving of one particular type of pedestal over another should not be more than about 1 per cent of the cost of the unit which it supports. Each type of pedestal has its field. For the smaller units it is believed that more concrete pedestals are in use, whereas the reverse is probably true of the larger units. The composite type, combining the advantages of both concrete and structural steel, is coming to be more and more favored for all sizes of turbo-generator units. (Paper before the Monthly Meeting, Dec. 20, 1922, of the *American Society of Civil Engineers*, abstracted from advance publication, 16, pp., 6 figs., *p*)

Increase of Economy by Changes in Boiler Design

Principles of Boiler Design, C. E. Stromeyer. Discussion of some features of boiler design, with particular reference to attempts to increase economy.

In view of the injury done to boiler parts and to brickwork if the furnace temperature is high, as it must be with perfect combustion, the author suggested some years ago the resort to double combustion. The fuel in the furnace would be burned not to carbon dioxide but to monoxide. The resultant temperature could then not exceed about 2500 deg. fahr. and the temperature curve in the boiler would run in a manner entirely different from that of today. This arrangement would present difficulties when using customary types of boilers and the present types are merely to be modified. There would be difficulties from the increase of furnace temperature and, in particular, from enormous heat radiations, which brings up the question as to whether heating surfaces can be screened from the radiation of the incandescent fuel.

Assuming that the radiant heat of the furnace has been disposed of one way or another, we are face to face with the question of convection. Let there be two fluids of different densities on both sides of a plate—heating surface—then, neglecting the very slight resistance offered by the plate to the passage through it of a certain quantity of heat H per hour, it appears that—

$$H = C\,(T_1 - T_0)\,D_1\,(1 + 0.02\,V_1) = c\,(T_0 - T_2)\,D_2\,(1 + 0.02V_2).$$

Here C is a constant which is, however, not quite the same for all gases and fluids. T stands for the various temperatures, T_0 being that of the plate, D stands for densities and V for velocities in feet per second. The two right-hand expressions determine the ratio of the subdivision of the available temperature difference $T_1 - T_2$. The ratio is $(T_1 - T_0)/(T_0 - T_2) = (D_2/D_1)\ (1 + 0.02\,V_2)/(1 + 0.02\,V_1)$. Let the one fluid be water, whose density is about 800 times as great as that of air, then for small values of V the ratio of the excess temperature of the air over the plate, $T_1 - T_0$, would have to be about 800 times the excess temperature of the plate over that of the water $T_0 - T_2$. To increase V_2 would only increase this disproportion, but this would be diminished, and the heat transmission per square foot of heating surface increased, if the air velocity V_1 were increased. Our efforts should therefore be centered on increasing the velocities of gases and steam and not on increasing the water velocity, except, of course, for circulating purposes and for liberating the steam as it is generated.

It could easily be shown that a minimum heating surface will be obtained if the temperature ratio $(T_1 - T_0)/(T_0 - T_1)$ is near unity. This is of importance as regards superheaters.

The problem of creation of the draft velocities is discussed and the author shows that the cost of a draft produced without a chimney and with gases cooled down to the surrounding temperature with the fan will be very much lower than when produced by natural draft in terms of coal used. Nevertheless, fans do not replace chimneys, because with present-day boilers the temperature of the waste gases cannot be reduced much below 400 deg. fahr., and because chimneys are necessary anyway to carry the gases above the housetops.

From this the author proceeds to a discussion of the employment of air heaters as a possible means of waste-gas cooling and shows the many difficulties involved in their design.

He considers the superheater a necessary adjunct of modern engines and makes an estimate of the relative velocities, using however, relative densities instead of temperatures in the calculations. The steam velocities, he says, should be less than those of the gases, but both should be high. The loss of power in the main engine, due to drop of steam pressure in the superheater, should be estimated, also the increased friction in the steam pipe due to increased volume, or increased radiation, due to the adoption of slightly larger diameters. The simplest way out of this complication would probably be to start with the pressure required at the engine, and to make the boiler strong enough to bear the few additions. The problem is then reduced to the simple one of taking into account the increased cost of the boiler due to the small increase of pressure. Steam users should not expect to gain in both directions. If by employing high velocities the superheater surface has been reduced, a loss of steam pressure must result. But steam users would have cause to complain if only one of the velocities were kept high, for then there would be friction losses with only one-half the possible gain.

The interesting problem has now to be solved as to where the superheater should be placed. It certainly cannot be placed next to the air heater, because here the temperatures are too low. The further we move away from the air heater, the hotter will be the waste-gas temperature, the better the heat transmission, the smaller the heating surface required, and the lower, if desired, can the velocity of steam and gas be fixed. The cost of each alternative would have to be worked out.

This is followed by a discussion of economizers, high velocity of flames (based on the experiments of Professor Nicolson), reductions of furnace temperatures and oil burning. (From a Report to the Manchester Steam Users' Association, 1922, abstracted through *The Engineer*, vol. 134, no. 3495, Dec. 22, 1922, pp. 672–673, *gt*. Compare editorial, dealing with other parts of the same report in the same issue of *The Engineer*, p. 669)

Steam Velocity. In an editorial a question is asked as to whether we should guess or know what the maximum steam velocity in a steam pipe should be, and whether it should be 6000 ft. per min. or 20,000. If 6000 is used where 20,000 would give entirely satisfactory results, a lot of money is wasted. On the other hand, if excessively high velocities are used, trouble is certain.

Most of our formulas for the flow of steam through piping and fittings were inherited from the era of low pressures and saturated steam, and it is the opinion of many practical designers that they are totally inadequate for the conditions found in large stations. Moreover, it appears that the laying out of steam pipes on a velocity basis is satisfactory only where a wide range of velocities is used to fit various conditions.

In this connection, considerable interest attaches to the recent statement of John H. Lawrence, Mem. Am.Soc.M.E.—who has had extensive experience in power-station design—that the proper steam velocities for the conditions found in large modern power stations may be roughly approximated by allowing 1000 ft. per min. velocity for each inch of pipe diameter. If this rule is approximately correct, it is seen that 6000 ft. per sec., while about right for a 6-in. pipe, is far too low for a 20-in. pipe. This rule of thumb was not proposed by Mr. Lawrence as a hard-and-fast law of good practice, but merely as something tangible in the field between pure guesswork on the one hand and incorrect formulas on the other. In reference to the latter Mr. Lawrence said that actual measurements at the Hell Gate Station showed pressure drops far lower than those figured by any of the standard formulas for steam flow. As to losses through fittings and valves, the condition of knowledge is, he said, even more chaotic.

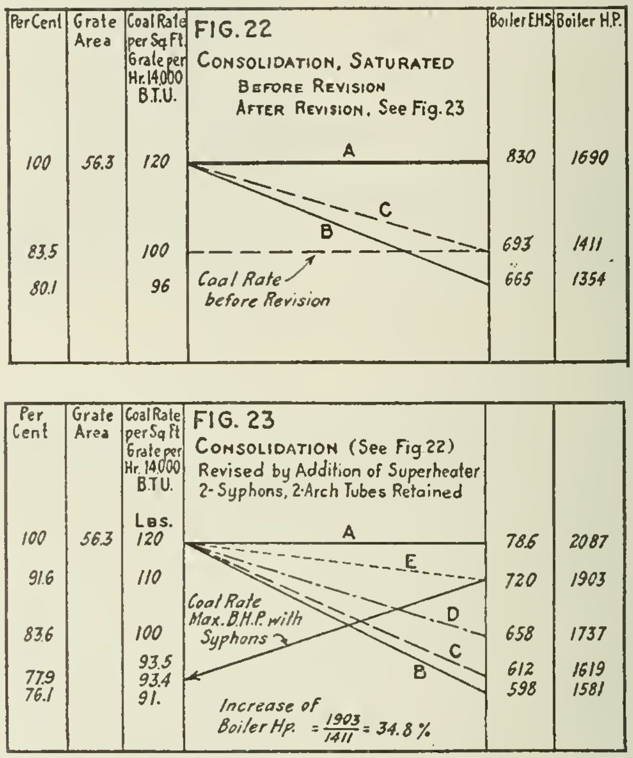
The writer expresses the hope that The American Society of Mechanical Engineers will follow the suggestions of those members who are fully alive to the importance of this problem, and believes that it should certainly be worth while to make an extensive field survey to determine the actual pressure drops obtained with the various fittings, pipe sizes, pressures, superheats and steam velocities found in existing plants. From a careful study of the tabulated data of such a survey it should be possible to develop formulas suitable to the need of the practical designer. (Editorial in *Power*, vol. 57, no. 3, Jan. 16, 1923, pp. 105–6, *p*)

RAILROAD ENGINEERING

Graphical Analysis of Locomotive Boiler Proportions

Graphical Analysis of Locomotive Boiler Proportions, C. A. Seley. A graphical analysis of locomotive boiler proportions developed with particular reference to the design of locomotives equipped with the so-called thermic siphon (For description of the thermic siphon, see Mechanical Engineering, March, 1919, p. 284). It is based on the engineering methods and data proposed by F. J. Cole in designing boilers on horsepower basis.

The article is not generally suitable for abstracting, but some of the conclusions arrived at may be reported here. One of the figures (No. 16) illustrates the results of insufficient grate surface, which means high coal-burning rates and loss of economy and efficiency. It has been stated that a 120-lb. coal rate is about the maximum amount for economical evaporation, yet this diagram shows 134 lb., a very high rate for continued heavy service. The United States



Figs. 6 and 7 Diagrams of Consolidation Locomotive Before and After Revision

(The figure numbers above refer to the illustrations as placed in the original article.)

Railroad Administration 2-6-6-2 design is in a similar class, with high coal rate for heavy service.

A claim is made in the article that some of the deficiencies of present-day locomotives may be compensated for by the addition of a thermic siphon. By way of illustration of these claims the following may be cited:

An increase of tonnage rating of 20 per cent sounds big, but is actually being accomplished in the revision of a series of Consolidation locomotives originally heavily built and capable of such increase in tractive effort by cylinder and steam-pressure changes. The original boiler had four arch tubes but no superheater and was of 1411 boiler hp. The boiler revision consisted of superheating, adding two siphons, retaining two arch tubes, the combined effect being to give an equivalent equated heating surface of 720 sq. ft. or 1903 boiler hp., an increase of 35 per cent, with a very moderate coal rate, all as shown in Fig. 6.

Fig. 7 shows distribution in percentage of the heating surfaces and the effect of the revised design, as compared with the original dimensions equated to superheat ratio for comparison, or 74.14 per cent. The revised locomotive has successfully handled an increase of 20 per cent and over of the original engine tonnage rating, and, while this is an exceptional case, due to some of the features involved, no doubt, there are many locomotives that are

capable of a similar line of treatment. (*Railway and Locomotive Engineering*, vol. 36, no. 1, Jan., 1923, pp. 9–13, 24 figs., *cg*)

European All-Steel Sleeping Cars

European All-Steel Sleeping Car, Wm. Redpath. Description of what is said to be the latest word in Continental sleeping-car construction. These are not only the first all-steel sleeping cars built abroad, but the first European cars in which steel castings have been extensively employed to strengthen and simplify underframe and truck construction.

The whole of the structure of the body is of steel, the sides being constructed with 1/8-in. pressed-steel members of varying sections connected longitudinally to rolled-section angles at the base which rest on the underframes. At the top the vertical members are connected by the two angle rails. The sides below the waist are sheeted with 1/8-in. steel sheets of a special quality which give a superior finish. The sheeting above the waist is pressed in 1/8-in. plate to form the window openings, as many as four windows being pressed in one piece. Steel moldings are used to cover the butt joints of the body side plates, the whole side being riveted together with rivets countersunk on the outside to give a clean appearance to the outside of the coach. The sides thus become deep girders capable of supporting the whole of the superstructure.

The roof is elliptical, being constructed of a rolled-section angle carline riveted to upper partition plates. These latter extend down to the cantrail level across compartments and are shaped to suit the ceiling at the corridor. The roof is designed to allow of the water tanks being assembled or removed through the outside sheeting, covers with suitable joints being provided.

The structure of the body is entirely of steel, being built in jigs in units: full-length compartment side, full-length corridor side, full-length roof, body ends, platform ends and canopies, thus insuring complete interchangeability as well as ease of production. These units, which for the most part consist of pressings and rolled sections all machined to templets, are quickly assembled whole on the underframe, leaving the shell ready for the assembling of interior finish. To insure absence of vibration and drumming, the steelwork has been covered on the inside with canvas and insulation from heat, and cold has been well provided for. Free air circulation between the outer skin and inner finish is also arranged for the prevention of condensation.

These cars are arranged essentially in a different manner from sleeping cars in America. They have been designed to carry sixteen passengers, the arrangement being eight single compartments, four double compartments, and two lavatories, six of the single compartments being provided with communicating doors capable of being locked from either side. The seats of each compartment turn over to form the bed, the bedding being secured to the undersides of the seats in dustproof envelopes. The seat back of the double compartment is arranged to lift to a horizontal position to form an upper berth, being supported by pull-out brackets fixed to the body side and corridor partition; safety straps supported from the ceiling are also provided.

There are other facilities not available in American sleeping cars. Thus, incorporated with the vestibule ends are cupboards for ice and wine, utensils and coal, with linen cupboards in the ceiling. The cool wine cupboards are insulated with asbestos and are zinc-lined.

There are two heating systems: one, the usual through steam heating, and the other by hot-water circulation. For the latter a heating chamber is provided at one end of the corridor at which is fixed a coal-fired boiler; circulating pipes of copper are run from boiler to a hot-water tank in the roof, and from this around both sides of the car.

As the cars run over many railway systems, some of which use vacuum and others compressed air, it has been necessary to arrange the brake rigging for use with either system. When the vehicles are in use for the vacuum system, two 24-in.-diameter cylinders operate a pair of brake shafts from which the power is transmitted to the brake blocks by suitable rigging, and when the Westinghouse system is in use, the power is obtained from a 17-in. diameter cylinder. Further, the vacuum brake is fitted with a converter cock for use on certain sections. The Westinghouse brake is fitted with a double pipe line so that the system may be either automatic or controlled. The same brake rigging can be operated by hand from a wheel placed in the vestibule at one end of each car.

The cars were built at the Leeds Forge Company in England and their transportation to the coast and shipping them to France presented a difficult problem. It was, however, arranged to have the cars travel to the port of shipment on their own wheels complete, excepting for the removal of a few parts of minor importance. There it was found that the Channel ferry steamers built during the war for the purpose of carrying rolling stock to the Continent were available.

It was found necessary, however, to construct the new terminal at Immingham, where these cars could be loaded on to the boats. The problem of loading was not an easy one either and, for example, ramps were provided over which the cars were run on to the ferry-boat deck direct from the quay, an ingenious arrangement having been installed to allow for the rise and fall in the dock water level to prevent delay in loading owing to tidal conditions. (*Railway Review*, vol. 72, no. 1, Jan. 6, 1923, pp. 63–67, 8 figs., *d*)

REFRIGERATION (See also Special Machinery)

Comparative Ammonia Condenser Reports, P. Wilson Evans. For a number of years Armour & Co. have compiled a weekly comparative statement showing data on ammonia condensing for their principal plants. By means of these reports it has been possible to deduct and remedy inefficient operating conditions with a resulting saving in power and operating expense. A copy of one such report is given in the article here abstracted.

One of the columns of this report shows a total excess pressure over ideal conditions. It is the endeavor to hold this total excess pressure down to not over 25 lb., but it is difficult to accomplish this. It is only by keeping constantly after this phase of operation that this excess pressure is kept from going considerably higher. The red pencil marks on the copies of the reports sent to the different plants indicate whether the condenser should be purged or other steps taken to reduce the pressure.

In case a plant is found to be materially out of line in its condenser pressure the question always arises as to how much of a loss in dollars and cents this condition is causing. Cases have arisen where the total excess pressure has been as great as 80 lb.

The original article presents a chart showing the horsepower required to compress adiabatically the ammonia required to produce one ton of refrigeration, assuming the suction gas dry and saturated. The curves of the chart were calculated by the author and are plotted with horsepowers per ton as ordinates and absolute suction pressures in pounds per square inch as abscissas.

From an analysis of the figures as reported in one of the weekly comparisons it would appear that in many cases purging of the condenser is necessary to reduce the excess pressure present, and the author shows how materially a reduction of excess pressure affects the cost of operation.

While there is a well-grounded prejudice against too much condenser purging on account of the possibility of excessive ammonia loss, actually the amount of this loss depends largely upon the care taken in purging. In the author's opinion the most satisfactory method of purging an ammonia compressor is to shut it down and allow water to flow over it until there is no material difference between the temperature of the water going on and coming off. Then observe this water temperature and find from the ammonia table the corresponding condenser pressure. This pressure represents accurately the vapor pressure of the liquid ammonia in the condenser and if the gage on the condenser shows higher pressure, the excess is due to non-condensable gases such as air. The purging should be discontinued at a point somewhat above the pressure corresponding to the water temperature, thus assuring that there will be no great amount of boiling off of liquid ammonia.

The difficulty in purging below the pressure corresponding to that of the ammonia vapor at a specific temperature is to know just when to discontinue it, but this is due to excessive pressure of non-condensable gases assumed in this case. Under more normal conditions it is satisfactory to discontinue the purging just at or slightly above the ammonia vapor pressure corresponding to the temperature of the water flowing over the condenser. If this is done, the loss of ammonia at all times will be insignificant. Or-

dinarily, it is considered better practice to purge several times in this manner than to continue the purging to a lower pressure. (*Power*, vol. 57, no. 1, Jan. 2, 1923, pp. 28–30, 1 fig., *dp*)

RESEARCH (See Engineering Materials)

SPECIAL MACHINERY

Vapor Recompression System for Evaporators. Discussion of regenerative evaporation, with comparison of operative economies with single and multiple-effect evaporators. A bibliography of patents and literature is appended.

The nozzle systems are considered to be the easiest to discuss qualitatively. For high efficiency it is necessary to work with a small temperature drop and very high-pressure steam. To get double-effect efficiency (1 lb. of vapor entrained per pound high-pressure steam), the total temperature drop may not be over 18 deg. fahr. for 100-lb. steam, 22 deg. fahr. for 150-lb. steam, or 22.5 deg. fahr. for 175-lb. steam. Ordinarily evaporators are designed to operate with from 5- to 15-lb. steam. If a single-effect evaporator with a nozzle compressor be compared with a double working between 10 lb. and 26 in. vacuum, it will be found that the double has a total available temperature drop of 100 deg. fahr. against, say, 20 deg. for the other. Hence, on material of no elevation in boiling point the double would have five times the capacity of the single, twice the heating surface, and would require the same amount of steam condensing water and accessories.

The comparison used is more strongly in favor of the double when the plant has exhaust steam to spare, as then the double saves either all the high-pressure steam used in the nozzle (if exhaust steam is available, which otherwise would be wasted) or it saves all the condensing equipment and condensing water otherwise needed for the prime movers.

The best use for the nozzle is the plant where all exhaust from prime movers is used in the evaporators and in addition make-up has to be supplied as live steam. A nozzle may be substituted for the usual reducing valve on the make-up steam line; provided, of course, that the evaporator in question is a multiple effect with a small enough temperature drop in the first effect to make the nozzle efficiency appreciable. Here again attention must be paid to the rapidly decreasing efficiency of the nozzle as the steam pressure drops; because if the amount of make-up needed is variable, the nozzle will give useful results only when the throttle valve is wide open. Under conditions demanding less than the maximum amount of make-up steam, its capacity will be negligible.

It has been suggested by Claassen that several small nozzles in parallel be cut in or cut out one at a time as the demand for make-up varies, but each to be either completely closed or wide open and never throttled.

The remainder of the article, though of considerable interest, cannot be abstracted here owing to lack of space. It is devoted to an extensive discussion dealing with the selection of the type of evaporation equipment as affected by the method of power generation at the plant either available or to be installed. A bibliography on vapor-recompression systems for evaporators, and, to some extent, evaporation generally, is appended. (*Chemical and Metallurgical Engineering*, vol. 28, no. 2, January 10, 1923, pp. 73–78, *gcA*)

Oxygen Enrichment of Blast in Blast Furnaces

Oxygen-Enriching, Superheating, and Drying of the Blast. The question of enriching the blast in oxygen is now the subject of an investigation by the U. S. Bureau of Mines. It is of interest to mechanical engineers as the majority of the methods now known to accomplish this purpose involve the use of compressor and low-temperature refrigeration equipment.

In a paper before the Liége Congress M. Derclave, as regards enriching the blast in oxygen, arrives at the following conclusions: The addition of 5 per cent (in volume) of oxygen does not improve the working of a blast furnace upon the whole, because the advantages gained in respect of coke consumption are lost by the reduced calorific value of the furnace gas. Any further increase in the oxygen content would have no effect, because the limit of the indirect reducing power of the gas has almost been reached, the ideal limit, according to Gruner, being reached when $m = 1.21$ is raised to 1.57—that is, when the whole of the oxygen in the burden is abstracted by the CO. This condition is, of course, impossible to attain so long as there is any water vapor in the flowing gas, as must be the case when damp and chemically hydrated ores are used, like minette. The 5 per cent to 6 per cent in volume of oxygen added must be considered the limit beyond which the point of equilibrium is approached, at which the quantity of CO required at the tuyeres for fusing the materials is equal to that necessary for the complete reduction of the charge by the gas. Beyond this point no further increase in efficiency can be realized in blast-furnace working. One has reached the most favorable conditions for the indirect reduction by CO, which is the essence of successful blast-furnace working, as shown by the equation:

$$Fe_2O_3 + 6\,CO = 2\,Fe + 3\,CO_2 + 3\,CO \ldots\ldots\ldots \quad [1]$$

for which the ratio CO_2 to CO in volume equals unity, or 1.57 in weight.

To obtain further economy in fuel consumption it would be necessary to oxidize the carbon directly by the oxygen in the ore, and to find some other apparatus than the furnace which would realize the reaction represented by the equation:

$$Fe_2O_3 + 2\,C = 2\,Fe + CO_2 + CO \ldots\ldots\ldots\ldots\ldots \quad [2]$$

which shows that carbon utilized in this direct way would give a reduction three times greater than when burned at the tuyeres of a furnace by the air in the form of CO. Because, according to Equation [2], to reduce two units of iron, two units of carbon are required in the case of direct reduction, while by Equation [1], on the contrary, six units of carbon are required in the case of indirect reduction.

It is easy to calculate that to obtain 1000 kg. of iron containing 3.5 per cent C, by the indirect method, 35 kg. of C are required to carbonize the pig iron, a further 515 kg. to reduce the iron oxides indirectly, and 25 kg. for the direct reduction of the other oxides; thus a total of 575 kg. would be required for the fusion of the iron and the slag and the consequent separation of the metal from the gangue.

By direct reduction no more than 192 kg. of carbon would be required, but it would be necessary to draw upon other sources of heat to insure fusion. By utilizing methods of heating not entailing the combustion of carbon, such, for example, as heating, drying, or enriching the blast in oxygen or electrical heating, the whole of the carbon would be utilized for the reduction of the ores and not for smelting, and the saving in fuel would thus be pushed to its maximum.

There is, then, a comparatively narrow limit to the extent to which oxygen can be added to the blast. Even with the addition of 5 per cent in volume, that is 27 per cent of oxygen by weight, the limit is reached; for the high temperature reached at the base of the furnace would destroy the lining, while at the top of the furnace there would be a rapid falling off in the reducing effect of the gas. As regards the hot blast, it, among other things, increases the ratio of CO_2 to CO in the furnace gas; that is, the ideal operation is more closely approached. The hotter the blast, the smaller will be the quantity of carbon consumed at the tuyeres, and consequently the volume of CO produced in that region will be reduced. Since the oxygen content of the ore remains the same, the proportion of CO_2 will increase and the ideal ratio of CO_2 to $CO = 1$ (in volume) will be attained. The excess of CO_2 in the reduction zone will then act on the soil carbon, and, while the consumption of fuel is reduced in the region of the tuyeres, it is increased in the reduction zone. The final result will be that there will be a notable reduction in fuel consumption without affecting the quality of the product. (Paper before the Liége Congress. Abstracted through *The Iron and Coal Trades Review*, vol. 106, no. 2863, Jan. 12, 1923, p. 53, *g*)

CLASSIFICATION OF ARTICLES

Articles appearing in the Survey are classified as *c* comparative; *d* descriptive; *e* experimental; *g* general, *h* historical; *m* mathematical; *p* practical; *s* statistical; *t* theoretical. Articles of especial merit are rated *A* by the reviewer. Opinions expressed are those of the reviewer, not of the Society.

Test Code for Internal-Combustion Engines

Preliminary Draft of Another Code in the Series of Nineteen Being Formulated by the A.S.M.E. Committee on Power Test Codes

The Power Test Codes Committee on Internal-Combustion Engines which developed this Code is headed by Dr. Charles E. Lucke as Chairman, the other members being Edward T. Adams, Harte Cooke, Max Rotter, and Arthur West.

The Committee and the Society will welcome suggestions for corrections to and modifications of this draft of its Code from those who are especially interested in the testing of Internal-Combustion Engines. These comments should be addressed to the Chairman of the Committee, in care of The American Society of Mechanical Engineers, 29 West 39th Street, New York, N. Y.

Introduction

Tests for determining the performance of internal-combustion engines by this code apply to all forms of internal combustion engines, but are limited to the engines alone. Separately driven auxiliaries that are essential to the operation of the engine, such as scavenging pumps or blowers and injection air compressors, for example, must be included in the tests, but the testing of such units must follow the other codes appropriate to the unit to be tested and the results in horsepower absorbed introduced and used in this code.

2 Internal-combustion engines, compared to others for which codes are available, include a much greater variety in form, size, speed, weight, fuels and other operating conditions, with more or less special features for particular applications. This fact makes it necessary in a single inclusive code like this to leave many details of the test to the judgment of the test engineer, or to be made the subject of expressed agreement before the test is started. Suggestions are offered in this code as to limitations, alternatives and difficulties to aid in making selections of details, always with the understanding that suitability to the case shall be the basis of judgment.

3 Sizes of internal-combustion engines coming within this code range from one horsepower to several thousand. Speeds range from less than 100 r.p.m. to over 3000 r.p.m. Numbers of cylinders range from one to twelve or more; some horizontal and others vertical; some single-acting and others double-acting; some two-cycle and others four-cycle, with every variety of attached and separate scavenging pump for two-cycle engines. Fuels range from the lightest distillates to the heavy residue fuel oils, organic and mineral in the liquid-fuel class, and in the gaseous form include every combustible gas commercially available. Purpose and variety of load or other service conditions normal to and proper for each engine cover equally wide ranges. Stationary engines operate at all loads normally at constant speed under governor control, for any period of time and any degree of intermittence of use. Marine engines operate normally at full load, and the constant speed fixed by the propeller, but must be maneuvered ahead and astern at any speed under hand control, and may operate for any period of time from short intermittent runs to the continuous full load for a month or more required of seagoing motorships. Aircraft engines must meet about the same service conditions as marine engines, except that a smaller length of single run is required, but they must operate in the greatest known ranges of atmospheric pressure and of temperature. Other engines of the automotive group, those for land transportation, including those for automobiles, motor trucks, tractors, railroad locomotives and self-contained cars, are essentially variable in speed as normally used, and equally variable in torque, horsepower being as much a matter of secondary importance as in a hoisting engine or steam locomotive. The engines of this last group drive their vehicles through gear sets of different speed ratios, at changing vehicle speeds and changing vehicle resistance, and tests of them must be conducted with due regard to these service conditions.

It is obviously impossible in any single code to prescribe tests in detail that could be equally applicable to all these conditions, so that some exclusions are necessary. At the same time it is highly desirable that tests for all internal-combustion engines set by this code should have as much in common as may be possible, even if some latitude of judgment is necessary to make this possible.

4 Excluded from this code are the following:

(*a*) Complete internal-combustion engine stationary power plants using gaseous or liquid fuels, which have power-generating or power-absorbing auxiliaries separate from the engine
(*b*) Motor-boat and motorship power plants and the vessels themselves
(*c*) Aircraft and their power plants
(*d*) Land propelled vehicles, with or without speed-change gears, including motorcycles, automobiles, motor trucks, tractors and rail locomotives or self-contained cars
(*e*) All internal-combustion engine "sets," consisting of an internal-combustion engine so combined with a driven unit as to make it impossible to separately determine the performance of the engine itself, or such as falls within the scope of other codes, excepting only electric generating sets. Among these sets herein excluded are internal-combustion-engine pumps, compressors and hoisting outfits, whether used for hoisting or for hauling
(*f*) All internal-combustion engines, the construction or operating conditions of which prevent an output determination in terms of either brake horsepower or kilowatts, for a generating set.

5 Included within this code are the following internal-combustion engines not excluded by any of the items of Par. 4:

(*a*) Stationary engines, and electric-generating sets even if not intended for stationary use, burning gaseous or liquid fuels, including the scavenging pumps of two-cycle engines, and injection air compressors, if used and separately driven
(*b*) Marine engines exclusive of propeller, and burning light or heavy liquid fuels
(*c*) Aircraft engines limited to block tests, exclusive of propeller, and burning light liquid fuels
(*d*) Land vehicle engines limited to block tests and burning light and heavy fuels.

6 Reference is made, in connection with the exclusions of Par. 4, to the separate codes for testing:

(*a*) Displacement Pumps
(*b*) Centrifugal and Rotary Pumps
(*c*) Reciprocating Displacement Compressors and Blowers
(*d*) Centrifugal and Turbo-Compressors and Blowers
(*e*) Refrigerating Machines and Plants
(*f*) Locomotives.

Reference is also made in general to other codes prescribing items forming part of this code, which must be considered in connection with it. All directions in these codes, noted below, applicable to this one must be followed:

(*g*) General Instructions
(*h*) Definitions and Values
(*i*) Instruments and Apparatus
(*j*) Fuels.

Object

7 In accordance with the "General Instructions," the object of the test, and if more than one, then each separately, should be determined and recorded.

This code is limited to tests in which the object is of a commercial nature. It excludes all tests forming part of experimental investigations, research or development. But while no engineer undertaking tests of a research or development nature needs any code if he is competent to make such investigations, it will usually be found that parts of such research work will be aided and in no way hampered by following parts of this code. It is also in the interests of those branches of engineering, whose progress is based on experimental data, if any parts of an investigation are carried out in accordance with the code, and recorded in accordance with the code. Results so obtained are more easily comparable with the large numbers of tests always being carried out on the lines of the code. The research data then enter readily into the general body of knowledge of the internal-combustion engine.

8 Tests of the kind contemplated by this code and for which it has been prepared, are those in which the object of the test is *definition* of an engine by its performance characteristics.

9 When the object of the test is wholly or in part the determina-

tion of fulfillment of a contract guarantee, an agreement should be made before the test between the interested parties on all matters that involve any possible elements of uncertainty, or that may later be a cause of dispute, as noted in Par. 3 of the "General Instructions," and the points agreed upon should be stated in the report of the test.

10 Agreements between interested parties should also be made and recorded even when a contract guarantee is not involved, before undertaking any test in which an element of judgment is involved in the selection of any instrument, piece of apparatus, physical constant, test method, operation condition or other matter that will promote the accuracy, the value, conclusiveness or the general acceptability of the results when obtained. This matter is one of special importance in tests on internal-combustion engines because of their great variety.

11 Sub-objects of the main object may often be of value in improving the value of results obtained in the test for the main object and may themselves be made the subject of separate tests, but in all cases *only* when made the subject of previous agreement as to the nature of the sub-objects and the test procedure. Sub-objects of a test must be separately reported as such to clearly distinguish them from the main object, and it is advisable that reasons be given for making such special tests. This is especially important when the special test for the sub-object is to be conducted at the same time as the test for the main object. Some sub-objects that may be expected to arise in connection with code tests of internal-combustion engines are listed below, but no special instructions concerning them are included in this code. Selection is left entirely to the judgment and agreement of the test engineers, but none of these sub-objects will be considered as tests made "according to the A.S.M.E. code," unless specifically added to the requirements by agreement and so marked in the report. It is recommended as good practice that they conform as far as possible to such parts of this and other codes as may be found applicable, especially those enumerated in Par. 6.

(*a*) Exhaust-gas analysis, with special reference to the determination of air not utilized by the engine in combustion, and of unburned fuel or combustible
(*b*) Exhaust-gas temperature, with special precaution to get accurate results in view of high velocity of gases, intermittent flow, and cooling conditions in exhaust ports and pipes, determined with special reference to equalization of load between cylinders of multi-cylinder engines, or accuracy of adjustment of combustion conditions, or percentage of fuel heat discharged in the exhaust
(*c*) Amount of air taken into an engine, with special reference to the volumetric efficiency and the completeness or incompleteness of the charging as a factor in actual as compared to possible power developed
(*d*) Properties of liquid or gaseous fuels with reference to suitability for use in the engine, or with reference to identity of the fuel as to some specification
(*e*) Determination of variations in the quality of lubricating oil or its contamination by use, especially by fuel or fuel products, and particularly for engines provided with a fixed amount of lubricant successively reused
(*f*) Nature of solid deposits in combustion chambers, on pistons, valves and ports, resulting from use and originating in fuel or lubricant or in solids carried by the air
(*g*) Amount of air required to start an engine provided with air-starting equipment, in relation to the capacity of starting compressors, especially for engines that must be frequently maneuvered in service
(*h*) Electrical starting requirements of engines using electricity for starting on heaters or electric motors, in relation to generator and storage battery
(*i*) Amount and pressure of air required for air-spraying apparatus of air-injection oil engines using fuel oils, in relation to the spray-air compressor capacity
(*j*) Power consumed by each or all of normally attached auxiliaries, with or without other operative characteristics of these auxiliaries, which include electric generators or magnetos, storage batteries or complete electric ignition apparatus, jacket-circulating pumps, direct or radiator cooling fans, lubricating-oil and fuel-oil pumps, starting and spray-air compressors, scavenging pumps of two-cycle engines, attached fuel and lubricating-oil heaters and coolers
(*k*) Smoke quantity and color or density, and particularly when smokelessness in some degree is a matter of importance or of specification.

Measurements

12 The measurements that must be made in a performance test of an internal-combustion engine will be the following quantities:

(*a*) Cylinder diameter, stroke and clearance volume of working cylinders.
(*b*) Diameters of piston rods and tail rods of working cylinders of double-acting engines
(*c*) The brake-horsepower or shaft-horsepower output
(*d*) The kilowatt output if engine is direct-connected to a generator
(*e*) The speed in revolutions per minute
(*f*) The horsepower to drive the water-cooling pump and fuel-pump (if any)
(*g*) The horsepower to drive the independent scavenging pump or blower
(*h*) The horsepower to drive the independent injection air compressor
(*i*) The amount of fuel supplied: cubic feet of gas for gas-burning engines, or pounds of liquid fuel for liquid-fuel engines. If more than one kind at the same time, the amount of each kind
(*j*) The calorific value of the fuel, high value.

13 The measurements which may be made in addition to those required by Par. 12, will be some or all of the following as may be agreed in advance by the test engineers:

(*a*) Cylinder diameters and strokes of injection air compressor
(*b*) Two-cycle engine scavenging pump diameter and stroke
(*c*) Diameters of piston and tail rods of scavenging pumps of two-cycle engines
(*d*) Diameters of piston rods and tail rods of injection air compressor
(*e*) The indicated horsepower
(*f*) The number of explosions per minute, or fuel injections per minute, or in general, combustion times per minute, for each and for all working cylinders
(*g*) The spray-air pressure of air-injection oil engines
(*h*) The exhaust back pressure at the engine
(*i*) The scavenging-air pressure of two-cycle engines, constant or maximum values
(*j*) The manifold vacuum of carburetor engines
(*k*) The jacket-water or oil-supply pressure at the main, and if jackets are divided with separate supplies, the pressure at the supply point or branch pipe to each
(*l*) The jacket water or oil back pressure at the main outlet, or if jackets are divided with separate discharges, the pressure at the outlet of each
(*m*) The pressure or vacuum or the hydraulic head, positive or negative of the supply of liquid fuel at the carburetor connection of carburetor engines, and at the injection-pump suction of injection oil engines
(*n*) The pressure or vacuum of the gas supplied to gas-burning engines at the mixing valve connection
(*o*) The total pressure, static and velocity of cooling-air supply of air-cooled engines
(*p*) Barometric pressure
(*q*) Atmospheric humidity
(*r*) The pressure of lubricating-oil supply to bearings of engines lubricated by pump forced-feed circulation
(*s*) The temperature of the atmospheric-air supply
(*t*) The temperature of the fuel for gas at the mixing valve, or for liquid fuel at the carburetor or injection-pump suction
(*u*) The temperature of the jacket water or oil as supplied to the engine as a whole, or if jackets are divided with separate supplies, the temperature of each separate supply
(*v*) The temperature of the jacket water or oil leaving the engine as a whole, or if jackets are divided with separate outlets, the temperature at each outlet
(*w*) The temperature of the scavenging air of two-cycle engines
(*x*) Temperature of injection air
(*y*) The temperature of the lubricating oil supplied to the engine at as many points as there are different supplies of pump-circulated lubricating oil, or in the crankcase of engines without pumps or having pump deliveries that do not permit of temperature measurement
(*z*) The temperature of the cooling air supplied to an air-cooled engine
(*aa*) The amount of lubricant consumed, pounds
(*ab*) The amount of jacket water or oil supplied, pounds, for engines as a whole, and when jackets are divided for each if both supply and discharge are separate
(*ac*) Amount, pounds or cubic feet, of cooling air supplied to air-cooled engines
(*ad*) Amount, pounds, of jacket water evaporated in jackets of hopper-cooled engines
(*ae*) Amount, pounds, of injection water supplied internally to cylinders of some oil engines, as a liquid or as steam
(*af*) The compression pressure in cylinders when hot and cold, at normal or at reduced speed at wide-open throttle.

14 In preparing a list of measurements from the items of Pars. 12 and 13, to be made preparatory to the planning of the log, and as a guide to their selection, it must be noted that in the above lists of measurements there are provisions for three groups:

(*a*) Measurements required for the determination of results required for this code, namely, those of Par. 12.
(*b*) Measurements to indicate the maintenance or variation of important operating conditions which might be described as the steady state required for the test prescribed, but which measurements do not themselves enter into the results except as specifying conditions under which the results were obtained. For example,

this is the case with all jacket water or oil and all lubricating-oil measurements of pressure, temperature and quantity. These are included in the list of Par. 13.

(c) Measurements for one or more of the determinations required by such sub-objects listed in Par. 11, as may be made the subject of an agreement by the interested parties. These are included in the list of Par. 13.

Instruments and Apparatus

15 Directions regarding the application, use and calibration of instruments and apparatus, do not form part of this code. Such information is given in the Code on Instruments and Apparatus, supplemented by that on Definitions and Values, in which will also be found statements on scope and limitations of use, and on accuracy.

The instruments and apparatus required for a performance test of an internal-combustion engine as prescribed by this code will include some or all of the following:

(a) Scales with or without special auxiliary apparatus for weighing liquid fuel, with or without tanks to be used in coöperation
(b) Gas meters for measuring gaseous fuel, or gas-metering methods with indirect observation apparatus
(c) Gas calorimeters for determining the heating value of gaseous fuels
(d) Baumé oil hydrometer for petroleum liquid fuels, and for indirect determination of calorific power
(e) Pressure gages and mercury or water columns for measuring small pressures and vacua
(f) Thermometers
(g) Barometers
(h) Gas-engine and oil-engine indicators for working cylinders and steam-engine indicators or special low-scale springs for cylinders of two-cycle scavenging pumps and low-pressure cylinders of injection air compressors
(i) Pressure-indicating or recording instruments for compression pressures or injection pressures in cylinders
(j) Planimeters
(k) Tachometers, revolution counters or other apparatus for measuring speed or number of fuel admissions per minute
(l) Absorption dynamometers of appropriate type for the horsepower, speed and torque of the engine to be tested, especially hydraulic brakes and electric dynamometers
(m) Appropriate electrical instruments and apparatus, if the engine is direct connected to a generator, to provide a suitable electrical load and to measure it.

16 In making a selection of instruments suitable for the measurement of quantities required by the performance test under this code, and constituting its main object per Pars. 7 and 8, it is necessary to exercise considerable latitude of judgment in view of the variety of internal-combustion engines noted in Par. 3, to insure proper relation of selected instrument to the conditions of measurement to be made. Some suggestions are offered below as a partial guide to such selection.

17 Indicators cannot be used at all on some internal-combustion engines and in other cases only within limits. In no case can an indicator be regarded as a precision instrument on an internal-combustion engine to the same degree as on a reciprocating steam engine. Some special cases are noted:

(a) When the engine speed exceeds 400 r.p.m. an indicator must not be used for determining the cylinder mean effective pressure of an internal-combustion engine. This excludes it and the determination of indicated horsepower for all engines of Par. 5(c) and 5(d), and all engines of Pars. 5(a) and 5(b) operating over 400 r.p.m.
(b) When the engine speed exceeds 400 r.p.m. optical indicators may be useful as a means of adjustment of valve or spark timing, but have no other value, and are of no use even for such adjustments in the case of multi-cylinder engines
(c) On all hit-and-miss-governed engines the indicator must not be used for determination of the cylinder mean effective pressure for indicated-horsepower determinations, thus excluding such determinations from tests of hit-and-miss-governed engines
(d) When indicator cards taken even at speeds of 400 r.p.m. or less are not constant in shape and area over long periods of time while a constant load is maintained, the indicator must be rejected as a means of determining cylinder mean effective pressures though it may be used as a means of adjustment of timing, especially as a guide to equalizing the timing for multi-cylinder engines or the two ends of a double-acting cylinder. The test as to constancy of area shall be ± 2 per cent, so that when the largest area differs from the smallest area by 4 per cent or more of their arithmetical mean, all shall be rejected. At various odd intervals of time, at least ten diagrams shall be taken on one card in addition to those taken at regular intervals, for comparison as to constancy
(e) When indicator cards taken even at speeds of 400 r.p.m. or less are apparently constant in area, according to the conditions (d), they may still be useless as a means of determining cylinder mean effective pressure and indicated horsepower, when the cylinder pressures are very high, the spring scale large, 500 lb. more or less, and the whole measured card area at the same time is very small. Under these conditions the precision will be very low and the indicated horsepower much in error. Just what set of conditions will produce a result bad enough to reject must be left to the judgment of the test engineer, with the suggestion that the accuracy of planimetering the smaller area be used as a basis of judgment. This condition makes it hopeless to undertake determinations of indicated horsepower for many oil engines of the high-pressure type, developing only small mean effective pressures
(f) Even in the cases where the indicator cannot properly be used as an instrument for measuring mean cylinder pressures and indicated horsepower, it can be usefully employed as a means of adjusting and equalizing the cylinder compression, the adjustment of main valves, the point of ignition in electrically ignited engines, of spray-valve timing of Diesel oil engine, or the injection-pump timing of injection oil engines with direct pump injection
(g) When the conditions of proper use of indicators for mean-effective-pressure determinations are all fulfilled, no indicated-horsepower determination shall be made unless a separate indicator is used on each working cylinder of a multicylinder engine (each end).

18 Brakes or absorption dynamometers when used must be suitable for the engine to be tested, in capacity, in speed-torque relations, and in ability to maintain an adjustment without necessity for constant hand manipulation to hold scale beam steady.

(a) For testing all engines of Par. 5(c) and (d), nothing but an electric dynamometer shall be used to determine brake horsepower
(b) For brake-horsepower tests of engines of Par. 5(b), the electric dynamometer shall be used, or hydraulic, if reversing tests are to be run. On engines of this class of large size and lower speed, hydraulic brakes of the type in which brake torque varies with the nth power of the speed, and in which n is equal to or greater than 1.5, shall be used as the preferred form.
(c) Other forms of brake may be properly used with engines of Par. 5(a) and so also when available may the hydraulic type and the electric dynamometers above described
(d) When brakes of any kind cannot be mounted directly on the engine shaft without other supports, due precautions must be taken, per instructions in the Code on Instruments and Apparatus, to avoid errors due to these supports
(e) In no case may a brake driven by a belt or otherwise than by direct coupling to or mounting on the engine shaft, be used for engine brake-horsepower measurements
(f) With due precautions and under proper provisions brake-horsepower determinations may be made by the indirect or substitution method, and this is important because in some cases it is the only means available. According to this method the engine may be tested with a load such as a propeller (air or water type), a club or a fan, which propeller or fan may later be, or previously have been, tested for its speed-torque characteristic curve, and the horsepower of the engine determined by reading from this curve the horsepower for the speed maintained by the engine. The special precautions referred to relate to assurances of identity of conditions of flow through and resistance of the propeller or the fan under the two separate tests of use and of calibration. This is so difficult that none but test engineers of special experience should undertake it. In no case can results of test-stand torque alone be acceptable in brake-horsepower determinations for an engine.

19 In measuring speed, the choice of instruments is determined by the character of the test carried out. Continuous speed counters may be used only for slow-running engines, where a constant speed of considerable duration is maintained. Hand speed counters placed directly against the engine shaft may be used, if handled carefully and well made. Tachometers may be used of the centrifugal, liquid pumping, or magnetic type, but these must be carefully calibrated and records of recent calibration must be available. Tachometers must be connected by a reliable tachometer shaft or by positive gearing to the engine shaft, and in no case should belting be used as a connecting link.

20 The heating value of fuels to be used in calculations of results of tests of internal-combustion engines must be the "high value" products condensed or the direct reading of a water calorimeter properly used in accordance with the procedure specified by the Code on Fuels.

Accordingly the following recommendations are made:

(a) When gaseous fuel is burned in an engine under test, a standard form of gas calorimeter shall be used as one of the instruments of the test, and its determination shall be used as the heating value of the gas as supplied. Calculations of heating value from the gas analysis are not permissible according to the code, but with all details of apparatus, methods and physical constants involved may be made the subject of previous agreement
(b) When liquid fuel is burned in an engine under test, its heating value shall be determined in a standard bomb calorimeter by a recognized physical or chemical laboratory, the selection of which

should be a matter of previous agreement, and in the report the "high value" should be used in calculating final results. In no case shall such a determination be part of the duty of a test engineer, nor should his results be regarded as acceptable

(c) The heating value of gasolines and kerosenes may be estimated by the Sherman & Kropff formula, modified by Strong, from the Bé. reading without the bomb test, if such procedure is made the subject of previous agreement.

21 Gas measurements for engine burning gaseous fuel must be made with meters or by methods yielding the greatest possible accuracy consistent with availability and cost in the large sizes.

In no case can the results of proportional meters be regarded as satisfactory, nor those of vane meters of the anemometer type. Within the limits of size and cost, positive displacement meters are to be preferred, but these are not available for measurements of large capacity.

Large capacity measurements are best made by means of one of the various types of flow-rate measurements, and that one, applied to mixed gases, should be used that requires the simplest and most accurate determination of physical or chemical properties.

When physical or chemical properties of a mixed gas must be determined for use in a metering calculation, even if only gas density direct or computed from the analysis, a recognized chemical laboratory shall be agreed upon to make the determination and its report shall be accepted and used. In no case shall the test engineer make a determination of physical or chemical properties of gases, nor shall his results be acceptable if he does so.

If measurements of volume of injection air or of scavenging air are desired, the orifice-flow method will be sufficiently correct if used as prescribed in the Code on Instruments and Apparatus, but the formula and conditions for such test must be agreed upon in advance between the engineers.

22 Liquid fuel supplied to an engine should never be measured by volume; it must be weighed directly as used. Combinations of weighing and volume measurements are acceptable if the volume of the tank itself is not the measure but only a reservoir from which the engine draws a supply, starting with a predetermined level marked by a hook gage or on a glass, and a weighed quantity subsequently supplied to restore the original level. In this case the weight is the measure and the result acceptable if proper precautions are used to limit the weight error of reading levels to something less than the error of the scale weighing.

In no case shall meters be used to measure liquid fuel supplied to an engine.

When volatile fuels are used, and especially when heavy liquid fuels containing light volatiles must be heated to make them flow, precautions must be taken to prevent losses of weighed fuel by evaporation, and the main supply must be protected against evaporation that may fractionate or concentrate it and change its quality with time.

Preparations

23 Before proceeding with a test, Pars. 4 to 8 of the "General Instructions" should be reviewed. The dimensions and physical conditions of all parts of the engine should be determined and recorded. The same should be done for all parts external to the engine to be tested, the condition of which might effect the success of the test in many ways.

24 Things external to the engine should always be given attention first, and if on inspection and preliminary trial anything should be found that might impair the value of the test, it should be corrected before starting or even before the condition of the engine is examined. In view of the great variety of engines and operating arrangements, it is impossible to enumerate all of these things, but for their suggestive value a few are noted below:

(a) Jacket-water supply should be assured in proper quantity, of proper cleanliness as to freedom from sediment, non-corrosive, and of a kind that will not deposit scale in the jackets when its temperature is raised. It is necessary also to arrange for as nearly constant a supply temperature as possible to maintain a steady state as to temperature of heated engine parts. The exceptions to this are: air-cooled engines; engines with boiling hopper jackets or with thermosiphon circulation to tanks, or with any sort of circulation of a fixed amount of water between jackets and a radiator or cooler. In these cases a proper supply of cooling water or air for the cooler or radiator must be assured. Engines operating with oil in jackets are included in the last group. Air-cooled engines must be assured of a supply of cooling air proper in amount, velocity and direction as well as temperature

(b) Engines operating with electric ignition, especially in the larger sizes, may be dependent on an external supply of current for the ignition system, or especially in small engines be supplied from primary or storage batteries. Assurance of continued supply at proper voltage for the whole test must be provided, and the most reliable means is an alternate source

(c) When liquid fuel is to be used, there should be a sufficiently large supply of the grade to be burned to last for the whole period of the test, and in the case of viscous or semi-viscous oils, which do not mix well without heating, special care should be taken to assure the mixing of new oil supplied to the tanks with that already in the tanks. This is especially important for that group of oil engines most sensitive to grade of oil

(d) Lubricating oil in sufficient quantities to complete the test should also be available before starting. When the lubricating system includes a tank or sump, especially when it is of considerable capacity, this should be drained and new oil provided or new oil in sufficient quantities properly mixed with it to prevent any changes during the test, other than those normal and incident to its operation.

25 If the engine is by previous agreement to be tested "as is," or in whatever condition it may happen to be, there is nothing further to be done before starting the test except to determine all those dimensions required to identify the engine, or necessary for the calculation of results.

On the other hand, and normally, the engine should first be put in proper condition to perform in a manner proper and normal to it, so that the test results will be not only a measure of what it did do, but also of what it is capable of doing.

In the absence of any agreement to the contrary, it will always be assumed that before starting the test the engine will be put in proper condition so far as can be done by cleaning, by stoppage of all leaks and by adjustment, including replacement of small parts, such as spark plugs or spray valves. Some suggestions are given as a guide to these several groups of items, but these must not be regarded as a substitute for the judgment of the test engineer, who should in all cases record not only the condition in which the equipment was found, but also everything done to change the condition.

26 Dimensions and other data not necessary for calculating test results but useful to identify an engine or to increase the value of future comparative analyses may properly include some items of its commercial specifications not properly classifiable as dimensions. Among such items, including some that are necessary for calculating test result, are:

(a) Bore, stroke, number of working cylinders and in the case of two-cycle engines, the same information for scavenging pumps, with notes as to single- or double-acting arrangement for either or both and notes regarding injection air compressor if used

(b) Dimensions of other principal fixed and running parts, diameter and length of all important bearings and pins, including piston rods and tail rods

(c) Dimensions of certain minor parts, fixed and running parts having important functions, such as valve lift, port area, area through mixing valves of gas-burning engines, carburetor choke area and nozzle sizes, injection-pump plunger bore and stroke, push-rod or valve-rocker clearances

(d) All items of adjustment and timing and for each cylinder of multi-cylinder engines such as spark of electric ignition engines, spray valve of injection oil engines when mechanically operated, opening and closing angles, injection pumps of injection engines delivering directly to spray valves not mechanically operated, start and stop angles, normal pump by-pass valve, timing of injection oil engines, inlet and exhaust valves of four-cycle engines opening and closing, all special valves of two-cycle engines

(e) All nameplate information, together with important identification items of specifications especially concerning attached auxiliaries, nature, size, capacities, with proper working pressures, temperatures or other items of operation or adjustment

(f) Certain dimensions in addition to the above, not matters of identity nor necessary for calculation of test results but of importance in judging the condition of the engine as a machine and useful in judging the value of the results of the test. Here are included all items of alignment, clearances of bearings, pins, rods and slides, pistons in cylinders, rings in grooves, valve stems in guides, pump plungers in pump body, throttle in seat, together with variations from straightness or roundness of cylinders, pistons and other parts.

27 Cleanliness, especially internal, is of great importance in the operation of internal-combustion engines. Attention should be given, among other things, to the following suggestions:

(a) Jacket surfaces on the heat-receiving side must be free from water scale, rust or other deposits, including carbonized oil, if oil is used

in place of water. Any deposit will cause the engine to operate unduly hot and may prevent operation entirely

(b) Combustion-chamber walls, including piston heads and all inward-facing parts, such as spark plugs, spray valves, air starting valves, relief valves, as well as inlet and exhaust valves and the ports of four-cycle engines, and the ports of two-cycle engines, should be free from deposits, especially carbon, oil, gum or tar, and solids derived from uncleaned air. This also applies to cylinder walls and piston rings

(c) The lubricating-oil system should be free of all deposits of whatever kind, and all flow passages freely and fully open, especially with circulating forced-feed systems

(d) The exhaust system, including expansion chambers, mufilers and pipes should be clean and free and so arranged as to not develop excessive back pressure. Other engines exhausting into the same system must not interfere with the engine under test. It is always preferable however that no other engines should exhaust into the system of the engine under test

(e) Fuel-supply and regulating systems must be clean and free of sediment, tar or other foreign matter, and passages fully open, especially for liquid-fuel engines, at the carburetor or injection pumps.

28 Leakages must be located and corrected. Among important leakages to be investigated attention is called to the following:

(a) Cylinder leakage outward, lowering the compression and efficiency or possibly preventing operation. These leakages may be best checked by an indicator if the engine is one suitable for indicator use. When there is any clear space between the compression and expansion lines of a card taken when there is no combustion and when cooling water is not running then it may be assumed that leakage is excessive. In this case, and in cases where an indicator cannot be used to check leakage, the several possible sources of such leakage must be separately checked. These are piston ring, cylinder, cylinder-head gasket, air starting valve, relief valve, spray valve or spark-plug seat, inlet or exhaust valves of four-cycle engines, or air scavenging valves of valve-scavenging two-cycle engines.

(b) Leakage into the cylinder may occur from the jackets through bad joints, cracks or porous spots and blowholes in the castings, compressed air from the starting air system through leaky air starting valves, fuel oil past spray valve at improper times and high-pressure spray air when air spraying is used in oil engines

(c) Miscellaneous leakages not into or out of the cylinder but elsewhere may be sought; in the manifold system of carburetor engines anywhere between carburetor and inlet-valve seat, especially at flanges and valve-stem guides; fuel oil in injection oil engines at pump valves, pump plunger, oil-delivery pipe or spray valve, lubricating oil at pump, tanks or in piping, spray air at compressor storage bottles, valves or piping, starting air at compressor storage reservoir, valves or piping. Insulation of electrical circuits must be checked as a leakage item.

29 Adjustments must be corrected if found to be wrong.

Operating Conditions

30 The operating conditions conforming to the object in view should prevail as pointed out in Par. 19 of the "General Instructions." If it is a matter of agreement that the engine is to be tested in whatever condition it may be, and under whatever conditions may prevail, then there is nothing to be done except to keep a record of all these conditions, with special emphasis on variations of every item that might effect the operation, or be useful in a subsequent effort to explain results.

On the other hand, if by agreement operating conditions are specified more or less completely, then instruments shall be used and observations made to establish their maintenance or variations.

In either case a record should be made and included in the final report.

This matter of operating conditions prevailing during the test is of very great importance in internal-combustion engines, not only because of their great variety and the corresponding variety of conditions normal to any one sort of engine, but also because the internal-combustion engine is self-contained, actually or essentially, and sensitive to many conditions within itself, not noticeable unless sought. Many of these have already been noted under "Preparations," as concerned with supplies, flows, leakages, clearances and fits or adjustments, but in addition to these there always arise questions of propriety of conditions of test in relation to conditions of service.

Doubt and confusion will always result in internal-combustion engine tests if any assumption is made to the effect that the conditions of test shall be "normal." If the word "normal" is used at all to describe the conditions, it must be defined by agreement. An agreement defining the conditions of the test is regarded as essential to all internal combustion engine tests. The definition should include all the items necessary in two groups noted below, one concerned with conditions in relation to service, and the other purely matters of test procedure.

31 Operating conditions to be maintained during the test are the ones most uncertain as will be clear from the following note:

Aircraft engines must normally work in altitudes varying from sea level to perhaps 30,000 ft., and in temperatures varying from highest in summer in the tropics, perhaps 120 deg. fahr., to the coldest known, under 50 deg. fahr. below zero, and in any weather—dry, fog clouds, rain and snow. They must also operate well at any angle of inclination and even upside down but always with an air-propeller load. In view of the fact that the only tests contemplated under this code are fixed block tests, it is clear that service conditions cannot be closely reproduced and only approximated even in the special altitude room of the Bureau of Standards with its air-refrigerating apparatus

Engines for land vehicles are essentially variable in speed and variable in load in normal operation, and must instantly respond to controls that are constantly and suddenly varied in heavy street traffic, or perhaps maintained for long periods of time in tractor or rail operation, and rarely develop maximum horsepower though frequently called upon for maximum torque. There can be no such thing as normal horsepower or speed for such engines and acceleration is quite as important as horsepower. They must, furthermore, operate on a fixed supply of jacket water or oil with an air-cooled radiator or directly air-cooled, so that external wall temperature varies not only with engine load but with vehicle speed, with weather and with climate.

As used, especially with tractors, the air supply is usually dirty, and may be heavily laden with gritty dust, requiring the use of more or less effective dust separators or air washers. Again, it is clear that service conditions cannot be maintained during the block tests contemplated by this code.

Marine engines, ranging from small single and multiple cylinder gasoline engines, often of very high speed, especially for racing boats with gear drives and clutches, to the direct-coupled large reversing low-speed Diesel oil engine of motorships of 2000–3000 hp., always with a propeller load, also operate under service conditions that cannot be reproduced in block tests.

Even stationary engines as a class while normally operating under conditions easier to reproduce in the block tests of tests in place according to this code, do also include considerable variety as to what is normal. Some of these, especially the smaller ones, such as farm engines or home lighting sets, operate for only short periods of time, and rarely if ever at full load. Others, especially those for irrigation pumping, may work continuously at the maximum possible load 24 hours per day for the irrigation period, of perhaps three months, and then be shut down for the rest of the year. Still others, especially those operating town water works or oil-pipe-line pumps may operate at full load 24 hours per day for a whole year or more. Still others, notably the generating units of central stations, must meet the widest and most sudden fluctuation of electrical load without varying in speed enough to affect voltage or synchronous operation of alternating-current systems.

The importance of agreement on these matters should be clear from these citations but the details must be left to the judgment of the test engineer.

32 Operating conditions during the test include mainly matters of load and speed to be maintained, with other points incidental to these. These should be agreed upon in all details, and should not be inconsistent with the conditions prescribed below:

(a) Engines of the stationary class, including all engine-driven generator sets, Par. 5(a), shall be tested at constant speed under governor control or as near constant as the governor will maintain it, and at whatever load in horsepower or kilowatts may be required by agreement or specific object of the test

(b) All engines for the propulsion of land vehicles, Par. 5(d), except such tractor engines as are fitted with speed governors and operate normally under governor control, shall be tested with throttle wide open, with brake torque regularly varied from nothing to a maximum and back to nothing, at whatever speeds may result, and the horsepower-speed curve typical of the engine shall be determined instead of the horsepower at any given speed. In no case should a *safe* speed be exceeded and when the highest speed used is the safe limit, it should be so stated. The maximum torque applied shall in all cases be greater than that which will produce maximum horsepower unless the speed required for this is too high to be safe

(c) Marine engines, Par. 5(b), and aircraft engines, Par. 5(c), may be tested according to the conditions prescribed for engines of land vehicles, in all respects according to conditions prescribed for stationary engines except that the speed shall be maintained by the brake torque and not by a governor. Marine engines may also be tested at constant speed for full-load operation fixed by their propellers.

Special attention should be given to questions of safety that may arise during operation, such as excess speed, or torsional vibrations at a given speed within the normal range, and the procedure to be adopted in such cases should also be included in the agreement.

Starting, Stopping and Duration

33 Before recording the test observations it is essential that an internal-combustion engine, together with all attachments and

appurtenances, be brought to a condition of *steady state.* The test cannot be considered as having started until the engine has been in operation for a sufficiently long time to have attained its steady state for the conditions of the first run, and until preliminary observations have been made and recorded to prove that such steady state has been reached. If successive runs are to be made, each under some different conditions, these must be repeated for each run.

The preliminary observations establishing the attainment of a steady state for the conditions of operation of the test or each run of the test, must be made a part of the record.

For an internal-combustion engine itself this is a matter of utmost importance, because the combustion chamber is a furnace in which heat is developed at a given rate, depending on the fuel burned per minute in each cylinder (or each end), and in which the metal temperatures vary with this rate of combustion. Metal temperatures vitally affect the performance of the engine especially those of cylinder, cylinder head, and piston, with all attached parts, and in addition those of all bearings.

The length of time necessary to establish the steady state will be different in engines of different class, and in any one class different for different sizes. In general, the weight of metal in contact with the combustion chamber directly or indirectly through thermal conduction will determine the length of time necessary, but the rate of combustion in B.t.u. per hour per square foot of cylinder area will also be a factor. The greater the metal weight and the lower the rate of combustion the larger the time necessary to reach the steady state. While jacket-water or oil temperatures are important factors, they are not the controlling ones. Lubricating-oil temperature in the sump or leaving the bearings in a circulating system, is a guide to steady state of both bearings and of combustion-chamber metal, but not a conclusive one. In no case shall an engine be regarded as having attained its steady state unless jacket and lubricating-oil temperatures are substantially constant.

The means whereby the attainment of the steady state is proved must be a matter of agreement, but the time of operation itself for the preliminary period may be substituted.

In no case shall steady state for the first run be regarded as established in a shorter time than one hour after the operating conditions have been imposed and before test observations have started. For successive runs at other conditions the minimum time for any engine shall be ten minutes, the actual time being determined by the extent to which conditions are changed in successive run. Maximum time to reach the steady state for any internal-combustion engine shall not be taken as greater than 24 hours, which may be regarded as permissible for the largest sizes of low-speed Diesel engines for motorships and double-acting stationary gas engines.

34 The duration of the test after the establishment of steady state for the set operating conditions shall be a matter of previous agreement, but should be greater for engines where reliability is a question of importance and which require the longest time to reach the steady state.

In no case shall the length of run be less than the period required to reach the steady state, subject to the additional condition that the length of run shall be great enough to insure the accuracy of fuel measurement within 1 per cent, except when gaseous fuel is metered and when metering accuracy is not improved by lengthened runs.

In some cases it may be found desirable to make a physical inspection of engine parts after the test to determine injury due to operation, but only when agreement has been made as to details should this be done.

Records

35 The general data should be recorded as pointed out in Pars. 20 to 30 of the "General Instructions." Instruments should be read at least quarter-hourly when the conditions are uniform, and oftener when there is much variation. Indicator cards, if taken, must be taken from every working cylinder of multi-cylinder engines. If there are wide fluctuations in readings, they should be shown by recording instruments.

Each indicator card should be marked when taken, with the number, date, time, scale of spring, number and kind of cylinder and end of cylinder, if double-acting.

The log should contain the records of the readings of all instruments, and these readings should be obtained at practically the same time as the indicator cards, if any, are taken.

If indicator cards are taken, the areas, lengths, mean effective pressures, compression pressures and maximum cylinder pressures, should all be recorded in the log. One or more sets of specimen indicator diagrams should be carefully selected for inclusion in the record. If, after taking indicator cards they are rejected, because of excessive fluctuation in area or insufficient area with high pressures for accuracy, a sample set of the rejected cards shall be included in the record with the data to support the rejection and justify the elimination of indicated horsepower from the results.

Calculation of Results

36 The calculations necessary for deriving results from observations or from physical constants should not be undertaken without previously consulting Pars. 31 to 35 of the "General Instructions," and the Code on Definitions and Values.

37 *Fuel Consumption.* For liquid-fuel engines the actual fuel measured is stated in pounds in the report of the test, and is subject to no corrections.

For gaseous-fuel engines the cubic feet of gas at whatever pressure and temperature prevailed, indicated or recorded by the meter or calculated from the reading flow-rate devices, is stated in the report of the test. This is to be corrected for the pressure and temperature at which the gas calorimeter burned the gas. The correction is to be made by multiplying the cubic feet of gas measured by the ratio of the absolute pressure at the meter to that at the calorimeter and by the ratio of the absolute temperature of the gas at the calorimeter to that at the gas meter. The product is the cubic feet of gas supplied to the engine measured at gas-calorimeter pressure and temperature.

38 *Heat Consumption.* The number of heat units consumed by an engine per hour is found by multiplying the consumption by the heating value. The heating value for gaseous fuels is stated in the report of the test as found by the gas calorimeter, in B.t.u. per cubic foot, high value. The heating value of liquid fuels is stated in the report of the physical or chemical laboratory engaged for the determination, in B.t.u. per pound of fuel, high value.

39 *Indicated Horsepower.* If indicated-horsepower determinations have been specified in the agreement before test and when the indicator can be used, and when in addition after using it the indicator cards are found to be acceptable as to accuracy for determining mean effective pressure, per Par. 16, then the indicated horsepower shall be calculated as follows:

For four-cycle engines the indicated horsepower for each single-acting cylinder and for each end of each double-acting cylinder shall be found by using the formula—

$$\text{I.hp.} = \frac{PLAN}{2 \times 33000}$$

where P represents the mean effective pressure in pounds per square inch; L the length of the stroke in feet; A the area in square inches of the piston less the area of the piston rod or tail rod, if any; and N the number of revolutions per minute. The total indicated horsepower of a double-acting cylinder is the sum of the horsepower developed in the two ends, and the indicated horsepower of a multi-cylinder engine is the sum of the horsepower developed in each cylinder.

For two-cycle engines the indicated horsepower for each single-acting working cylinder, and for each end of each double-acting working cylinder, shall be found by using the formula—

$$\text{I.hp.} = \frac{PLAN}{33000}$$

where the symbols have the same meaning as above. The total indicated horsepower of all working cylinders is the sum of the horsepower developed in each cylinder, and in each double-acting cylinder it is the sum of the horsepower developed in each end.

The mean effective pressure, P, should be found by dividing the area of the diagram in square inches, as determined with a correct planimeter, by the length of the diagram, in inches, and multiplying the quotient by the average corrected scale of the indicator spring.

Accuracy tests must be applied to determine the acceptability of the mean effective pressure thus determined, especially when cylinder pressures and spring scales are high (as for injection oil engines) and card areas small, as is more usual for two-cycle engines of smaller size.

40 *Brake Horsepower.* The brake horsepower is found by multiplying the net force, W in pounds on the brake arm, by the circumference of the circle whose radius is the horizontal distance, L, in feet between the center of the shaft and the bearing point or weight center at the end of the brake arm, and by N, the number of revolutions of the brake shaft per minute, and dividing the final product by 33,000.

$$\text{B.hp.} = \frac{2\pi LWN}{33000}$$

Reference must be made to the Code on Instruments and Apparatus for descriptions of brakes, especially the hydraulic and electric dynamometer types, referred to in Par. 17 for methods of applying them, and especially for methods of correctly determining the net force W from the gross force, and for incidental or special errors in brake use and calculations.

41 *Electrical Horsepower.* The electrical horsepower of a generator is found by dividing the output at the terminals expressed in kilowatts by the constant 0.7457. In the case of an alternating-current generator, the quantity of output determined whether expressed in electrical horsepower or kilowatts, should be the net output. When the power for excitation or ventilation is taken directly from the engine shaft, the net output is that indicated at the terminals. When the exciting current is obtained from the generator through a motor or from some outside source, the net output is found by deducting the current furnished as excitation from that delivered at the terminals. When the exciter is driven from the engine shaft, the engine supplies the belt losses and the exciter losses without being credited. When the exciting current is obtained from the generator through a motor, and the excitation current is deducted from that delivered at the terminals, the exciter losses are not credited. Where as with a separately driven exciter, it is really the exciter net output which is deducted from the power delivered at the terminals. In a close test these differences may be of some interest. It is regarded as important to have the basis of power determination definitely agreed to in advance to suit the particular case and to be suitable to local conditions prevailing.

42 *Thermal Efficiency.* The fraction of the heat consumption converted into work is the "thermal efficiency" and is found by dividing 2547 (B.t.u. equivalent to 1 hp-hr.) by the number of heat units actually supplied per indicated hp-hr., Par. 37. The quotient is multiplied by 100 to express the thermal efficiency in per cent. The formula is

$$\text{Thermal Efficiency} = \frac{2547}{HQ}$$

where H = heating value of the fuel (high value), B.t.u. per pound or per cubic foot and Q = amount of fuel supplied per indicated horsepower hour, pounds or cubic feet.

Data and Results

43 The data and results should be reported in accordance with the form of Table 1 for horsepower tests made at constant speed, and in accordance with the form of Table 2 and chart, Fig. 1, for horsepower tests made over the whole speed range of a variable-speed engine. Lines may be omitted if not required for the object of the test, or new lines may be added for additional data desired. For marine engines either or both forms may be used.

TABLE 1 DATA AND RESULTS OF INTERNAL-COMBUSTION ENGINE TEST AT CONSTANT SPEED

General Information

(1) Date of test..
(2) Location..
(3) Owner..
(4) Builder..
(5) Test conducted by..
(6) Object of test..

Description, Dimensions, etc.

(7) Type of engine, two- or four-cycle, single- or double-acting, horizontal or vertical, if four cycle, the valve arrangement L, T, or I head, if two-cycle, the type of scavenging, if single-acting, whether crosshead or trunk piston, if multi-cylinder the arrangement of cylinders and cranks, gas or liquid fuel, and if liquid fuel, carburetor type, or other class name fixing manner of treating fuel, such as Hvid, Diesel, or solid injection for example..
(8) Class of service, stationary and special feature, marine, aircraft or vehicle, and what kind..
(9) Auxiliaries attached, such as magneto, fuel-injection pump, fuel-circulating pump, lubricating-oil pumps, jacket circulating pumps, scavenging pumps, spray-air compressor, maneuvering or starting air compressor, radiator fans, oil or fuel coolers or heaters..............
(10) Auxiliaries, independent or separately driven, and power..........
(11) Details of type, capacity, maker's name and other features of auxiliaries..
(12) Rated brake horsepower of engine, or kw. of electric generating set, and speed..
(13) Grade of fuel for which engine is designed, kind of gas or specification of liquid fuel, and what was used in test..................
(14) Special structural features for fuel utilization..................
(15) Special structural features of speed and power control, and governor or reversing gear..
Number of working cylinders..
(16) Diameter of all cylinders working, 4-cycle or 2-cycle..........in.
(17) Diameter of piston and tail rods of working cylinders.........in.
(18) Stroke of working cylinders..............................ft.
(19) Head-end hp. constant for working cylinders, (stroke × net piston area ÷ 33,000)..
(20) Crank-end hp. constant for working cylinders, (stroke × net piston area ÷ 33,000)..
(21) Capacity of generator or other apparatus consuming power of engine..
(22) Characteristics of generator,—d.c. or a.c., volts, cycles, phase....

Test Data and Results

(23) Duration of test.......................................hr.

Pressures, Average

(24) Barometric pressure......in. of mercury......lb. per sq. in.
(25) Spray-air pressure (air injection Diesel engines) average (say whether gage or absolute)..........................lb. per sq. in.
(26) Exhaust back pressure..............................in. of water
(27) Jacket water supply pressure..........................lb. per sq. in.
(28) Manifold vacuum (carburetor engines).............in. of water
(29) Gas pressure in main gaseous fuel....inches water..lb. per sq. in.
(30) Lubricating-oil pressure, circulating forced-feed system...... ....lb. per sq. in.
(31) Scavenging-air pressure average, two-cycle engines..lb. per sq. in.

Temperatures

(32) Engine-room temperature..........................deg. fahr.
(33) Temperature of fuel..................................deg. fahr.
(34) Temperature of main air supply....................deg. fahr
Location of thermometer..
(35) Temperature of main jacket water or oil inlet..........deg. fahr.
(36) Temperature of main jacket water or oil outlet........deg. fahr.
(37) Temperature at inlet of separate jacket ....deg. fahr.
(38) Temperature at outlet of separate jacket ....deg. fahr.
(39) Temperature of mixture at intake port (carburetor engine) ....deg. fahr.

Fuel Properties

(40) Heating value of gas, high value..............B.t.u. per cu. ft.
(41) Heating value of liquid fuel, high value............B.t.u. per lb.

Total Quantities

(42) Total gaseous fuel at meter pressure & temperature cu. ft
(43) Correction factor for gas (Item 29 × Item 33 + 460 ÷ Item 29 × Item 39 + 460)..
(44) Total gaseous fuel at carburetor or atmospheric pressure....cu. ft.
(45) Total liquid fuel..lb.

Hourly Quantities

(46) Total gaseous fuel per hour at calorimeter or atmospheric pressure and temperature...cu. ft.
(47) Total liquid fuel per hour..................................lb.

Heat Consumption

(48) Total heat in fuel supplied per hour (Item 46 × Item 40, or Item 47 × Item 41)..B.t.u.

Indicator Diagrams

(49) Mean effective pressure, average, four-cycle.........lb. per sq. in.
(50) Mean effective pressure working cylinders, average, two-cycle ....lb. per sq. in.

Speed

(51) Revolutions per minute.................................r.p.m.
(52) Piston speed ....ft. per min.

Power

(53) Indicated horsepower of all working cylinders..............i.hp.
(54) Indicated horsepower of each single acting cylinder, or each end of each double acting four cycle
No. 1 head end..i.hp.
No. 1 crank end ....i.hp.
No. 2 head end..i.hp.
No. 3 crank end...i.hp.
etc.

(55) Brake horsepower developed by whole engine by brake or dynamometer measurement . . . . b.hp.
(a) Brake mean effective pressure . . . . lb. per sq. in.
(56) Total horsepower of independent scavenging pump and injection air compressor . . . . hp.
(57) Net or actual brake horsepower of engine, (Item 55 − Item 56) . . . . b.hp.
(a) Net brake mean effective pressure . . . . lb. per sq. in.
(b) Net torque at 1 ft. radius equivalent to brake horsepower . . . . ft-lb.
(58) Friction and attached auxiliaries horsepower (Item 53–Item 55) . . . . hp.

Economy Results
Fuel consumption per i.hp-hr., gas (Item 46 ÷ Item 53) . . cu. ft.
Fuel consumption per i.hp-hr., liquid (Item 47 ÷ Item 53) . . . . lb.
(59) Fuel consumption per b.hp-hr.: Gas (Item 46 ÷ Item 57) . . . . cu. ft.
Liquid (Item 47 ÷ Item 57) . . . . lb.
(60) Heat consumed per i.hp-hr.: (Item 48 ÷ Item 53) . . . . B.t.u.
(61) Heat consumed per b.hp-hr. (Item 48 ÷ Item 57) . . . . B.t.u.

Efficiency Results
(62) Thermal efficiency referred to i.hp. (2547 ÷ Item 60) . . per cent
(63) Thermal efficiency referred to b.hp. (2547 ÷ Item 61) . . per cent

Specimen Diagrams

Economic Features of the Machine-Tool Industry

(Continued from page 153)

times. That reserve is cost, not profit. If he does not have such a reserve he goes out of business by the bankruptcy route. An investigation showed that although they made a large part of the output, representative machine-tool companies did not earn quite 9 per cent on their investment for 10 years preceding the war. All of those earnings could not be taken out in cash dividends. Most of the earnings were reserves to carry over depressions.

Before the war, machine-tool prices were very low compared to the utility they gave their buyers. The prices advanced with the war, but advanced far less than prices of most war goods. The industry made money of course, but out of larger production, not out of excessive prices. The tax laws penalized the industry unjustly. The machine-tool builders financed their own expansion instead of asking the Government to do it. They now find themselves with expanded capacity that is much too large for any demand likely to arise in a few years. The prewar demand was largely foreign, and that is gone. Likewise the rapid growth of the automobile industry required many machine tools that have now been supplied. The second-hand market was glutted with all sorts of tools from dismantled war shops. All these factors combined to make the machine-tool business a very unhappy one for nearly three years.

As to remedies, the machine-tool builders have few choices. The first is, to design something new and revolutionary that will make a new market by obsolescence of old types. Naturally, this is not easy, and very few companies will be able to work out this plan.

The second is, by mergers and consolidations to reconcentrate the industry in fewer shops and reduce overhead in proportion. But the individualistic machine-tool builder prefers to be his own boss, and may do his best work as such.

The third choice is to take on some entirely different product along with machine tools, which involves establishing an entirely separate selling plan, connections, etc.—not an easy thing to do.

The fourth choice, for those who cannot for any reason take either of the other three, is to quit the field before bankruptcy closes the shop doors.

The machine-tool industry has an ethical standard—that simple one on which dependeth all the law and the profits, the Golden Rule. Through long years the leading machine-tool builders have built up their business on that standard. The violation of the Golden Rule by some of their customers cost them a lot of money in the deflation of the last boom.

Abuses became so audacious and common that the industry is now determined that the Golden Rule is good enough to work both ways. To protect the industry and its honorable, considerate customers, steps are being taken to make available to the industry full information regarding those who use unfair methods of various sorts. The responsible, reliable machine-tool builder will hereafter take an order to be a contract, not a buyer's option subject to cancellation. He believes in a price that is right all round, right for the customer, right for his own stockholders, for his employees, for his family, and for himself. He believes in the same price for all his customers, without the discriminatory shading here and there that only gives some shrewd buyers an inside edge on the fair ones who are willing to pay a right price.

As a result of the depression of 1921 and 1922 the wide-awake machine-tool builder is giving close attention to the economics of his industry and the nature of his demand. He is studying what to do and what not to do at various stages of his business cycle. He is contributing statistics whereby the stages of his cycle are disclosed. In his mind he is correlating his shop as a part of the industry, and his industry as a part of the big industrial machine that turns out goods of all kinds for the world's comfort. He realizes that his is one of the intermittent gears in the machine, and that as long as the other elements of the machine compel him to work so much more slowly at times, he must regulate his finances so as not to get caught in a squeeze. Such correlation will make a better industry with sounder, saner conditions than the machine-tool builder has ever known, either in booms or depressions.

ENGINEERING RESEARCH

A Department Conducted by the Research Committee of the A.S.M.E.

Résumé of the Month

A—Research Results

The purpose of this section of Engineering Research is to give the origin of research information which has been completed, to give a résumé of research results with formulas or curves where such may be readily given, and to report results of non-extensive researches which in the opinion of the investigators do not warrant a paper.

Electrochemistry A1-23. A New Method for Determining the Rate of Sulphation of Storage-Battery Plates. Technologic Paper No. 225 of the Bureau of Standards, just issued, describes experiments which have been made to develop a speedy and accurate method for measuring the effect of impurities in storage-battery electrolyte. In the present paper the fundamental theory of the method and measurements of the rate of sulphation of the plates in the pure acid are given. An extension of the investigation is planned which will include the effect of added impurities following the method here described. Address Superintendent of Documents, Government Printing Office, Washington, D. C. Price 5 cents.

Fluid Flow A1-23. Experiments in the Flow of Water in Vertical Tubes of Diverging Cross-Section. Messrs. R. H. Morris and A. J. Houston have recently completed a series of experiments on this subject at the Hydraulic Laboratory of the Massachusetts Institute of Technology. This research was a continuation of the one carried on a year or so previous under the direction of Prof. George E. Russell.

It was hoped to establish some relation between the length and angle of the tube, or the length and ratio of end areas, which would give the maximum discharge for a given head. The authors in their conclusions state that, while the data obtained are unsufficient to warrant the deduction of any general formula expressing the relation between angle and length of tube which would give the greatest discharge for a given head, it may be quite definitely said that, within the limits of the present investigation, for any given head, the longer the tube the greater the discharge and, for a given length of tube, the maximum discharge is obtained with a tube having an angle of between seven and ten degrees. They feel that there is a great field for further investigation along these lines.

One copy of this research is on file with the Librarian of the Engineering Societies Library, 29 West 39th Street, New York.

Fuel Utilization A1-23. Carbon Monoxide in the Products of Combustion from Natural-Gas Burners. Many gas appliances are notoriously inefficient. Solid-top stoves with low-set burners and grid-top stoves with low-set burners consume from two to eight times as much gas as stoves with raised burners and grid tops. On account of the liberation of carbon monoxide, a poisonous gas, with the products of combustion when the flame is improperly aerated, it is not practical to place burners at the distance from utensils where the maximum efficiency is obtained. Burners of the "star" type should be placed about one in., the "slot" burner about $^3/_4$ in., and the "disk" type about $1^1/_4$ in. from the utensil.

From the many tests for carbon monoxide made with five different burners and different types of flames at rates of consumption of 6.0 and 8.0 cu. ft. per hour (6480 and 8640 B.t.u. per hour), the maximum rate of liberation of carbon monoxide was found to be 0.25 cu. ft. per hour and was obtained with a very soft flame and a close position of utensil which caused the flame to "float" and extend up the side of utensil. It is not a dangerous rate unless one works directly over the bürner, or several burners are in use at the same time for several hours, or the room is unventilated.

No carbon monoxide was found where the blue inner cone of the flame was not allowed to touch the utensil. A yellow flame will produce carbon monoxide at a rate much greater than a blue flame when the utensil is so close to the burner as to cause a floating flame.

A natural-gas flame was found to be smothered from deficiency of oxygen when the content of the atmosphere had been diminished to about 15.5 per cent. When one considers the natural ventilation which takes place through the windows and doors it would seem that the danger from carbon monoxide poisoning with natural-gas top burners is quite remote.

This Technologic Paper No. 212 of the Bureau of Standards was prepared by Messrs. I. V. Brumbaugh and G. W. Jones and may be obtained from the Superintendent of Documents, Government Printing Office, Washington, D. C., for 10 cents.

Fuel Utilization A2-23. Value of Coke, Anthracite, and Bituminous Coal for Generating Steam in a Low-Pressure Cast-Iron Boiler. Technical Paper No. 303 of the Bureau of Mines records the results of a series of tests conducted primarily for the purpose of determining the relative steaming values of coke, anthracite, and bituminous coal when burned in a low-pressure boiler, and fired by hand in fairly large quantities at a time.

A secondary purpose of the tests was to separate the heat losses, and to examine them carefully to determine the change in efficiency with the method of firing the fuel and manipulation of the draft dampers, with the rate of evaporation, and with the various fuels burned.

Address Superintendent of Documents, Government Printing Office, Washington, D. C., for a copy of this paper. Price per copy, 10 cents.

Fuel Utilization A3-23. Economic Combustion of Waste Fuels. Since its establishment the Bureau of Mines has conducted investigations relating to efficiency in the utilization of fuels, including the utilization of fuels of such low grade that they are in many places classed as waste. Because of the decreasing supply and increasing cost of high-grade fuels, the efficient utilization of those that are low-grade is becoming a problem of major importance to many industries and to the commercial progress of the nation. The data in this paper, consequently, are published as a contribution to the literature on the conservation of national resources.

This bulletin known as Technical Paper No. 279 was prepared by Mr. David Moffat Myers. It consists of 51 pages and may be obtained for 10 cents from the Superintendent of Documents, Government Printing Office, Washington, D. C.

Fuels A1-23. Economic Combustion of Waste Fuels. See *Fuel Utilization A3-23.*

Gases A1-23. Carbon Monoxide in the Products of Combustion from Natural-Gas Burners. See *Fuel Utilization A1-23*

Gases A2-23. Fixation and Utilization of Nitrogen. This report has been prepared in order to correlate and make available under one cover such information on the fixation and utilization of nitrogen, collected by the Nitrate Division since its organization in July, 1917, as may aid in the further development of that art in the United States. It was prepared with the assistance of the Fixed Nitrogen Research Laboratory of the Department of Agriculture and is based to a very considerable extent on reports, papers and articles prepared by the officers and civilians associated from time to time with the activities of the Nitrate Division, as well as on the published technical and economic papers of several others. A bibliography of many of the papers pertaining thereto that have appeared in the last few years is included. Address Nitrate Division, Ordnance Office, War Department, Washington, D. C.

Lubricants A1-23 Reclamation of Used Petroleum Lubricating Oils. A series of tests recently completed by the Bureau of Standards' staff have demonstrated that used lubricating oils may be reclaimed by apparatus already commercially available and thus saved for further use. Such reclaimed oils will pass all the commonly accepted tests for new oils, such as flash point, viscosity, and sediment. This investigation is fully described in Technologic Paper No. 223 of the Bureau of Standards, for sale by the Superintendent of Documents, Government Printing Office, Washington, D. C. at 5 cents per copy.

Petroleum and Allied Substances A1-23. Reclamation of Used Petroleum Lubricating Oils. See *Lubricants A1-23.*

Radioactivity A1-23. Mesothorium. The chemistry of mesothorium, the radioactive element found in monazite sand and other thorium minerals, which is used as a substitute for radium in the manufacture of certain luminous paints and for medicinal purposes, is discussed in Technical Paper 265, just issued by the United States Bureau of Mines.

B—Research in Progress

The purpose of this section of Engineering Research is to bring together those who are working on the same problem for coöperation or conference, to prevent unnecessary duplication of work, and to inform the profession of the investigators who are engaged upon research problems. The addresses of these investigators are given for the purpose of correspondence.

Building Materials B1-23. Fire Resistance of Hollow Building Tile. An investigation of the fire resistance and related physical properties of hollow building tile has been conducted by the Bureau of Standards during the past two years in coöperation with the Hollow Building Tile Association. A furnace, suitable for making fire tests of small panels up to 4 ft. square, was built and tests of unprotected panels built from tile of representative clays have been made in order to establish characteristic behavior under fire. A wide range in fire resistance was found, depending mainly on the mineral composition of the clays employed. As a possible means of increasing fire-resisting properties, grog additions up to 10 per cent were tried, but it was found that the small addition which can be conveniently made in manufacturing practice had no effect, and that additions of 5 per cent or more decreased the fire resistance. The protection afforded by typical plasters has been determined, obtaining, generally excellent results.

The effect of the addition of combustible filler to the raw material, of the fineness of grinding of the raw material, of the size of the unit, and of changes in design of the tile, will be ascertained. Address the Director of Bureau of Standards, Washington, D. C.

Fire Prevention B1-23. Fire Resistance of Hollow Building Tile. See *Building Materials B1-23.*

Electrical Instruments B1-23. Electric Telemeter. During the past two years or more the Bureau of Standards has been engaged in developing electric telemetric devices based upon the fact that carbon contact resistances vary with pressures or displacements applied to their terminals. In the past there have been several inherent difficulties with apparatus of this kind. The Bureau has investigated all of these sources of trouble and has found means of eliminating all of them to a degree which makes the apparatus well adapted to a great variety of engineering measurements.

These measurements include those of strains in bridge members and other engineering structures, of accelerations, vibrations, and pressures of practically every description. The apparatus can be made either indicating or recording as desired. Up to the present time both indicating and recording instruments embodying this principle have been made for and largely used by the Bureau of Aeronautics of the Navy Department for measuring stresses both in airplane members and dirigibles where it is very important to read such stresses at a point more or less remote from the member under test. Similar apparatus has also been used extensively by the Bureau of Standards in laboratory tests on large structural members and also in connection with certain dynamometer work, and for much of this work the new instruments have been found to be substantially equal in accuracy to anything heretofore available in the line of indicating instruments, and they possess the additional advantage of permitting remote reading as well as graphic records to be made when desirable. Work is now in progress on the extension of the field of application of these instruments to various lines of engineering work to which they are adapted.

Instruments and Apparatus B1-23. Electric Telemeter. See *Electrical Instruments B1-23.*

F—Bibliographies

The purpose of this section of Engineering Research is to inform the profession of bibliographies which have been prepared. In general this work is done at the expense of the Society. Extensive bibliographies require the approval of the Research Committee. All bibliographies are loaned for a period of one month only. Additional copies are available, however, for periods of two weeks to members of the A.S.M.E These bibliographies are on file at the headquarters of the Society.

Electricity, General F1-23. Electrical Insulating Material. In connection with the Bureau's investigation of the properties of certain types of electrical insulating materials, a rather comprehensive bibliography of papers, books, patents, and periodicals has been prepared.

Since a considerable demand has arisen for copies of these, they have been issued in mimeographed form as Letter Circulars Nos. 50 and 51 "Bibliography of books and titles of periodicals on properties and uses of insulating materials" and "Lists of the more important U. S. patents covering the materials and methods of manufacture of an insulating material." Only a limited supply of these two letter circulars is available, but a copy will be sent on request, as long as the supply lasts, to any person who can show an actual need for them. Address the Director, Bureau of Standards, Washington, D. C.

Gases F2-23. Fixation and Utilization of Nitrogen. An eleven-page bibliography on this subject forms an appendix to Report No. 2041 of the Nitrate Division of the War Department just issued. It contains references to material published from 1917 to the present.

CORRESPONDENCE

Contributions to the Correspondence Department of Mechanical Engineering are solicited. Contributions particularly welcomed are discussions of papers published in this journal, brief articles of current interest to mechanical engineers, or comments from members of The American Society of Mechanical Engineers on activities and policies of the Society in Research and Standardization.

The Surge-Tank Problem

In discussing a paper on surge tanks by Professor Durand[1] which appeared in the October, 1921, issue of Mechanical Engineering (p. 643), R. D. Johnson,[2] in a letter published in a later issue (August, 1922, p. 541) stated that a differential surge tank *without exception* is cheaper than a simple surge tank for fulfilling the same conditions. This statement was challenged by B. F. Jakobsen[3] in a communication printed in Mechanical Engineering, November, 1922, p. 764, and further in the closure to the discussion of his paper on surge tanks before the American Society of Civil Engineers. The paper in question is mainly devoted to a general consideration of the problem of surge-tank action in the Kerckhoff plant of the San Joaquin Light and Power Corporation. Special reference is made to the design and tests of the Kerckhoff surge tank, a simple cone-shaped tank 17 ft. in diameter at the top and 39.5 ft. at the bottom.

In his closure Mr. Jakobsen states that the Larner-Johnson Valve and Engineering Co. was asked to furnish a design of a differential surge tank and accordingly submitted one consisting of two independent shafts, one 7 ft. in diameter rising directly above the tunnel, and the other 20 ft. in diameter offset from the tunnel and connected at the bottom to the tunnel and at the top to the riser. This design was not adopted because it would have been as expensive to excavate as the simple surge tank, and also for the following reasons:

"This differential surge tank would permit an increase from no load to full load in 3 min., as will also the Kerckhoff surge tank. For such a load increase, this tank is comparable with the Kerckhoff tank. However, when the load is increased instantaneously, or within a few seconds, from 1000 to 1500 sec-ft. (1500 sec-ft. being about full load on the plant), the water surface in the differential surge tank is decreased from Elevation 965 to Elevation 932, or the head on the plant is reduced by 33 ft. (about 10 per cent of the total head) in 10 sec.; whereas in the Kerckhoff surge tank the decrease in head is only 8 ft. in 10 sec. Both surge tanks meet the condition imposed on them, but during the first minute after the turbine gates have opened, the plant with the Kerchkoff surge tank supplies on an average nearly 2000 kw. more than the one with the differential surge tank, and 10 sec. after the moment of regulation the Kerckhoff surge tank supplies about 2700 kw. more than the differential surge tank. As this is nearly the ultimate capacity of the plant and for nearly full gate and at a time when every kilowatt counts, it is an advantage in favor of the Kerckhoff surge tank. The normal full load on the Kerckhoff plant is 35,000 kw., although 40,000 kw. have been generated for several hours when the tail-race elevation was relatively low."

Denying the statement of R. D. Johnson that the differential principle produces without exception a cheaper tank, Mr. Jakobsen believes that "the differential surge tank has its advantages, but it is not always the best possible type, as is shown by the previous discussion. Each plant requires a special study, and the size and shape of the tank depend on the conditions to be met and the physical constants of the plant. The success of the design depends also largely on the designer's ability to appreciate properly the operating conditions which will be imposed on the plant."

The dispute between Mr. Jakobsen and the advocates of the differential surge-tank principle resolves itself, therefore, not to the question as to whether the differential surge tank has its advantages over the simple type under conditions favorable to the former, but whether there can be any conditions under which the simple tank might be preferred, and, in particular, whether the conditions at the Kerckhoff project were such as to warrant the use of the differential surge tank in preference to the simple surge tank.

The editors have recived a number of letters advocating the differential-tank principle, but because of lack of space it is impossible to reproduce all of them, notwithstanding their interest. It has

[1] Prof. M. E., Leland Stanford Jr. Univ., Past Vice-Pres. Am.Soc.M.E.
[2] Hydraulic Engr., New York, N. Y. Mem. Am Soc M.E.
[3] Construction, Hydraulic and Electrical Engr, Fresno, Cal

been decided, therefore, to publish in full a communication received from Mr. Johnson, the earliest champion of the cause of the differential surge tank, and to give extracts from the other letters. It is believed that this will serve to bring out the salient points of the discussion.

R. D. Johnson's Letter of November 29

To the Editor:

With further reference to my letter on the subject of Surge Tanks, appearing in your December number, I now have in hand a reprint of Mr. Jackobsen's closure of his A.S.C.E. paper to which he referred in your November issue and therefore I can answer his statements with a little more idea of what he is driving at.

He shows two surge diagrams, one for a small differential surge tank and one for a larger conical simple tank, which have the same amplitude of surge for a given instantaneous load change.

The load on the plant previous to the instantaneous load demand is the same in both cases and is proportional to the product of 1000 c.f.s. and a head represented by elevation 961 at the tank. The load change, he says, is such as to practically reach the limit of the capacity of the turbines, when discharging 1500 c.f.s. at the lessened head (equal in the two cases) which exists at the lowest point of the surge shown as Elevation 932. These two cases are therefore equivalent, if the computations are correct, and serve in no way to prove his contention of a "distinct disadvantage." There is obviously no shortage of power of 2000 or 2700 kw. or any other amount and it was some time before I could guess where he got this idea, but it appears that he has figured a hypothetical shortage proportional to the difference of head, in the two cases, at precisely the same time abscissas, which, of course, has no practical bearing on the case

It seems superfluous to point out that power output is made up of two factors, one of which is the head on which Mr. Jakobsen bases his conclusions and the other, which he does not take into account, is the varying discharge of the turbines during a surge due to the action of the governor in its effort to maintain at constant value the additional load which has been assumed to be suddenly demanded in the beginning.

The governor is capable of moving at a far greater rate of speed than is required to follow up the drop of water level either in a simple tank or in a differential regulator of proper design with adequate area of riser. The sudden accession of load is therefore adhered to in either case, if the governor is any good.

If he has inadvertently assumed a constant discharge of the turbines during the surge, thus making it possible to claim a shortage in power output proportional to a difference in head (at the same time abscissas in the two cases), he is then subverting the facts in substantiation of a claim which has no bearing on the practical operation of a power plant.

Some light on his method of figuring surges may be gleaned from a glance at his Fig. 9. This purports to be a surge diagram following a gradual increase in load from 9,000 to 27,850 kw. in 70 sec., after which, during the remaining minutes shown in the figure, the load is supposed to be maintained constant. At least, he gives the same figure for it when the water quiets down at Elevation 970.2.

While this is quite possible with a varying discharge through the turbines, it stretches the imagination to understand how the load can remain constant with a constant discharge of 1145 c.f.s. while, at the same time, the head is varying from elevation 954.1 to elevation 982.3, which variation, with a constant discharge of the turbines, would amount to as much as 3000 hp. to say nothing about the magic invoked to keep the discharge constant. An explanation of this is desirable.

This little study may furnish an index to his process of thought and may account for his views in regard to a shortage of power, due to differential action.

The two equivalent tanks which he illustrates differ in volume and they could only be considered to cost the same, as he says they do, by using a larger unit price on the extra shaft for the riser; but it is well known that the riser may just as well be placed within the tank, by adding its volume to the single excavation, or it might be run up on the outside slope of the hill, if the topography is suitable for such a course.

This particular sketch, I find upon inquiry, is a study which passed out of the office of the Larner-Johnson Valve and Engineering Company in the course of correspondence, setting forth arguments in favor of the differential regulator, and it never had any such final consideration as is always given to a design, favorably received, where there seems to be a desire to go thoroughly into the matter, looking toward its adoption.

Fortunately, it seems to be about all right, on casual inspection, except that neither this regulator with its small riser nor his own surge tank would be considered adequate for the usual requirements with which we are familiar, especially for low or medium-high heads.

Frequently such plants are fed by wood-stave pipe lines regulated by steel tanks built on high towers, where spilling large rates of flow at a high elevation is economically out of the question and where every foot of surge both upward and downward is a matter of importance. These are the very cases for which Mr. Jakobsen promised, at least by implication, to set forth in his advertised article, something better than the differential regulator and many will be disappointed to find nothing in support of his assertions.

The surge in the Kerckhoff tank, shown in Fig. 16 (Waldman's discussion of Jakobsen's paper), does not take into account the augmenting effect of governor action, and inasmuch as this is the only thing which works against the friction of the conduit to increase and keep alive fluctuations in water level, it will probably be clear to those familiar with these questions that the surges as shown would be much amplified if the customary governing action was to be imposed upon them.

Even here it will be seen that the water level returns, upon the first recoil, to an elevation slightly greater than that at which it started, although no load has meantime been rejected. This condition would of course be worse with a governor trying to hold the power output at constant value.

When a power plant is supposed, at times, to stand upon its own feet in respect to regulation and not therefore always able to shift some of its responsibility to other plants in parallel, which may be better equipped for the purpose, it is not considered good practice to permit much instability in the water level.

In Mr. Jakobsen's closing words, he distinctly leaves it to be inferred that rapid damping of oscillations is due to the conical shape of a surge tank.

With the use of a simple tank of whatever shape there is only one thing that tends rapidly to kill surges, and that is excessive friction in the conduit.

In the case cited, very rapid damping of oscillations would be taken as an indication that an unwarranted amount of useful head was being wasted in the conduit.

With a simple tank, rapid damping, so essential, if often very expensive; it is not a function of the conical shape and, furthermore, Mr. Jakobsen's example does not indicate rapid damping.

With differential action, however, the rate of damping is increased without the loss of useful head on the turbines.

In closing, I wish again to refer to the words of mine, which Mr. Jakobsen quoted at the beginning of his letter, viz: "It is difficult for the writer to find any excuse for omitting the differential principle when its use, without exception, produces a cheaper surge tank, which will fulfill the same conditions."

It must be understood that this is merely a rule and possibly subject to the inaccuracy of all rules which are said to require an exception to prove them. However, in running through my mind some two score surge-tank designs with which I am familiar, I am able to state that the ratio of cost of the simple tank to the differential varies greatly with the physical conditions; it has rarely been found higher than 3, not infrequently as high as 2, commonly as high as 1.75, sometimes lower, but never, up to date, nearly as low as unity.

The ratios seem to be larger for structural tanks than for excavated ones and it is probably in that field, if anywhere, that an exception might be found.

Perhaps someone will feel enough interest in the matter to ferret out and publish the exception which is now lacking for a thorough establishment of the rule and then its acceptance might possibly be made universal.

New York, N. Y. R. D. Johnson.

In a letter dated November 27, Norman R. Gibson[4] questions whether Mr. Jakobsen's conclusions were based upon a comparison of the actual performance of representative surge tanks of both types and adds that it is obvious that not all surge-tank designs are correct, nor any one design of any type suitable for all conditions.

T. H. Hogg[5] in a letter dated November 21 points out that "the differential tank acceleration is faster than that of the simple tank, due to the greater drop in the water surface in the riser of the differential tank during the early part of the first quarter cycle, which results in a lower operating head on the turbine. If sufficient flywheel is provided to prevent an undue change of speed during the initial movement of the governor this condition does not give less power during the period than would result from the action of a simple tank, because the greater acceleration in the conduit, together with the capacity of the riser itself, more than compensates for the additional decrease in head, and as a result more power is available during this period with the differential tank than with the simple tank. Since the water level in the simple tank at the end of the first quarter-cycle is lower than in the differential tank, a greater amount of water is required by the turbine to meet the power demand, and, therefore, the gate opening on the turbine and hence the work done by the governor must be greater than for a differential tank.

"While the drop in the water level in the riser of the differential tank is more rapid than in the simple tank, it requires considerably greater time to reach its low level than the time necessary for the governor to make a full-gate stroke, and it is quite evident that with a governor set to take care of a given load change in a reasonable time, with constant head, it is perfectly capable of taking care of the same change with the slight and comparatively gradual change which occurs in the riser during the interval."

F. J. Howes[6] (letter dated November 13) states that "a thorough discussion of the relative merits of simple and differential surge tanks is made so difficult by the vast amount of arithmetical integration required that a proper sense of proportion is likely to be lost. The writer had occasion not long ago to compare the dimensions of both types of tank which would be required to give equivalent speed regulation on a station of 33,000-kw. capacity on a head of 130 ft. The results from a differential tank 52 ft. in diameter had as good commercial characteristics as could have been obtained from a simple tank 90 ft. in diameter, in spite of the extreme drop in head occurring on the occasion of a sudden demand."

Eugene E. Halmos[7] (letter dated November 16) says that from his experience the differential surge tank results in considerable economy in first cost where a fixed maximum or minimum head on the conduit or penstocks is of importance. He adds, however, that it is just conceivable that where the surge tank is an unlined excavated hole in solid rock, the cost of additional excavation to obtain the diameter necessary for an equivalent simple tank might balance the cost of the riser of the differential tank.

Lewis F. Moody[8] in his letter of December 2, 1922, formulates the broad problem of surge-tank functions, which is to handle in the best possible manner the oscillations which must inevitably occur as the result of the inertia of the water column. The engineer has first to limit the magnitude of the disturbance, and second, to provide for damping it out. Mr. Moody believes that the simple surge tank will accomplish the object of limiting the amplitude of the oscillations if the tank is sufficiently large. Unless relatively very large in dimensions a simple tank will not accomplish the second purpose of damping out the surges, and, in any event, it is not the tank which produces the damping but the friction in the hydraulic conduit. In his opinion, therefore, the so-called simple surge tank is a *surge* tank indeed, since it provides for a continuance of the periodic fluctuations until these are absorbed by friction in the pipe line. If the simple surge tank is not as large as it should be—and this is often the case—it may cause perpetual surging or even augmenting surges.

C. W. Larner[9] (letter dated December 4) objects to Mr. Jakobsen's assumption that an instantaneous load change requires an increase of plant discharge from 1000 c.f.s. to 1500 c.f.s. in a few seconds, and to the further assumption that the 1500 c.f.s. discharge is to be constant in spite of the fact that the head on the plant begins to fall off immediately due to the downward surge in the tank. He believes that such a load increment could not possibly occur in practical operation. This condition is illustrated by a curve in the letter.

Objection is also made to Mr. Jakobsen's alleged argument that the differential tank is not as good as the simple because at each instant during the early part of the surge, the head in the differential tank is lower and the power output less. The writer claims that both surges are identical if we eliminate the element of time. Both start at the same elevation and both end at the same elevation. For every point on the differential-tank curve there is a corresponding point on that of the simple tank. The only difference is that one occurs later than the other.

Mr. Larner suggests that load change be expressed in kilowatts instead of cubic feet per second. He further suggests as the only proper hypothesis for design or comparison of designs, the facts that the discharge of the wheels during the surge will vary and the gates will not be wide open until the bottom of the surge is actually reached. Hence, while it is clear that earlier in the surge the plant could turn a little more power if the gates were opened wider, he does not attach any importance to this because this additional power would have to be dropped a few seconds later.

Minton W. Warren[10] (letter dated December 20) states that if the matters of first cost and interest on the investment are left out, Mr. Jakobsen's statements as to the superiority of the simple surge tank over the differential for the Kerckhoff project are certainly true. He points out that the differential tank is rapidly becoming standard practice and states his belief that in cases where labor, material, and physical conditions are such as are found in the medium-high-head plant in the United States, the differential principle utilized in some form will be found to be an advantage.

Fred W. Ely[11] (letter dated January 31, 1923) in analyzing the reasons which led Mr. Jakobsen to reject the differential surge tank, states that while it is true that during the first 60 sec. the differential tank gives an average of nearly 2000 kw. less than the simple tank, in the next 97 sec. the level in the simple tank is still slowly flowing while that in the differential tank is rising, and therefore the power lost in the first quarter-cycle is gained in the second. The writer believes that the flywheel effect of the rotating machinery could be relied upon to tide over the period during which the short water column in the penstocks is accelerating. Moreover he believes that actually no deficiency of power exists at any time under operating conditions involving constant power; the above is simply predicted on Mr. Jakobsen's condition of constant discharge which the writer claims is impossible. Furthermore, the final quiescent level for the changed conditions will be attained in the differential tank in about one-half the time this level is reached in the simple tank.

While the discussion has been primarily devoted to the argument as to whether, in the face of developments of the differential surge tank, there are any contingencies still left in which a simple tank would be preferable, it has brought out in passing some interesting suggestions as to the problem of surge-tank design to meet special conditions. Thus, Mr. Ely, in his letter referred to above, discusses the case of a tank extending some distance above the ground, where excessive spilling in most cases is impracticable. One plant with which he has had some experience—the Colton Plant of the St. Lawrence Transmission Company at Potsdam, N. Y.—required a tank extending 250 ft. above the ground. A simple tank in such a location would be out of the question, even though this plant falls within the scope of Mr. Jakobsen's classification of low- and medium-head plants. The differential surge tank on this development has furnished satisfactory regulation with no indication of a deficiency of power or fall in speed on suddenly demanded loads.

Letters have also been received from Messrs. P. Wahlman and O. V. Kreuse, but cannot be quoted here because of the lack of space.

Variations in Design of Milling Cutters

(Continued from page 158)

metal, and energy required per chip on rise in temperature. Aside from this condition and in the case of work where the wide spacing of teeth would cause undue hammering, coarse-tooth cutters should always be used.

Effect of Spiral Angle and of Rake Angle

A large number of runs were made on a set of three 10-tooth cutters having spiral angles of 10, 20 and 30 deg., respectively, and on two 20-tooth cutters having spiral angles, respectively, of 20 and 30 deg. In addition two series of tests with a three-tooth 60-deg. spiral cutter are shown in Figs. 1 and 2. As noted earlier in the report, the metal used in the tests of the first five cutters mentioned was not uniform, so no definite figures are given. The average of the tests, however, shows practically no difference in power required for the different spiral angles. In the case of the three-tooth cutter the authors believe that the lower power requirement is due to the number of teeth instead of the spiral angle.

While increased spiral angles showed no advantage from the standpoint of power, they were of very great benefit in reducing tendency to chatter and in giving smoother action. The vertical pressure between cutter and work was also somewhat less. The end thrust with the 60-deg. spiral cutter was not noticeable as far as the machine was concerned. In general a considerable spiral angle is desirable, the only limitations being end thrust and the danger of burning the sharp corners at the ends of the teeth if the work extends beyond the end of the cutter.

Tests were made with three 10-tooth cutters having rake angles of 0, 10, and 20 deg. and with two 20-tooth cutters having 0 and 10 deg. rake. The increase in rake angle from 0 to 10 deg. caused a saving in power of 20 to 25 per cent, and a somewhat smaller saving was shown on the increase to 20 deg. On the other hand, tendency to chatter increased only slightly between 0 and 10 deg. rake, but became so great as to definitely limit the capacity of the cutter when increased to 20 deg. This limitation seemed to be much more serious than the danger of burning or chipping the edge. Rake angles of 10 deg., therefore, are desirable on cutters, but any considerable increase beyond this point limits the usefulness of the cutter.

Chatter

Chatter rather than the power of the machine is often the limiting factor in milling. For this reason many engineers urge that more rigid machines be built to eliminate this trouble, without realizing that a great deal may be accomplished by the proper choice of cutters. A summary of the elements which affected chatter in these tests is therefore given in the following paragraph.

The most important point in connection with this subject is the fact that tendency to chatter was greatly reduced as the number of teeth in the cutter approached a low figure. On many cuts where it was impossible to eliminate chattering of the twenty-tooth cutter by any reasonable change in speed, absolutely no trouble was experienced with the four- or eight-tooth cutters. Furthermore some trouble was experienced with the eight-tooth cutter on wide and deep cuts at high feeds, but no chattering occurred on any cuts with the four-tooth. Increase in spiral angle also reduces the tendency to chatter, and a combination of wide-spaced teeth and steep spiral angle in a cutter will give the maximum capacity along this line. Moderate rake angles increase the tendency to chatter but little, while large rake angles greatly decrease the capacity of the cutter. The proper consideration of these factors in the choice of cutters will eliminate much trouble in this respect.

Conclusions

Coarse-tooth milling cutters require less power to remove a given amount of metal per minute than fine-tooth cutters. This is true on both wide and narrow work, although the margin in favor of the coarse-tooth cutter is greater on wide cuts. It is also true if both cutters are compared on a chipper-tooth basis.

When compared on a chipper-tooth basis the finish given by the coarse-tooth cutter is better than that by the fine-tooth cutter on account of the closer spacing of revolution marks.

Low-cutting-speed operation of fine-tooth cutters to give a large feed per tooth is objectionable on account of the increased stresses in the machine and holding fixtures.

Fine-tooth cutters are much inferior to coarse-tooth cutters when the relative tendency to chatter is considered.

Moderate rake angles reduce the power consumption and are desirable on all cutters to be used on mild steel. Large rake angles are undesirable due to the tendency to chatter.

The spiral angle has little effect on the power consumption. A considerable spiral angle is desirable, however, because it makes possible the use of fewer teeth, gives smoother cutter action, and reduces the tendency to chatter.

Hence, with the few exceptions noted, coarse-tooth cutters of the type now generally manufactured are superior to fine-tooth cutters for all classes of production work.

U. E. S. Report for 1922

THE report[1] of the treasurer of United Engineering Society for the calendar year 1922 shows a balancing account on December 31, 1922, of $17,014.77, as compared with a balancing account on December 31, 1921, of $26,434.31. The cash on hand as of December 31, 1922, amounted to $138,294.27. Following is a statement of the treasurer's receipts and payments for the year:

RECEIPTS		
Cash on hand January 1, 1922		$14,219.35
From Founders and Associates	$138,294.27	
From societies not in building	17,811.17	
From various accounts	41,994.08	
From Library Service Bureau Photo Department	5,515.06	
From Library Service Bureau Search Department	9,274.28	212,888.86
		$227,108.21

PAYMENTS		
For Operating Payroll	$46,919.31	
For Operating Expenses	37,225.22	
For Equipment, Repairs and Alterations	10,195.56	
For Miscellaneous, Including Taxes	53,144.50	
For Library	56,868.73	$204,353.32
Cash on hand January 1, 1923		$ 22,754.89

SUMMARY OF FUNDS, DECEMBER 31, 1922	
Depreciation and Renewal fund	$133,233.69
General Reserve fund	10,000.00
Library Endowment fund	93,357.40
Engineering Foundation fund	502,074.80
John Fritz Medal fund	3,500.00
Total	$742,165.89

The assets and liabilities as of December 31, 1922, were as follows:

ASSETS		
Property		$1,959,140.67
Land	540,000.00	
Building	1,361,969.51	
Equipment	33,171.16	
Founders' Preliminary Expenses	24,000.00	
Investments—Engineering Foundation		502,074.80
Library		93,357.40
Depreciation and Renewal		133,233.69
General Reserve		10,000.00
Operating Cash	13,350.01	
Library Petty Cash	50.00	
Accounts Receivable	3,869.65	17,269.66
		$2,715,076.22

LIABILITIES		
Founders Equity in Property		$1,959,140.67
Engineering Foundation Fund		502,074.80
Library Endowment Fund		93,357.40
Depreciation and Renewal Fund		133,233.69
General Reserve Fund		10,000.00
Deferred Credits-Unexpended balance in International Dinner Fund	$ 54.89	
Library Income for year 1923	200.00	254.89
Balance in Activity Accounts		17,014.77
		$2,715,076.22

Overdeveloped Coal Industry Cannot Furnish Cheap, Plentiful Coal

THAT the coal industry is overdeveloped is an outstanding definite statement in the first report of the United States Coal Commission. This overdevelopment has been common knowledge for some time, but its authoritative statement by the Commission should focus the attention of the public upon the high prices, faulty transportation, and unsatisfactory labor conditions that have resulted from an excess of two hundred thousand miners and a mining capacity of eight hundred million tons per year, when the annual consumption has never been greater than five hundred and seventy-nine million tons.

The final paragraphs of the report furnish an interesting commentary on this overdevelopment. Quoting from the report:

The way in which to reduce the overdevelopment of the mining industry is fraught with so many complications, not all of which are evident at first glance, that the Commission has not yet had time to ascertain sufficient facts on which to base any recommendations now to be made to the Congress. While it might be expected that in an overdeveloped industry aggressive competition would have driven out mines with high producing costs and forced prices to the consumer down to a minimum, so many such complex factors have operated to prevent the free play of economic forces that a very detailed and comprehensive investigation is required before a valid conclusion can be reached.

The inquiry involves the whole question as to what is best for the people, free competition, government or private ownership, regulation or control in the coal industry. Should the operators in given areas be permitted to combine so that the low-cost mines would furnish the product to the people and the high-cost mines be kept in abeyance to meet an emergency, properly regulated as to price and profit by some governmental agency, or should this prime necessity of life and business be left wholly to open competition in the market? This problem is of so great moment, with reference not only to theories of government but also to the economic life of the Republic, that the view of the Commission must be left to its final report.

The Commission believes that the public interest in coal raises fundamental questions of the relation of this industry to the nation and of the degree to which private right must yield to public welfare. It may be that both private property in an exhaustible resource and labor in a public-service industry must submit to certain modifications of their private rights, receiving in return certain guarantees and privileges not accorded to purely private business or persons in private employ.

In the absence of facts the Commission refrains from comment as to the effect of profiteering, labor difficulties, transportation deficiency, and lack of storage upon high coal prices and unsatisfactory supply. The Report clearly shows the gravity of these problems, however, and points out the many troublesome phases of each which must be investigated before the final report of the Commission can be written. Following is an abstract of the Report which was made public on January 15 and was signed by the entire Commission.

The coal problem begins with a contradiction. Yet, with resources of coal in the ground adequate for the needs of perhaps a hundred generations of Americans, the nation's coal bin is too often depleted and too often the prices paid for coal are much higher than seem warranted by the wealth of coal available. While it is true that a large majority of the states have coal mines within their limits, it is significant that all the anthracite comes from a narrow area of 480 square miles in eastern Pennsylvania and 93 per cent of the bituminous coal comes from three major areas: the Appalachian region, extending from Pennsylvania to Alabama, the greatest storehouse of high-rank coal in the world; the Eastern Interior region, comprising Illinois, Indiana, and Western Kentucky; and the Western Interior region, extending from Iowa to Arkansas and Oklahoma.

The coal-mining industry, in point of numbers employed, outranks any single manufacturing industry and stands next to transportation and agriculture. Approximately three-quarters of a million men are employed in this industry, of whom 90 per cent work underground. The capital invested, according to the rough figures of the census, is $2,330,000,000, of which $430,000,000 is invested in the anthracite region and the remainder in the bituminous fields. There are only 174 producers of anthracite and eight of these control over 70 per cent of the annual output, while there are at least 6000 commercial producers of soft coal, to say nothing of thousands of wagon mines and country coal banks. These producers operate 9000 commercial mines.

The bituminous output is consumed approximately in the following percentages: Railroads, 28; Industrials, 25; Coking, 15; Domestic, 10; Iron and Steel, 7; Public Utilities, 7; Export, 4; Mines, 2; Bunkers, 2. The coal industry does not end at the mines. Some 180 railroads take the coal at the mine mouth and transport it to thousands of destinations. Because the railroads are the largest customers of the bituminous industry, and because coal—anthracite and bituminous—constitutes one-third of the railroad's freight, the problems of the two are closely interwoven and their interests interdependent.

Nor does the coal industry end with transportation. To connect the thousands of producers, big and little, with more than 90,000 buyers of carload-lot coal scattered over 48 states, requires a widespread system of wholesale marketing. There are some hundreds of large wholesalers and a much greater number, perhaps 3500 in all, of smaller middlemen. Like the business of running mines, the business of selling has its problems and, like mining, it has also its abuses. The final link in the chain of coal supply is the retailer, who receives coal in carload lots from car or yard storage and delivers it in smaller quantities to the consumer. There are some 38,000 retail coal dealers, most of them conducting a small business. They handle about 130,000,000 tons of coal, or 14 per cent of the bituminous and two-thirds of the anthracite produced. Combined charges of the railroads, the wholesaler, and the retailer in most localities exceed the price of the coal at the mines. Therefore it is readily seen that the problem whether the transportation and marketing charges are just and fair is of the utmost concern to the consumers of coal.

It has been suggested to us that one of the causes of high prices of coal is profiteering. There has been profiteering in the sense that grossly exorbitant profits have been taken at times by many operators, brokers, and retailers; profits that have been disproportionate to the cost of the coal or the service rendered or the risk incurred. But this Commission has not obtained the figures for the past ten-year period specifically required by the Act in order to settle this question.

There can be no doubt that two of the three periods of high prices since 1916 have been caused largely by labor troubles. In the first period of scarcity—August, 1916, to March, 1918—there were no strikes of consequence and therefore some other explanation of the high prices and distress must be found. The second period of runaway prices, November, 1919, to late in 1920, was originally caused by a nation-wide strike of miners beginning November 1, 1919. In this case the shortage created by the strike was aggravated by difficulties in transportation resulting in part from severe weather and in part from a strike of railway switchmen, and was further intensified by an unprecendented demand for export and by boom times at home. In the third period of shortage and high prices, from which we have not yet emerged, the primary cause was a nation-wide suspension of mining, involving practically all union men, which closed the anthracite region completely and shut down two-thirds of the capacity in the bituminous fields of the United States and Canada.

An opinion commonly expressed before the Commission is that the primary cause of scarcity and high prices of coal is transportation deficiency. There have been recurring periods of "car shortage," and such periods have generally been accompanied by high prices of coal. There are many other causes for the inadequacy of transportation beside the absence of cars, such as lack of motive power, congestion of yards, terminal facilities, or gateways, single tracks where double tracks are needed, inability to coördinate movement of boats and cars at ports, strikes of railway labor, and severe winter storms temporarily blockading traffic. The so-called "car shortage" is not always due to insufficient coal-carrying equipment alone. In part it has been due to an overload upon the transportation system beyond what that system could reasonably or properly be expected to bear.

We find that in the bituminous industry since 1890 the mines have averaged over the country as a whole, only 213 days out of a possible working year of 308 days. These averages, of course, show nothing as to the relative annual earnings of individual miners or their individual opportunity to work. In 1920, a year of active demand, the average time worked was only 220 days,

and in 1921, the year of depression, it dropped to 149 days, with many districts showing a figure much below this average. Over a long period comparatively little of the time lost has been on account of strikes and that in the years when there are no strikes the aggregate time lost from all causes is about as great as in those when strikes occur. In the twenty-three years over which the statistical record of strikes extends, the time lost because of strikes has averaged 9 days a year, or less than 10 per cent of the time lost for all causes combined. Short working time is the result of overdevelopment in the industry. There are more mines and more miners than the needs of the country require.

Although the country has never been able to absorb in a year more than 579,000 000 tons of bituminous coal, the present capacity of the mines is well above 800,000,000 tons.

The steady increase in the army of bituminous coal miners during the last four years, notwithstanding a lessened demand for their product is also a fact that stands out in the statistical records furnished the Commission by the U. S. Geological Survey. In 1918, the year of maximum coal output, when 579,000,000 tons were mined, 615,000 men were employed in the bituminous coal mines, nearly 622,000 the next year, over 639,000 in 1920, and in 1921, 663,000 mine workers were employed in producing about 416,000,000 tons. To get a year comparable in soft-coal output with 1921 we have to go back to 1910, when 417,000,000 tons were mined, and it is significant that in that year less than 556,000 mine workers were employed—or about a million more tons of coal with 100,000 fewer miners.

The Commission is convinced that there can be no permanent peace in the industry until this underlying cause of instability is removed. Diverse causes have apparently promoted overdevelopment and inquiries are in progress as to the relative importance, among others, of the following: The policy of railroads toward encouraging the opening of new mines and new mine fields as sources of revenue; car distribution rules that permit, if they do not encourage, larger capacity than the market obviously requires; the opening of new mines by large consumers; the establishment of freight rates that encourage the development of new fields; shifts in centers of consumption that abandon old fields and encourage new fields; the difference between union and non-union wage costs; large-scale suspensions in the unionized fields; and irregularity of demand.

American Railroads

THE PROBLEMS of our American railroads should be considered with two thoughts clearly in mind, both of them of intimate relation to American industry and engineering generally. First, our railroad system is the fundamental in a national scheme of production and distribution; and second, the railroad industry with an investment conservatively estimated at twenty billion dollars, has an annual purchasing power, when in healthy condition, of over a billion dollars. The factors that impair this purchasing power immediately reduce industrial activity.

The relation between transportation—and in particular, railroad transportation—and production was effectively discussed by Julius H. Barnes, president of the Chamber of Commerce of the United States, before the American Society of Civil Engineers at its recent annual meeting. While Mr. Barnes considered motor-truck and water transportation, he was careful to emphasize that our railroads remain always the chief channel of transportation. He was not able to give definite figures, but he did point out that the ultimate effect of the increasing ability of the individual to produce, his increasing buying power and his ever-widening demand for goods will result in the not-far-distant future in the serious embarassment of our transportation scheme. While the railroads have, during the past two decades, kept step with the increased transportation needs of the country, Mr. Barnes called attention to the fact that any material expansion of transportation service must require large additional capital investments. It is probable that some single- and even double-track lines are approaching the maximum load possible for the capacity of their present rails, and any substantial increase means at once new roadbeds. The service limit of existing terminal facilities is even nearer to the maximum possible, largely because not enough money has been spent on terminal improvements during the last fifteen years.

There is a general acceptance of the principle of regulation of transportation by railroads, but it is Mr. Barnes' belief that in the past this regulation has been over-rigid and shortsighted. It destroyed the current earning power of the railroads and undermined their credit, leaving them unable to adequately expand their facilities with the increasing tonnage of the country and in anticipation of future growth. It is becoming clearer and clearer that enlightened self-interest requires a fair and even generous interpretation of regulation of these great arteries of commerce, but before large investments are made in terminal or special facilities and equipment of railroads, there should be a comprehensive survey of the future of transportation in all its various forms, and then intelligent preparation to utilize them in caring for the expanding commerce of the country.

The other aspect of the railroad problem in which the railroads figure as an industry that can spend money and provide business for others, is considered in an editorial in The New York *Times* of February 7, 1923. According to this, railway construction would rival building construction if the companies were helped or even let alone. Chicago is planning a union station which will exceed in size either of those in New York. The Illinois Central alone needs to spend forty-five million dollars. All railroads would spend the billion they should spend in the aggregate to give necessary facilities, if they were allowed reasonable profits with which to solidify their credit. It would be an enormous relief to the industrial situation if the railroads were permitted to finance themselves. The vitalizing of twenty billions of capital would strengthen the domestic financial situation quite as much as foreign purchases of our excess food production stimulate our farmers. Railroad consumption forms a larger proportion of the domestic iron and steel demand than the foreign demand does of the total of our agricultural products.

In this connection, however, it should be remembered, that although in 1907 the railroads were the largest consumers of steel and iron, today sheets, plates and pipe for general industrial use are the major products of the iron and steel industry, this of course being largely due to the fact that the railroads did not keep up with the country in their expansion.

There are many indications, however, that the outlook for the future is brightening. After all it was not lack of capital in the country that prevented the development of the railroads, but lack of good will in certain powerful groups and resulting lack of confidence in the future of the railroads among the general investing public. There has been of late a vigorous effort to reëstablish good will toward the railroads and a healthier spirit of coöperation is now being exhibited by the public generally, and by the governments of the various states in particular. Regardless of what our individual opinions concerning railroad management may be, the country needs successful and efficient railroads perhaps more than it needs anything else, and every effort within reason should be promptly directed toward making them both successful and efficient.

International Coöperation in Research

IN A RECENT communication William Henry Patchell, vice-president of the Institution of Mechanical Engineers of Great Britain, and a recent visitor to America, made a plea for the closer coöperation in research of the engineering societies of English-speaking countries. During his visit to America Mr. Patchell found that investigations on similar subjects were occupying the attentions of both British and American engineers, notably the work in steam, an investigation on steam flow through nozzles, and the codes for testing engines and boilers. Mr. Patchell suggested that an immediate solution might be the appointment of corresponding members by The American Society of Mechanical Engineers and the Institution of Mechanical Engineers on the Steam Nozzles Research and Steam Research Committees, respectively. Such contact would expedite the formulation of codes and provide opportunity for international criticism which would clarify the field and look toward the possible adoption of international codes and correlated international research.

It goes without saying that any relations set up between national engineering societies will be helpful in cementing permanent affiliations.

American engineers will gratefully receive this fortunate expression of coöperation from Mr. Patchell, an outstanding man in his profession in England, having been honored not only by being chosen as vice-president of the Institution of Mechanical Engineers, but also as vice-president of the Institution of Electrical Engineers. American mechanical engineers will recall his leadership in the use of large boilers at the Bow Street Station, London, in 1905 and his memorable paper dealing with superheater experiments in 1896.

The Federated American Engineering Societies

AN OUTSTANDING result of the recent annual meeting of the American Engineering Council was the quickening of the sense of responsibility in each member of the Council for the establishment of a more complete understanding of the aims and objects of The Federated American Engineering Societies in the minds of the individual members of the constituent organizations. That the Federation is dependent for its growth and success upon the unswerving loyalty and increased activity of each Council member was emphasized by President Cooley, doubly stressed by Executive-Secretary Wallace, and touched on again and again during the two days of the meeting.

The Council adopted a resolution "That it shall be the established policy of the F.A.E.S. to advise its member societies promptly and as fully as obligations of confidence will permit, of the consideration or the undertaking of all matters of material interest and to seek and obtain the advice and counsel of the member societies so far as that can be done without delay or detriment to the matter under consideration." This resolution was proposed by John Lyle Harrington as chairman of the A.S.M.E. delegation to the Council. The debate lasted over two hours. While its adoption puts a responsibility upon the American Engineering Council to advise and consult, there is a still greater responsibility upon the delegates to the Council and the governing bodies of the constituent societies to organize so that the desires and opinions of the individuals making up the member organizations may be available promptly for the guidance of the American Engineering Council and its Executive Board. Gladly shouldering this responsibility, the A.S.M.E. delegates to the American Engineering Council during the coming months will address individual members of the Society and Local Sections officers for expressions of opinion on various activities that the F.A.E.S. is carrying on, and will solicit suggestions for new activities for The Federated American Engineering Societies.

Engineers must grasp the remarkable opportunity offered by the F.A.E.S. to demonstrate the leadership of their profession in solving the tremendous economic and industrial problems facing this country.

L. P. Alford.[1]

The Engineer in Public Life

THE KEYNOTE of the annual meeting of the American Engineering Council was struck by Dean M. E. Cooley, in his presidential address, as follows: "We are, I feel, entering upon a new era. The engineer, not so much in the technical as in the social sense, is about to take that part in the world which rightfully is his. I am speaking not of civil engineering, mechanical engineering, chemical engineering, electrical engineering, or any other branch of engineering, but of the engineering profession as a whole........After fifteen months of service as president of the Federation I am convinced that the opportunities of the engineer are very great. I have the utmost faith that the engineering profession of this country and, through affiliation with foreign organizations, of the world, can bring to pass a new epoch in man's history."

This attitude has recently been expressed by the technical press, as shown in the following extracts.

Public Service and the Engineer

"Five engineers constitute the personnel of a rapid-transit commission brought into being at Detroit. Engineers as such will take satisfaction in the appointment. Formerly these engineers would have been employed as members of the staff, but here is public recognition that technical ability and executive ability may be found in the same man. There is a tendency for engineers to think of themselves as representing a quality of mind not possessed by others. It is true they are not so bound by tradition as are many other members of the community and they think in terms of the future as well as the present, in a day of industrial marvels. Also they are growing numerically strong, for the broadening range of engineering undertakings has held out promising opportunities, and the conspicuous successes the best brains have won in industrial life and in public places have brought high credit to the profession. Promotion activities like those of The Federated American Engineering Societies have done their part in bringing such recognition, and so has the equipment the average engineer now brings to his task."—*Iron Age.* February 1, 1923, p. 361.

The Engineer in Civic Life

"Recent developments (referring to the appointment of Prince Caetani as ambassador from Italy, to the adoption of American management methods by Czechoslovakia, and to the work of the F.A.E.S.) indicate the occurrence of two interesting events—the realization by the public of the service it can command from the engineer and the awakening of the engineer to the fact that he can be a valuable public servant.

"'Engineering thinking' and 'the engineering approach' may perhaps have fallen to the status of mere catchwords, but there is nevertheless a real need for the methods of the engineer in public office, and the more of him this country can induce to enter its service, the better."—*American Machinist,* January 25, 1923, p. 166.

The same issue of the *American Machinist* (p. 158) quotes from an address by Dr. J. A. L. Waddell, a consulting engineer of New York City, before the engineering students of the University of Barcelona, with the comment that although the engineer has begun to interest himself in politics and to make himself felt in this field, there is still much to be desired from those engaged in all classes of engineering work. Dr. Waddell's statement is as follows:

> Every individual should pay proper attention to his duties as a citizen of the country in which he resides Engineers in America are great sinners in this particular; and the result is that our profession has very little to say regarding the government of our country. In the Administration, the Senate, and the House of Representatives at Washington engineers are generally conspicuous by their absence. This is a condition that should be corrected as soon as possible, for the benefit not only of our profession but also of that of the country, because who is there so competent in thought and action as an engineer?
>
> In European countries, I believe, engineers take a more prominent part in politics than they do in the U S. A.—for instance, in Italy there are twenty-three engineers who are members of parliament. What the conditions in Spain are I do not know; but I notice that the Alcalde of Barcelona is a distinguished engineer.

In an editorial on The Federated American Engineering Societies in *Power* for January 30, 1923, Fred R. Low makes the following pertinent statement:

"The orderly reorganization of a system of diversified and often conflicting self-centered interests into an interlocking system of production, transportation and distribution devoid of wasted effort and lost motion; the impressment of the necessary regulative and directional forces without cramping initiative and motivating purpose; must be done against the inertia and resistance of established privilege and with the repression of unreasoning radicalism.

"The belief is growing that the unemotional, analytical, practical engineering type of mind and of man must be looked to to bring this about."

Indiana Engineering Society

The twenty-ninth organization to join the F.A.E.S. is the Indiana Engineering Society, comprising a membership of nearly 400. The object of this association, which has its headquarters in Indianapolis, is "the encouragement of professional intercourse between the engineer and surveyors of the State of Indiana, and the advancement of its members in scientific research in the various branches of engineering."

While public service is not included in this clause from the constitution of the Society, Indiana has ever had the coöperation of this group of engineers in such matters of public concern as flood prevention, sewerage, road construction, and water works. The president of the society is W. H. Elliott and its secretary is Charles Brossman.

Engineering and Industrial Standardization

Standardization of Methods of Testing Wood Now Under Way

INNUMERABLE misunderstandings and disagreements concerning strength of lumber and timbers, and such accidents as grow out of miscalculation of the strength of various kinds of lumber, should be greatly reduced as a result of the standardization of methods of testing wood, recently undertaken by the many interests involved, under the auspices of the American Engineering Standards Committee.

The U. S. Forest Service and the American Society for Testing Materials have been appointed joint sponsors for this undertaking, and 16 additional organizations are represented on the sectional committee which is to make an intensive study of the subject.

The scope of the committee's activities embraces the standardization of physical (including mechanical) tests of wood specimens. Of immediate importance is the application of these tests to (*a*) small clear specimens, and (*b*) structural timbers. The most important desideratum involved is the establishment of standard practice in testing wood which will make data obtained at different sources of the broadest possible value and insure the attainment of comparable results.

L. J. Markwardt of the Forest Products Laboratories at Madison, Wisconsin, has been elected chairman of the sectional committee and Prof. M. O. Withey, Professor of Mechanics, University of Wisconsin, secretary.

Automobile Headlight-Testing Specifications Approved by A.E.S.C.

ONE of the tribulations of the touring motorist—the hopeless attempt to comply with the automobile headlighting regulations of all states through which he passes on his trip across the continent—will be removed as soon as the various state motor-vehicle departments have all adopted the Specifications of Laboratory Tests for Approval of Electric Headlighting Devices for Motor Vehicles which has just been approved by the American Engineering Standards Committee. Nine states have already indicated that they will adopt the specifications, while in three they are already in effect.

These specifications were submitted to the A.E.S.C. by the Illuminating Engineering Society. This organization and the Society of Automotive Engineers have been appointed joint sponsors for any revision and further development of the code which may be necessary. Approval of the specifications was recommended to the American Engineering Standards Committee by a Special Committee which had been appointed to investigate their practicability and acceptability. This Committee, of which David Van Schaack, vice-president of the National Safety Council, was chairman, was made up of representatives of the automobile manufacturing industry, automobile accessory manufacturers, the officials of motor-vehicle regulatory bodies, insurance companies, safety organizations, technical societies, and of the U. S. Bureau of Standards.

Safety Code for Power Presses and Foot and Hand Presses

THE use of power presses and foot and hand presses for stamping and forming pieces of metal and other material has grown so rapidly, and the loss of hands or fingers on these presses as commonly operated is so frequent, that this hazard has become one of the most serious mechanical problems in accident prevention.

This code is one of a number of safety codes which have been or are being formulated under the general auspices of the American Engineering Standards Committee. One purpose of the code is to serve as a guide to state authorities. Part I includes such requirements as may properly be enforced by a state industrial commission or labor department such as the location and installation of presses, feeding and removing material, making and setting of dies, and operating rules. Part II contains illustrated descriptions and discussions of press hazards and the methods that have been used to remove or protect against them. Both parts are fully illustrated.

This code, sponsored by the National Safety Council, was formulated by a committee of twenty-one men, including two representatives of the manufacturers of presses, five users of presses, one representative of employers, five governmental bodies, five specialists in the subject of power-press operation and safety, and three insurance representatives. Mr. C. B. Auel, manager, employees' service department, Westinghouse Elec. & Mfg. Co., Pittsburgh, Pa., was Chairman of the Sectional Committee, and Mr. S. J. Williams, chief engineer, National Safety Council, 168 N. Michigan Ave., Chicago, Ill., was its secretary. For copies of this code address the National Safety Council.

Building Code Committee Issues First of Its Series of Reports

INVESTIGATIONS by a Congressional Committee during 1919 and 1920 disclosed the fact that existing building laws through variations and inconsistencies of their provisions and through unduly restrictive or expensive requirements, were operating to prevent needed activity in the building industry. That these conditions might be remedied, a committee of experienced engineers and architects was organized by Secretary Hoover, to investigate building practice and code requirements and to prepare standard building regulations based on the latest and best information, which might be recommended to cities and states adopting or revising building codes.

In order that its recommendations might have sound bases of information and opinion, the committee is coöperating with nearly one hundred engineering and architectural societies, builders' exchanges, and industrial organizations producing building materials. Special questions also are referred to large groups of individual engineers, architects, building officials, to the Bureau of Standards, and to others whose experience qualifies them to discuss such subjects.

Owing to the pressing need for dwelling houses the first report of this Committee only presents recommendations for the construction of one and two-family houses having exterior walls of solid or hollow masonry, concrete, and frame, the latter including veneer and stucco surfaces.

The Committee recommends that building codes permit 8-in. solid brick and 6-in. solid concrete walls for $2^1/_2$ and 3-story dwellings accommodating not more than two families each; that 8-in. hollow building tile, hollow concrete block, or hollow walls of brick (all rolok) shall not exceed 20 ft. in height to the gables; and that frame construction be limited to $2^1/_2$ stories. Metal lath and plaster on wood studs properly firestopped is approved for party and division walls, but at least every alternate wall in row houses must be 8-in. solid brick or concrete or 12-in. hollow building tile, concrete block, or hollow wall of brick.

The report recommends revised working stresses for timber used in dwellings, based on investigations of the U. S. Forest Products Laboratory. Live loads to be required as bases for design are 40 lb. per sq. ft. for floors of wood, and 30 for those of monolithic type, or of solid or ribbed slabs. Foundation walls of brick are required to be 12 in. thick for excavated enclosures, and similar concrete walls shall be as thick as the walls they support but not less than 8 in. Special hollow building tile 12 in. thick is permitted for foundation walls of frame buildings. Detailed recommendations are given for firestopping and chimney construction, also for treatment of built-in garages.

Subsequent reports will deal with the construction of multi-family dwellings, hotels, clubs, office buildings, stores and other mercantile buildings, factories, work shops, amusement places, churches, institutions, schools, public buildings, garages, and other non-residential buildings.

The Committee is composed of the following members: Ira

H. Woolson, Chairman, consulting engineer, National Board of Fire Underwriters, New York City; Edwin H. Brown, architect, Minneapolis, Minn.; William K. Hatt, professor of civil engineering, Purdue University, Lafayette, Ind.; Rudolph P. Miller, formerly supt. of buildings, New York City; John A. Newlin, in charge of section of timber mechanics, Forest Products Laboratory, Madison, Wisconsin; Ernest J. Russell, architect, St. Louis, Mo.; and Joseph R. Worchester consulting engineer, Boston, Mass.

This report, comprising 100 pages and thirty illustrations, may be purchased from the Superintendent of Documents, Government Printing Office, Washington, D. C. Price 15 cents.

Bureau of Standards Conducts Investigation on Welded Pressure Vessels

Meagerness of scientific data on which to base proper requirements for safety without placing unjust restrictions on the use of welding has raised a difficult problem for the Boiler Code Committee of The American Society of Mechanical Engineers in its effort to draw up a code to govern the construction of unfired pressure vessels. However, with the coöperation of the American Bureau of Welding, which is the advisory committee on welding research for the American Welding Society and the National Research Council, a Pressure Vessel Committee was appointed to coöperate with the Boiler Code Committee and a series of tests was arranged to be carried out by the United States Bureau of Standards. Eight manufacturers placed forty tanks at the disposal of the Committee and provided funds for the test. A hydrostatic and hammer test was finally decided upon to determine whether a vessel was safe for the purpose for which it was designed.

The shells of most of the tanks were 6 ft. long and 2 ft. in diameter, and made of $^3/_8$-in. mild steel plate. Both electric and oxy-acetylene welding were used. The hydrostatic and hammer test developed that the welded pressure vessel, according to the regular formulas for working pressure, has a factor of safety of about 6.

A remarkable feature of this undertaking is the rapidity of accomplishment. The first meeting of the committee was held in New York on August 17 last, and a plan outlined. The tanks called for in the program were immediately built by manufacturers distributed widely (one of them on the Pacific Coast), and shipped to the Bureau of Standards in Washington. Most of the tanks arrived by the first of December. Under the supervision of Dr. H. L. Whittemore, Chief of Section VII-1, Physical Tests of Structural Materials Division, who is also chairman of the Committee, testing was started December 4 and carried on continuously to January 10. Many visitors, including members of the Boiler Code Committee, insurance inspectors, tank manufacturers, American Welding Society and National Research Council, have witnessed the tests.

A complete report will appear in the April issue of Mechanical Engineering.

Boiler-Furnace Refractories

The subject of Refractories and their relation to the furnace problem of modern central stations drew an interested audience to the meeting of the Metropolitan Section of the A.S.M.E. in New York City on January 23. Kenneth Seaver[1] in a very interesting talk, told of the problems of the manufacturer of firebrick and pointed out the manufacturing difficulties that must be overcome by proper furnace design and construction. Mr. Seaver emphasized that the main dependence of the power-plant operator is ordinary firebrick, for silica brick, which is suitable for high temperatures, such as are achieved in metallurgical work, is unstable for boiler settings on account of its contraction and expansion in the lower temperature ranges. Long freight hauls for firebrick are uneconomical and therefore brick made from clay handy to the user must be employed. This makes standardization of material very difficult, but the manufacturer, by study of the clays available in each district, may obtain the best results by compounding or other treatment. The operating engineer requires uniform sizes of firebrick, as thin joints, which seem essential to long furnace life, are impossible where firebrick vary in thickness. Mr. Seaver pointed out that variations in sizes are due only partly to the effect of heat in the kiln and mostly to the effect of variation in pressure in the different layers. He told of methods being employed, by certain power plants in the construction and repair of furnaces, such as spraying the inside of the furnace with a half-inch layer of high-temperature cement, or the use of relieving arches, or, by slight changes in form or location, correcting improper draft distribution. In the discussion the importance of uniformity was again emphasized by firebrick users. Edwin B. Ricketts[1] stated that the troubles due to high furnace temperatures might be solved by locating passages in the walls through which air may be passed on its way to the combustion chamber.

MEETINGS OF OTHER SOCIETIES

American Institute of Chemical Engineers

Historic and industrial Richmond was headquarters for the fifteenth annual meeting of the American Institute of Chemical Engineers, held December 6 to 9, 1922, inclusive. The excursion program included trips to points made famous by the Civil War as well as to modern industrial plants. A large delegation visited the Virginia-Carolina Chemical Company's plant, where sulphuric acid, acid phosphate, and mixed fertilizers are made. Materials handling has been reduced to a minimum in this plant; transportation is carried out on elevated tracks by means of an electric engine and also by means of electric cranes on either side of the building. At Hopewell, which now has a population of some 9000 and contains a number of thriving industrial plants, the Hummel-Ross pulp factory was inspected. The Richmond Cedar Works, the Richmond Car Works, the Standard Blotting Paper Co., and other industrial plants were also visited. An inspection of the tobacco factories was preceded by an instructive address by T. M. Carrington, president of the Tobacco Association of the United States, on the American tobacco industry. Of special interest were the automatic packing and wrapping machines used in the factories.

The technical program of the meeting contained a number of papers of general interest. A. E. Marshall, of Baltimore, Md., spoke on the use of pyrex glass as an engineering material. Dr. J. R. Young, Mellon Institute, outlined the development of asbestos-protected metal. Three papers on the absorption of gases in towers were presented: F. C. Blake, of the Du Pont Company, discussed the resistance of packing to fluid flow and W. B. Van Arsdale, of the Brown Company, and Prof. R. T. Haslam, Massachusetts Institute of Technology, the effect of rate of flow on absorption. Among other topics considered were the various uses of wood and concrete in chemical industries, waterproofing concrete, and stirrer performance.

American Petroleum Institute

The third annual meeting of the American Petroleum Institute was held in St. Louis, Mo., December 6, 7, and 8, 1922. It was preceded by a meeting of the Association of Natural Gasoline Manufacturers, making a four-day convention for the consideration of problems of the oil industry, a number of which involve mechanical engineering. Among the subjects discussed at general and group sessions were standardization of equipment, internal-combustion engines, natural gasoline as a motor fuel, and the relation of the "knock" to the gasoline problem.

Under the general topic of standardization, simplification and improvement of oil-drilling methods and equipment a number of important papers were presented. S. F. Speller, National Tube Co., discussed the physical qualities of pipe, with special reference to iron, bessemer steel, and open-hearth steel, and the activities of the Mid-Continent Oil Gas Association regrading pipe for deep-well drilling were recounted by J. Edgar Pew, of The Sun Co. Drilling

equipment, from the point of view of the essential qualities and analysis of raw materials entering into its manufacture, and also the value of heat treatment, was the subject of an address by Prof. F. F. McIntosh, of the Carnegie Institute of Technology. Papers on the standardization of tool joints, rig irons, and cable tools were followed by a general discussion of the question, What Does the Oil Industry Wish to Do About Standardization? This subject of standardization in the oil industry was also discussed at one of the sessions from the points of view of the engineer, the field man, and the supply manufacturer.

Several group sessions were devoted to the subject, What is Good Gasoline? Dr. S. W. Stratton, of the Bureau of Standards, gave the answer as so far formed by the joint research program of the Bureau and the oil and automotive industries. Thomas Midgley, Jr., General Motors Research Corporation, pointed out the relationship of "knock" to the gasoline problem and discussed the remedy for knocking. A paper on the use of natural gasoline in motor fuel was presented by O. P. Kenney, of the Tide Water Oil Co., at a session of the Association of Natural Gasoline Manufacturers. Henry L. Doherty, New York, gave his interpretation of the problem of heavy fuels for internal-combustion engines.

Society of Automotive Engineers

An unusual educational opportunity was afforded automotive engineers and executives during the week of January 8, when two automobile shows and the annual meeting of the Society of Automotive Engineers were held in New York City. S.A.E. members attending the annual meeting were guests at both the National Automobile Show and the Automobile Body Builders' Show, and it is more than probable that their inspection and study of new developments displayed at the shows gave impetus to their discussion at the sessions of the annual meeting.

There were seven technical sessions, two on body engineering, and one each on engine cooling, aeronautics, fuels, detonation, and research. One of the most novel ideas brought out during the meeting was a new all-fabric closed body described in a paper on Cheaper Closed Body Construction, presented at a body engineering session, by George J. Mercer, of Detroit, Mich. This body consists of a wire-covered wood frame on which are applied a layer of heavy buckram and a covering of highly finished fabric. Mr. Mercer outlined the merits of the fabric body and stated that he expected to put it on the road in the near future in order to determine its durability.

At the same session J. B. Davis, of the Standard Textile Products Co., New York, N. Y., described methods of testing leather substitutes and top material recently developed by his concern in coöperation with the Bureau of Standards and the Society for Testing Materials.

Testing automobile finishing varnish was the subject of a paper by L. Valentine Pulsifer, chief chemist, Valentine & Co., New York, N. Y. Mr. Pulsifer stated that the three most important factors in estimating the service-giving qualities of varnish are elasticity, moisture resistance, and film thickness. Mr. Pulsifer performed actual tests for these qualities and discussed the testing of varnish qualities in general.

The fourth paper presented at the body engineering sessions was by F. F. Murray, advisory mechanical engineer, Hardwood Manufacturers' Institute, Chicago, and dealt with the needless waste of hardwood lumber in the automotive industry. He pointed out that the cost of body production could be considerably reduced by a revision of specifications for grading, and commended the work of the Central Committee on Lumber Standards which is endeavoring to produce a new and scientific grading schedule that by common accord will establish a lasting instrument to be entitled the American Lumber Standards.

A symposium of papers on commercial airplane design was held on the evening of January 9. Prof. E. P. Warner, Massachusetts Institute of Technology, named economy, safety, speed, and comfort as qualities which the finished plane should possess, and discussed the relative importance of these factors. Other speakers spoke of the obligation which the Government has in carrying forward development, and possibilities of commercial aviation, emphasizing the necessity for "selling" the public as to its safety and practicability.

At the detonation session Thomas Midgley, Jr., of the Dayton Research Laboratories, outlined the prevailing theories of detonation and described experiments which he has conducted to determine the laws governing detonation. S. M. Lee and S. W. Sparrow, of the Bureau of Standards, described methods used and results obtained in two investigations of fuels for high-compression aviation engines. A paper by J. H. Hollaway, H. A. Huebotter, and G. A. Young, all of whom are connected with Purdue University, discussed their research work into the operation of internal-combustion engines under comparatively high compression on ordinary gasoline without detonation.

Reports on fuel-volatility research at the Bureau of Standards, and on the work of the research department of the S.A.E., especially in regard to fuels, were presented at a research session of the meeting. At the fuel session, papers on the effective volatility of motor fuels, the proper utilization of natural gasoline, and a survey of gasoline and kerosene carburation were presented. The latter paper gave a general discussion of gasoline carburation requirements, the use of petroleum fuels, and reasons for the present wastage of fuel by improper carburation.

An interesting paper on aircraft-engine practice as applied to air-cooled passenger-car engines was presented at the engine-cooling session. This article showed wherein the automobile designer and engine builder can profit by the use of practice developed for air-cooled aircraft engines and contained a detailed discussion regarding cylinder design and performance, inclusive of valve location, type of finning, and form of cylinder head.

Elisha Lee, vice-president of the Pennsylvania Railroad, was the chief speaker at the annual dinner of the society. His subject was motor transport and our railroads, a problem in coördination. Herbert W. Alden, chief engineer, Timken-Detroit Axle Co., newly-elected president of the society, reviewed its progress during 1922 and announced that emphasis during 1923 would be laid upon production engineering.

American Society of Civil Engineers

The conferring of five honorary memberships, the election of Charles F. Loweth as president, meetings of four new technical divisions, reports of technical committees, an all-day excursion to Bethlehem, and technical sessions on engineering education, engineering research, and city planning—all these were outstanding events in the seventieth annual meeting of the American Society of Civil Engineers, held in New York January 17, 18, and 19, 1923.

The recipients of honorary memberships were Leon-Jean Chagnaud, Paris, noted for his subaqueous and subterranean excavation work; Sir Maurice Fitzmaurice, London, internationally prominent through his achievements in bridge engineering and irrigation and drainage work; Clemens Herschel, New York, past-president of the A.S.C.E., the inventor of the venturi meter; John Frank Stevens, New York, railroad engineer and well known for his work as chief engineer of the Panama Canal; and William Cawthorne Unwin, London, engineering educator and authority, honorary member A.S.M.E. and recipient of the Kelvin Medal in 1921.

Charles F. Loweth, who succeeds John R. Freeman as president, has been chief engineer of the Chicago, Milwaukee & St. Paul Railway since December, 1910. He has been active in the work of the society, serving as director and vice-president, and rendered valuable service as its representative on Engineering Council.

With the formation of four technical divisions, the A.S.C.E. has joined the ranks of those large engineering organizations which are recognizing the potentialities of such specialized branches. The technical division on sanitary engineering, which had previously been organized, held its first general meeting on January 16. H. P. Eddy, consulting engineer, Boston, Mass., read a paper on the Present Status of Sanitary Engineering and made valuable suggestions as to the aims of the division. Organization meetings of the three other divisions, on irrigation engineering, highway engineering, and power, were held on January 19. Tentative organizations and plans for procedure were drawn up and lines of work to be carried on by the divisions were discussed.

An all-day excursion to Bethlehem on January 18 included inspection of the new Hill-to-Hill bridge, which is 62 ft. wide and, with its approaches, about 6000 ft. long; the works of the Bethlehem Steel Company, especially the open-hearth department, the rolling

mill, and the fabricating shops; and the John Fritz Laboratory at Lehigh University.

Among the committee reports which were presented was the third report on stresses in railroad track, covering a study of curved track; the final report on bridge specifications, which differs from other current specifications in that it is shorter and restricts itself to general considerations, leaving details to the individual engineer; and a summary of tests of impact in highway bridges.

At the session on engineering education Charles F. Scott, professor of electrical engineering, Sheffield Scientific School, reviewed what is being done by various societies for the promotion of engineering education, and outlined the new project of the Society for the Promotion of Engineering Education; this was described in an editorial by him in the February issue of Mechanical Engineering. The Outlook of the Engineering Colleges of the Middle West was the subject of an address by William G. Raymond, dean of the College of Applied Science, State University of Iowa. A paper by Magnus W. Alexander, managing director of the National Industrial Conference Board, read by Mr. Trowbridge, a member of his staff, emphasized that the engineer, animated by his constant spirit of inquiry, should guide industry in basing its work upon ascertained fact and experience. John L. Harrington, president of the A.S.M.E., urged the coöperation of the national societies in a plan for a general undergraduate engineering society, directed by the students themselves rather than by the national societies or faculties.

The speakers at the research session were Arthur N. Talbot professor of municipal and sanitary engineering, University of Illinois; Alfred D. Flinn, director of Engineering Foundation and chairman of the Division of Engineering, National Research Council; George K. Burgess, chief of the Division of Metallurgy, U. S. Bureau of Standards; and Otto B. Blackwell, transmission development engineer, American Telephone and Telegraph Company, New York.

Mr. Talbot, who is a past-president of the civil engineers and chairman of their committee on research, discussed the society's research program, which has included such important subjects as working stresses for steel structures, flood-protection data, irrigation engineering, hydraulic phenomena, and impact in highway bridges. Mr. Flinn reviewed the development of the two organizations in which he is active, as previously named, stating that each of them is "an integral part of the organism of the founder societies, just as the Library is." Mr. Burgess reviewed the present status and probable future of steel as a structural material and outlined some of the work being carried on at the Bureau of Standards.

Subjects considered at the city planning session were parks and parkways, city planning and the engineer, zoning, and regional planning.

At an evening session on January 18 Julius H. Barnes, president of the U. S. Chamber of Commerce, presented an address on Transportation Keyed to Production, in which he emphasized the necessity for adequate transportation facilities for distribution of products.

LIBRARY NOTES AND BOOK REVIEWS

American Machinist Gear Book. By Charles H. Logue; revised by Reginald Trautschold. Third edition. McGraw-Hill Book Co., New York, 1922 Cloth, 6 × 9 in., 353 pp., illus., diagrams, tables, $3.

This book is intended to give practical data for cutting, molding, rolling and designing commercial types of gears, and to present this information by means of simple rules, diagrams and tables arranged for ready reference. This edition has been carefully revised and enlarged. Matter of little practical value has been omitted. The chief additions relate to spiral type and Williams "master form" bench gears, to the Williams system of internal gearing and rolled gearing. The last subject is here first presented in book form.

Annuaire du Bureau des Longitudes. 1923 By France: Bureau des Longitudes. Gauthier-Villars et Cie, Paris, 1922. Paper, 4 × 6 in., 860 pp., portrait, maps, tables, 6 fr. 5 c.

This convenient reference book has appeared annually for 128 years. The volume for 1923, like its predecessors, covers a wide field of statistical information, astronomical, physical, geographical and social. Five star maps are included, and an extensive review of the climate of France.

Cours Complet de Mathématiques Spéciales; Vol. 3, Méchanique. By J. Haag. Gauthier-Villars et Cie, Paris, 1922. Paper, 6 × 10 in., 188 pp. 12 fr.

In this volume on mechanics, Professor Haag lays emphasis on the experimental origin of that science, even though he proves that an entirely abstract exposition of it may be given, as of any other mathematical theory. His study begins with kinematics, from which topic he proceeds to dynamics and finally to statics, which is considered as a particular case of dynamics. Although primarily a work on theoretical mechanics, applied mechanics has not been neglected, but has been included by a large number of problems that occur in physics or in industry.

Dictionary of Applied Chemistry. Vol. 4. By Sir Edward Thorpe. Longmans, Green & Co., New York, 1922. Cloth, 6 × 9 in., 740 pp., $20.

This well-known work of reference has been thoroughly revised and brought down to date, the present volume including matter published as recently as 1922. Volume 4 includes many subjects of technical interest, such as the manufacture of matches, of nitric acid; the utilization of atmospheric nitrogen; the metallurgy of lead, magnesium, nickel, mercury, osmium and molybdenum; metallography; mercerizing; leather; naphthalene. Extensive articles on these and other topics, by well-known authorities, characterize the book.

The Dynamo, Its Theory, Design and Manufacture. Vol. 1. By C. C. Hawkins. Sixth edition. Isaac Pitman & Sons, New York, 1922. Cloth, 6 × 9 in., 615 pp., illus., diagrams. $6.

A standard British text of comprehensive character, covering both direct- and alternating-current generators. In this revision greater space is given to the treatment of the electromotive force of the dynamo by vectorial methods, the theory of armature winding has been reconsidered and expanded, and greater prominence is given to drum armatures. A section on the oscillation of a mechanical system, a discussion of the compressive stress on the mica plates in high-speed commutators, and the winding of shunt coils with two sizes of wire are among the new matters that have been added. The book has been largely rewritten and carefully revised.

Elementary Internal-Combustion Engines. By J. W. Kershaw. Second edition. Longmans, Green & Co, New York, 1922. Cloth, 5 × 7 in, 211 pp., diagrams. $1.75.

An elementary account of the construction and working of oil and gas engines and power-gas producers, intended as an introduction to more advanced books.

Internal-Combustion Engines. By J. Okill. Isaac Pitman & Sons, New York, 1922 (Pitman's Common commodities and industries). Cloth, 5 × 7 in., 126 pp, illus. $1.

A review of the development and construction of the various types of internal-combustion engines, written to show how gas and oil engines stand as competitors to steam for all power purposes, and to discuss some of the power requirements that are beyond the scope of the steam engine.

Introduction to Theoretical and Applied Colloid Chemistry. By Wolfgang Ostwald. Second American edition, translated from the eighth German edition by M. H. Fischer. John Wiley & Sons, New York, 1922. Cloth, 6 × 9 in., 266 pp., illus., diagrams, portrait. $2.50.

A revised and enlarged edition of the principal lectures delivered by the author during his American visit in 1913–1914. These lectures were intended for those with little or no knowledge of colloid chemistry and were intended as a general survey of the

subject, with particular emphasis upon its great possibilities of scientific and technical application.

Experimental Electrical Engineering and Manual for Electrical Testing. Vol. I. By Vladimir Karapetoff. Third edition. John Wiley & Sons, New York, 1922. Cloth, 6 × 9 in., 795 pp., illus., diagrams. $6.

This textbook on the testing of electrical machinery is based on the course of instruction given by the author at Cornell University, but the selection of material has been modified by comparison with the courses in other colleges, so that the book presents a composite picture of what is actually taught in the electrical laboratories in this country. This edition has been completely revised and reset. Volume 1 contains all elementary experiments and is sufficient for the needs of general students. Volume 2 contains advanced work needed by students of electrical engineering.

Jigs and Fixtures. By Fred H. Colvin and Lucian L. Haas. Second edition. McGraw-Hill Book Co., New York, 1922. Cloth, 6 × 9 in. 237 pp., illus., diagrams, tables. $2.50.

The authors endeavor to present the fundamental principles of design, arranged as nearly in the order of their application as possible, so that the tool designer can select such parts and methods as seem best suited to any problem. The new edition has been enlarged to include a greater variety of work and also to show a few boring bars and reamers.

Labor Turnover in Industry. By Paul Frederick Brissenden and Emil Frankel. Macmillan Co , New York, 1922. Cloth, 6 × 9 in., 215 pp., tables. $3.50.

The questions discussed in this work include the general extent of labor mobility; labor mobility in individual plants and in special groups within the work force, causes of turnover, seasonal influences, effects of length of service, responsibility for instability. The investigation is based on statistics collected for the United States Bureau of Labor Statistics, from over 260 establishments employing over 500,000 workers. The problem is treated primarily from the point of view of the individual establishment.

Machinery Foundations and Erection. By Terrell Croft. First edition McGraw-Hill Book Co., New York, 1923. Cloth, 6 × 8 in., 691 pp., illus., diagrams. $5.

Section 1 of this book considers the general requirements that foundations for machinery must meet. This statement of fundamentals is immediately followed by divisions treating of the design and properties of the different components of foundations, such as anchor bolts, anchor plates and anchors. Following these come instructions on the installation and reconstruction of foundations. The divisions in the next group give specific information on the design and construction of foundations for certain types of machinery, including steam engines and turbines, boilers, waterwheels, electrical machinery, hammers and planers. The concluding divisions explain methods for erecting machinery. The book is written for practical men, and avoids the use of higher mathematics. Little has been written previously on the subject.

Mechanical Engineering Detail Tables. By John P Ross. Isaac Pitman & Sons, New York, 1923. Cloth, 5 × 7 in., 197 pp., diagrams, tables. $2.25.

This compilation, by an experienced draftsman, is intended to supply machine designers with the proportions of a number of machine details that are common to all machines. The tables include dimensions for the usual sizes of studs, rivets, nuts, bolts, handles, ratchets, wrenches, links, joints, shafting, keys, keyways, bearings, hooks, chains, engine and pump details, condenser details, valves and cocks, pipes, flanges and fittings, ship's fittings and wire ropes. Follows English practice.

Oil Power. By Sydney H. North. Isaac Pitman & Sons, New York, 1922 (Pitman's Common Commodities and Industries). Cloth, 5 × 7 in., 122 pp., illus , tables. $1.

A concise, yet comprehensive account of the use of oil for power production, which covers the subject in a general manner, without attempting great detail on its many aspects. Intended for engineers, shipowners and users of fuel. Gives special attention to the economic ad antages of oil.

Practical Mechanics and Strength of Materials. By Charles W. Leigh. First edition. McGraw-Hill Book Co., New York, 1923. Cloth, 5 × 8 in., 293 pp., diagrams, tables. $2.25.

An elementary textbook presenting those principles of mechanics and strength of materials that are needed by the practical man. Intended for high schools and vocational schools.

Quantum Theory. By Fritz Reiche. E. P. Dutton & Co., New York, Cloth, 5 × 8 in., 183 pp. $2.50.

In this treatise the author has attempted to give in broad outline the most important features of the doctrine of quanta, its origin, its development and its ramifications. An appendix entitled Mathematical Notes and References provides a useful list of the important writings on the subject.

Die Statik des Eisenbaues. By W. L. Andrée. Second edition. R. Oldenbourg, Munich, Berlin, 1922. Paper, 6 × 10 in., 521 pp., diagrams, tables $3.

A practical handbook for the designer of steel structures, intended to give him a collection of the most useful methods for solving the problems of statics that arise in the design of ordinary structures. The book contains over one hundred examples, taken from practice, of steel buildings, shops, markets, craneways, hangars, shipways, conveyor frames, cooling towers, bridges, cableways, loading bridges, pontoon bridges, etc. In every case, the author has tried to present the most suitable method of calculation. An appendix presents, in concise form, the foundation and development of the most important method for statically indeterminate systems.

Treatise on the Principles and Practice of Dock Engineering. By Brysson Cunningham. Third edition. Charles Griffin & Co., London, 1922. Cloth, 6 × 9 in , 600 pp , illus , plates. $10.00.

Mr. Cunningham's treatise covers the subjects of dock design and construction; jetties, wharfs and piers; dock gates and caissons; sheds and warehouses; dock bridges and dock equipment. The book aims to be thorough, rather than extensive, in its treatment; and to investigate in detail rather than in general. This edition has been thoroughly revised and brought up to date by the inclusion of new material and illustrations.

Index to Volume 44 of Mechanical Engineering

THE Index to Volume 44 of Mechanical Engineering has recently been completed and is now available in printed form. Any member of The American Society of Mechanical Engineers or any other subscriber to the magazine may obtain a copy of this Index by sending a written request for it to the headquarters of the Society at 29 West 39th Street, New York, N. Y.

Acting Director of U. S. Standards Bureau

THE VACANCY caused by the resignation of Dr. S. W. Stratton as director of the U. S. Bureau of Standards has been filled temporarily by the appointment of Dr. Fay C. Brown as acting director. Dr. Brown has been assistant director since the War. He is a graduate of the University of Indiana and did graduate work at the Universities of Illinois and Chicago and at Princeton. He was instructor at the Universities of Illinois and Iowa previous to the War. In 1917 he entered the military service and was in charge of testing and ballistic work on airplane bombs.

New President of British Mining Engineers

THE INSTITUTION of Mining and Metallurgy, of England, which is international and comprises a large American membership, has selected Robert Gilman Brown as its president for 1923–1924. Mr. Brown is a graduate of Dartmouth and the Columbia School of Mines and was connected with various mining concerns in this country until 1907, when he went to England. He has since been associated, either as consulting engineer or director, with mining companies operating in Cornwall, North Wales, South America, Burma, and particularly in Russia. He has been a member of the council of the Institution for eleven years, and is the second American engineer to be its president, the first having been Hennen Jennings.

THE ENGINEERING INDEX

(Registered United States, Great Britain and Canada)

Exigencies of publication make it necessary to put the main body of The Engineering Index (p. 111-EI of the advertising section) into type considerably in advance of the date of issue of "Mechanical Engineering." To bring this service more nearly up to date is the purpose of this supplementary page of items covering the more important articles appearing in journals received up to the third day prior to going to press.

AIRPLANES

Manless. The Army's Manless Airplane. Aerial Age, vol. 16, no. 2, Feb. 1923, p. 73. Results of experiments by Army Air Service to produce small airplane of 20-ft. span, with 60-hp. air-cooled engine, capable of carrying useful load of 250 lb., which would operate without pilot; equipped with Sperry automatic pilot.

AUTOMOBILE ENGINES

Motor-Truck. Type K-4 Continental Truck Engine Goes Into Production. Automotive Industries, vol. 48, no. 5, Feb. 1, 1923, pp. 231–232, 2 figs. Has detachable cylinder head and full-pressure lubrication; gives 35 hp. at 1300 r.p.m., at which speed it is intended to be governed; weight, 680 lb.

AUTOMOBILES

Bodies in Sections. Manufacturing and Shipping Costs Cut by Building Bodies in Sections, J. Edward Schipper. Automotive Industries, vol. 48, no. 5, Feb. 1, 1923. pp. 215–217, 7 figs. 30 broughams packed in same freight-car space as 14 under usual method; Oldsmobile plan provides for shipping in seven sections; bolted and screwed together in car factory.

BELTING

Leather. New Federal Specifications for Leather Belting, Louis W. Arny. Indus. Management (N. Y.), vol. 65, no. 2, Feb. 1923, p. 92. Discusses new specifications adopted by U. S. Government.

BOILER FURNACES

CO_2 Distribution. Stratification of Gases Within a Boiler Furnace, W. C. Stronk. Power, vol. 57, no. 5, Jan. 30, 1923, pp. 166–168, 6 figs. Method of taking combustion-chamber gas samples; four sets of analyses show air distribution in furnaces; operation relation of CO_2 and O_2 shown; method suggested to improve combustion efficiency.

CARBURETORS

Venturi Diameters. Determining Correct Carburetor Size, W. H. Weber. Automotive Industries, vol. 48, no. 5, Feb. 1, 1923, pp. 220–221. Practical method for calculating cross-section of venturi tube necessary for carburetor to permit quick acceleration from minimum car speed in high gear.

DIE CASTING

Dies for. Dies for Die-Castings, A. G. Carman. Machy. (N. Y.), vol. 29, no. 6, Feb. 1923, pp. 430–432, 4 figs. Specific examples of design and construction of dies for making die castings of more intricate types.

Process and Equipment. Die Casting Process and Equipment, John W. Harriman. Am. Mach., vol. 58, no. 4, Jan. 25, 1923, pp. 137–141, 10 figs. Construction and operation of die; what to allow for shrinkage; methods of forcing molten metal into die are described.

DISKS

Rotating, Stresses in. Rotating Discs of Conical Profile. Engineering, vol. 115, nos. 2975 and 2978, Jan. 5 and 26, 1923, pp. 1–3 and 115–116, 4 figs. Determination of stresses due to centrifugal forces acting alone, application of load of, say, 1 lb. per in. run applied along knife edge forming periphery, and infinitely great pressure applied to the interior of an infinitely small hole drilled through the disk at its center.

GAS ENGINES

Steel Works. Large Gas Engines Installed in Steel Plants, C. G. Sprado. Blast Furnace & Steel Plant, vol. 11, no. 1, Jan. 1923, pp. 123–125, 5 figs. Comparison of B.t.u. recoveries by gas engines versus steam units; marked advance in valve-gear construction results in unexpected economy and capacity in new 3500-kw. machines.

GEAR CUTTING

Helical Gears. Methods of Generating Helical Gears, Franklin D. Jones. Machy. (N. Y.), vol. 29, no. 6, Feb. 1923, pp. 445–450, 15 figs. Methods of cutting teeth of helical gears on hobbing machines and gear shapers.

Sykes Generators. Large Sykes Gear Generators. Engineering, vol. 115, no. 2977, Jan. 19, 1923, p. 69, 11 figs. on p. 78 and supp. plate. Details of machines of two models, both capable of cutting wheels up to 15 ft. in diameter.

Tangent Rack Gears. Hobbing Tangent Rack Gears. Engineering, vol. 115, no. 2978, Jan. 26, 1923, pp. 106–107, 10 figs. Describes system of generating gearing by means of conical hob devised by H. E. Taylor of Hotchkiss et Cie., Coventry, England.

GEARS

Spiral Bevel. The Manufacture of Spiral Bevel Gears. Engineering, vol. 115, no. 2976, Jan. 12, 1923, pp. 32–36,13 figs., partly on p. 46. Describes works and methods used by E. N. V. Motors, Ltd., London.

INDICATORS

Steam-Engine. High-Speed Engine Indicators. Engineering, vol. 115, no. 2978, Jan. 26, 1923, pp. 119–126, 34 figs. Four papers read before Instn. Mech. Engrs. as follows: The Problems of the Engine Indicator, Loughnan Pendred; A New Form of Optical Indicator, F. W. Burstall; Micro-Indicator for High-Speed Engines, W. G. Collins; R. A. E. Electrical Indicator for High-Speed Internal-Combustion Engines, and Gauge for Maximum Pressures, Harry Wood.

Indicators for High-Speed Engines. Engineering, vol. 115, no. 2976, Jan. 12, 1923, pp. 31–32. Discusses optical indicators, including Hopkinson, Watson and Burstall in England, and Midgley, in America.

INDUSTRIAL MANAGEMENT

Engineering Department. The Successful Operation of an Engineering Department, W. E. Irish. Indus. Management (N. Y.), vol. 65, no. 2, Feb. 1923, pp. 93–97. Consideration of labor problems from engineer's viewpoint—men as "cogs," foremen as "bearings," etc. Shows how method has worked out in practice.

Lot-Quantity Determination. How to Determine Quantities for Lot Manufacture, Kenneth W. Stillman. Indus. Management (N. Y.), vol. 65, no. 2, Feb. 1923, pp. 84–86, 2 figs. Finding most economical lot quantity by graphs.

Production Methods. Undetected Faults in Production Processes, A. Whitehead. Engineer, vol. 135, no. 3499, Jan. 19, 1923, pp. 72–73, 1 fig. Points out influence of defects in workmanship or processes which ordinary methods of inspection commonly neglect.

IRON CASTINGS

Electric-Furnace. Gray Iron Castings from Electric Furnace, Larry J. Barton. Iron Age, vol. 111, no. 4, Jan. 25, 1923, pp. 269–273, 8 figs. Possibility of their commercial production; acid and basic practice compared; role of heat treatment.

JIGS

Design. Jigs and Tools, J. Moore. Engineering, vol. 115, no. 2976, Jan. 12, 1923, pp. 55–59, 13 figs. Considerations and principles of design. (Abstract.) Paper read before Instn. Production Engrs.

LOCOMOTIVE BOILERS

Washing-Out and Refilling Plant. Locomotive Washing-Out Plant for the Italian State Railways. Engineering, vol. 115, no. 2976, Jan. 12, 1923, pp. 42–44, 8 figs. Details of washing-out and refilling plant, underlying idea of which is to recover heat stored in boilers of locomotives returning to sheds, and use it in boilers of locomotives starting for day's work.

LOCOMOTIVES

Repairing. How Locomotives Are Repaired on Ford's Railway, Fred H. Colvin. Am. Mach., vol. 58, no. 4, Jan. 25, 1923, pp. 133–136, 14 figs. Describes repair shop at River Rouge and methods employed.

MONEL METAL

Forging. Considerations in the Forging of Monel Metal. Forging & Heat Treating, vol. 8, no. 12, Dec. 1922, pp. 542–545, 3 figs. Importance of heating in a reducing atmosphere or muffle furnace emphasized; correct temperature for forging; physical and chemical properties of monel metal.

MOTOR TRUCKS

Performance Tests. Production Tests of Loaded Chassis at the G. M. C. Truck Plant. Automotive Industries, vol. 48, no. 5, Feb. 1, 1923, pp. 224–226, 7 figs. To obtain more comprehensive and accurate data on truck chassis performance than would be possible through road tests, Gen. Motors Truck Co. has provided test room through which all completed chassis must pass.

OIL ENGINES

European. European Oil Engines, Edwin Lundgren. Power, vol. 57, no. 5, Jan. 30, 1923, pp. 171–172, 3 figs. Discussion of correct air-oil mixing; the Deutz engine; new Hesselmann solid-injection engine.

OPEN-HEARTH FURNACES

Developments. Developments in the Open Hearth, Herbert F. Miller, Jr. Blast Furnace & Steel Plant, vol. 11, no. 1, Jan. 1923, pp. 48–51, 3 figs. Gas-producer development and possibilities of coke-oven gas; furnace valves, door frames and ports; suggestion of evolution of open-hearth similar to modern blast furnace.

PRESSES

Forging, Hydraulic. The Practical Side of the Design of Hydraulic Forging Presses, W. R. Ward. Forging & Heat Treating, vol. 8, no. 12, Dec. 1922, pp. 553–557, 5 figs. Detailed discussion of design; calculations and materials; application and limitations of various presses.

REFRIGERATING PLANTS

Performance Scale. A Performance Scale for Ammonia Refrigerating Plants, T. M. Gunn. Power, vol. 57, no. 6, Feb. 6, 1923, pp. 211–214, 1 fig. Discusses performance and gives scale by which operating results may be compared with ideal ones for any pressure range.

ROLLING MILLS

Foreign Practice. Foreign Blooming Mill Practice, C. Kiesselbach. Blast Furnace & Steel Plant, vol. 11, no. 1, Jan. 1923, pp. 83–85, 7 figs. Series of production studies to determine proper number of passes; cooling due to roll contact rather than time intervals; power requirements at various reductions does not vary greatly. Translated from Stahl u. Eisen, Jan. 15, 1920.

STEAM ENGINES

Extraction-Type. Governing Devices of British Steam-Extraction Engines. Power, vol. 57, no. 5, Jan. 30, 1923, pp. 173–174, 2 figs. Methods whereby satisfactory regulation is obtained on British engines.

STEAM GENERATORS

Electric. Laurentide Electric Steam Generators Largest Yet Installed, W. P. Muit. Power, vol. 57, no. 6, Feb. 6, 1923, pp. 208–210, 4 figs. Two units, each consisting of three sections, connected on 6600-volt 3-phase circuit; each generator has normal capacity of 25,000 kw. and has absorbed 35,000 kw. and produced 50 tons of steam per hr.

STEAM POWER PLANTS

Compound-Engine. Plant of Brunswick-Balke-Collender Co., Muskegon, Michigan. Power, vol. 57, no. 6, Feb. 6, 1923, pp. 200–205, 7 figs. Compound-engine non-condensing plant in which exhaust steam is used for process work, dry kilns and heating; water raised by air lift; special coal and ash handling.

STEAM TURBINES

Axial-Flow Ljungström. Axial-Flow Ljungström Turbine. Power, vol. 57, no. 6, Feb. 6, 1923, pp. 229–230, 3 figs. Rotor is built up of a number of disks and annular rings; combined impulse-and-reaction-type unit forms part of 70-ton passenger locomotive that has seen regular service since March 1922; 1800 hp. developed at 9200 r.p.m. Translated from Zeit. des Vereines deutscher Ingenieure, Nov. 18, 1922.

Manufacture. Making Engineering Product on a Factory Basis, L. S. Love. Iron Age, vol. 111, no. 5, Feb. 1, 1923, pp. 333–336, 6 figs. Building turbines with consideration to variations of conditions of use by simplification and standardization.

STEEL

Fatigue Testing. Determination of the Fatigue-Resisting Capacity of Steel Under Alternating Stress, T. Robson. Engineering, vol. 115, no. 2977, Jan. 19, 1923, pp. 67–69, 4 figs. Describes arrangement adopted by Vincent Raven in testing department of North-Eastern Ry., machine used being Wohler cantilever type.

STEEL CASTINGS

Centrifugal Process. Special Products Made Centrifugally, George F. Tegan. Iron Age, vol. 111, no. 5, Feb. 1, 1923, pp. 337–338, 3 figs. Steel disk ingots for tires, wheels and other shapes produced by McConway process; billets and wire from such ingots.

Heat Treatment. Heat Treatment of Steel Castings, F. C. Langenberg. Iron Age, vol. 111, no. 6, Feb. 8, 1923, pp. 397–400, 2 figs. Methods of improving physical properties and bearing on specifications; effect on impact values of electric and open-hearth steel.

Heat Treatment of Steel Castings, H. C. Ihsen. Blast Furnace & Steel Plant, vol. 11, no. 1, Jan. 1923, pp. 95–99, 17 figs. Characteristics of steel castings in raw and thermally treated condition; consideration of correct treatment with relation to size and composition of casting.

STEEL MANUFACTURE

Calorific Value of Elements Used. Calorific Value of Steel-Making Elements, Henry D. Hibbard. Iron Age, vol. 111, nos. 2, 3 and 5, Jan. 11, 18 and Feb. 1, 1922, pp. 143–144, 211–213 and 347–349. Jan. 11: Chemistry of fusion or behavior and influence of each element on metallurgy of iron. Jan. 18: Role of silicon in bessemer and open-hearth furnace; proper use of aluminum; magnesium as deoxidizer. Feb. 1: Behavior of phosphorus, manganese chromium and other metals in steel processes; peculiarities of sulphur.

TERMINALS, LOCOMOTIVE

Design. An Innovation in Locomotive Terminal Design. Ry. Age, vol. 74, no. 4, Jan. 27, 1923, pp. 281–284, 3 figs. Rectangular or circular engine houses with inside cinder pits designed for promptly turning power. Designed by Nat. Boiler Washing Co., Chicago.

TERMINALS, RAILWAY

Chicago. Chicago Gets a New Passenger Terminal Plan. Ry. Age, vol. 74, no. 4, Jan. 27, 1923, pp. 263–267, 7 figs. Plans for new project by Chicago & West. Indiana, comprising study for new facilities on Dearborn Station site.

Contributors and Contributions

Large Machine Tools; Design and Construction

George H. Benzon, Jr., outlines in this issue the general character of the work of design and construction of large machine tools. This paper was one of a group of papers on machine tools presented at a recent joint meeting of the Philadelphia Local Section and Machine-Shop Division of the A.S.M.E. the Engineers' Club of Philadelphia and the Philadelphia Section of the A.I.E.E.

Mr. Benzon has been associated with Wm. Sellers & Co., Inc., Philadelphia, since 1898 when he served his drafting-room apprenticeship with that concern. In 1904 he was put in charge of planer design and construction, and four years later became chief draftsman. Since 1919 he has held the position of engineer.

Efficiency of Scotch Marine Boiler

In his paper dealing with this subject, C. J. Jefferson shows what has been effected by careful operation and provides a definite target of boiler efficiency at which marine engineers may aim with profit. Mr. Jefferson is a 1910 graduate of Cornell University. For seven years he was associated with the American Ice Co. as testing and mechanical engineer. During the War he served as a lieutenant in the U. S. Navy. Upon his discharge he took charge of the Boiler Unit, Technical Section of the U. S. Shipping Board. At present Mr. Jefferson is head of the Fuel Conservation Section of the U. S. Shipping Board.

Effect of Pulsations on Flow of Gases

This paper, by Prof. Horace Judd and D. B. Pheley, discusses work undertaken under the joint direction of the engineering Experiment Station of Ohio State University and the A.S.M.E. Research Sub-Committee on Fluid Meters. Professor Judd was graduated from Ohio State University in 1897 with the degree of M.E. and then served for two years as an instructor in the mechanical engineering laboratory, receiving his M.S. at the end of that period. For three years he held a similar position in Pratt Institute, Brooklyn, and then returned to Ohio State University to serve as assistant professor of experimental engineering until 1910 and as associate professor until 1920, when he was appointed professor of hydraulic engineering.

Mr. Pheley is at present junior engineer in the U. S. Coast and Geodetic Survey. He was graduated from Ohio State University in 1921 as a civil engineer and during that summer served as assistant to Professor Judd in the study of and experimental work in the problem of pulsating flow.

Engineering Aspects of the Design of Musical Instruments

The specific problems presented in the manufacture of pianofortes are considered by William Braid White, who shows that vast improvements would be achieved if the principles of mechanical engineering were more generally adopted as the foundation of such manufacture. Mr. White, an Englishman by birth, was educated at St. Paul's School and King's College, London. He came to the United States in 1896 and became interested in piano making. Since 1904 he has been technical editor of the *Music Trade Review*, New York; he is also associate editor of the *Talking Machine World*, New York.

Airship for Long-Haul Heavy-Traffic Service

The factors upon which the value of an airship as a carrier depends form the subject of this paper. Ralph H. Upson, the author, is chief engineer of the Aircraft Development Corporation of Detroit. He was graduated from Stevens Institute of Technology in 1910 with the degree of M.E. and entered the aeronautic department of the Goodyear Tire and Rubber Co., Akron, Ohio. He designed and built his first complete balloon in 1912, and in 1913 won the national and international balloon races. The Wingfoot Lake Flying School was started by Mr. Upson in 1917. He won national balloon races in 1919 and 1921, served on the Navy Department Commission in Europe, 1918–1919, and studied European methods in 1920. From 1915 to 1920 he was chief engineer of the Goodyear aeronautical department.

Hydraulic-Transmission Variable-Speed Drive

The progress that has been made in applying "hydraulic transmission" variable-speed drive to machine tools and ordinary manufacturing processes is reported in this issue by Walter Ferris. Mr. Ferris was graduated from Lehigh University as a mechanical engineer, class of '95. Until 1900 he was employed by the Pencoyd Iron Works in the master mechanic's office, and by the Laflin & Rand Powder Co. in charge of the design and erection of powder mills. From 1902 to 1921 he served the Bucyrus Co., South Milwaukee, Wis., as draftsman, chief engineer and consulting engineer, consecutively. The Oilgear Co., of which Mr. Ferris is vice-president, was organized in 1920.

Safety Engineering in Compression of Gases

This paper outlines a few of the chief hazards that are associated with the compression of some of the gases in common use in industry. Its author, A. D. Risteen, was graduated from Worcester Polytechnic Institute in 1885 with the degree of B.S. He received his Ph.D. from Yale in 1903. For twenty-three years he was associated with the Hartford Steam Boiler Inspection & Insurance Co. For the last ten years he has been in the engineering division of the Travelers Insurance Co., and is now director of technical research and safety publication work for that concern and the Travelers Indemnity Co.

Design and Construction of Large Machine Tools

Limitations Imposed on Design by Materials and Available Shop Equipment—Problems Involved in the Design and Construction of Large Boring Mills and Planers

By GEO. H. BENZON, JR.,[1] PHILADELPHIA, PA.

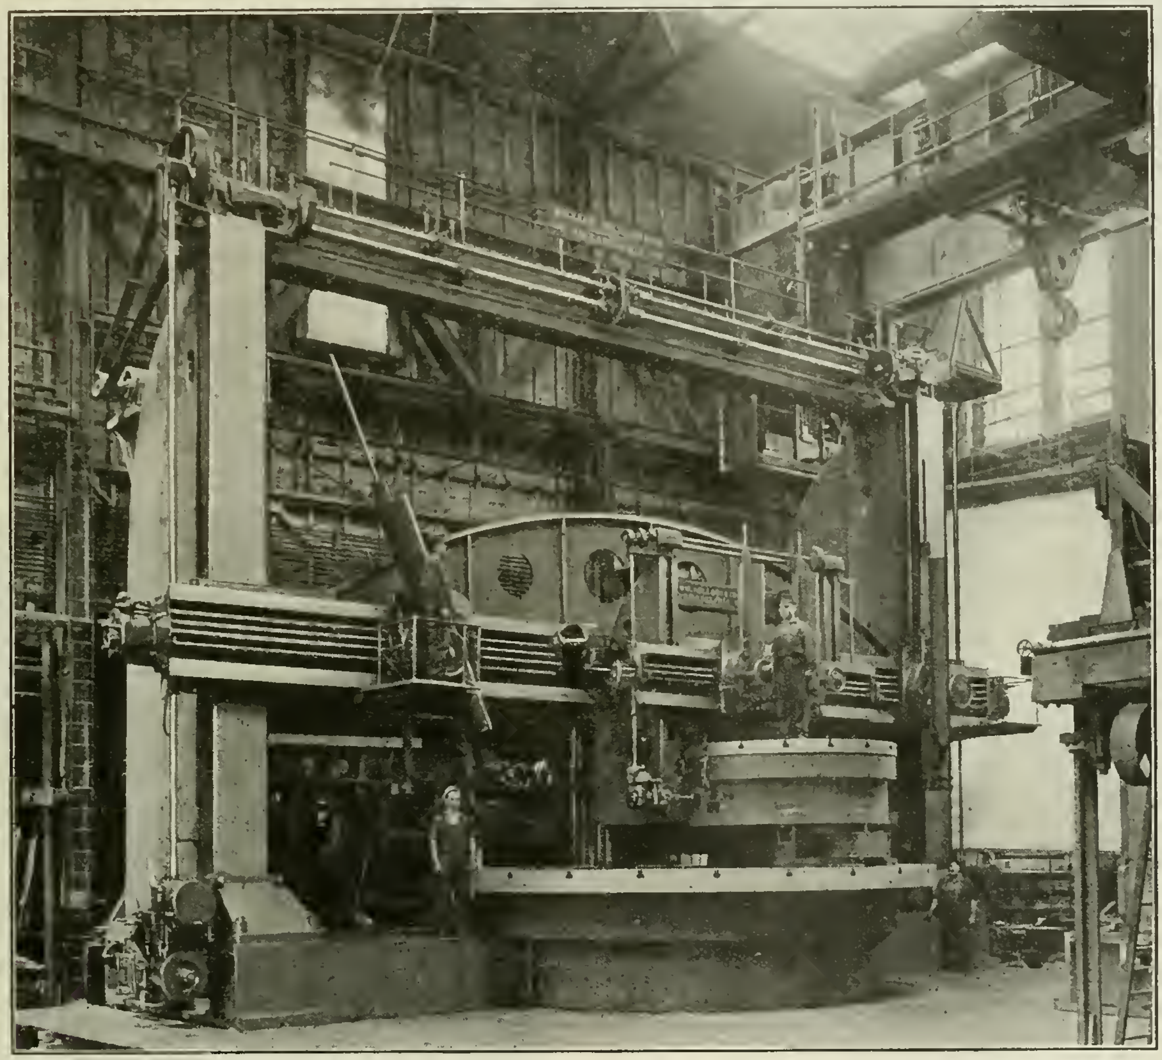

Fig. 1 Large Boring and Turning Mill
(Swing between uprights, 35 ft.; clearance between work table and underside of tool head, 18 ft.; total weight, 429,200 lb. Note small mill set on work table of large mill; swing between uprights, 100 in.)

IT HAS BEEN difficult in preparing this paper to sort out from the mass of every-day facts those points which might be of interest in a general discussion such as seems to be indicated by the title selected. The subject as generally understood is a very broad one. In fact, it covers two somewhat different types of machines commonly classed under the general title. There are machines which are used for accurate cutting and finishing; these belong distinctly in the machine-tool class. There are also those which are used for metal working other than finishing. While these may be, and are, often considered to be in this class, there is no sharp line between them and the machines used for metal working which are grouped under other machine divisions. The first-mentioned class, however, will be the one made the subject of this discussion.

The shops building hydroelectric machinery, marine engines, blowing engines, and rolling-mill machinery have been the main sources of demand for large machine tools. Ordnance and battleship development during the late war created demands that bade fair to swamp the large machine-tool builders, but these subsided and dropped out entirely after the cessation of hostilities. Large marine Diesel engines, if commercially developed in this country, will probably widen further the market for large machine tools.

It is obvious and natural that the demand for large tools di-

[1] Engineer, Wm. Sellers & Co., Inc. Mem. Am.Soc.M.E.

Presented at a joint meeting of the Philadelphia Local Section and the Machine Shop Division of The American Society of Mechanical Engineers, the Engineers' Club of Philadelphia, and the Philadelphia Section of the American Institute of Electrical Engineers, Philadelphia, February 27, 1923.

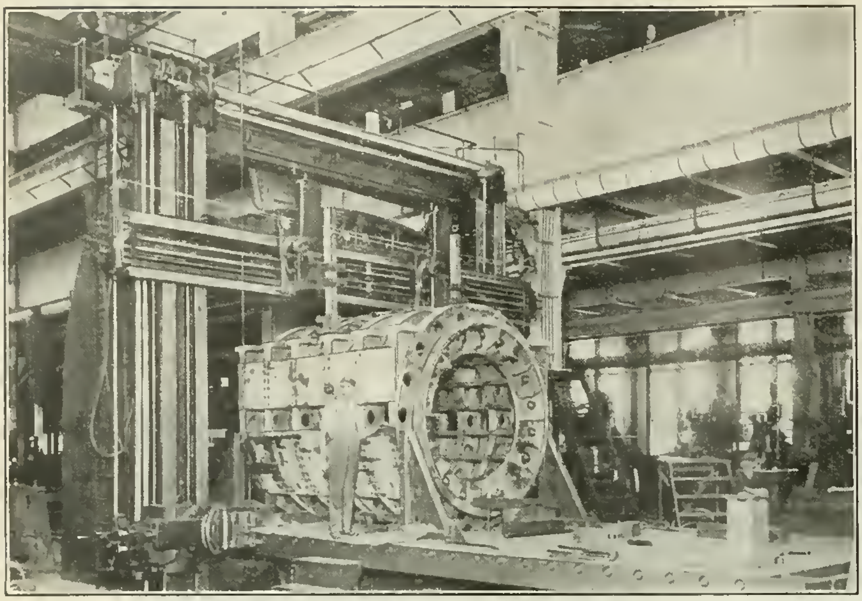

Fig. 2 Large Planing Machine

(Length of table, 38 ft. 6 in.; clearance between housings, 16 ft. 2 in.; distance from table to underside of crossrail, 13 ft. 4 in.; overall length of bed, 65 ft. 8 in.; total weight, 412,340 lb.)

minishes as the sizes of the tools increase. Developments of large mechanical and electrical projects of continually increasing size must include consideration of the means of production, and involve in many cases installations of large machine tools to accomplish the ends desired. The development of one such project frequently raises the general requirements in the particular industry to which it belongs and incites competing development. This may account in part for the spasmodic markets for the different lines of large machine tools. The requirement for these tools is very irregular. Some lines lie dormant for a long time, during which others are very active, and then the active ones drop out entirely for a period and others take their place. There are also times when the saturation point is temporarily reached, during which the whole market is dead.

From the foregoing it can readily be understood that large machine tools cannot be constructed or handled as a continuous manufacturing process. Consideration of this fact affects all branches of the industry from the design to the final inspection. The market has been so irregular as to make it seem inadvisable or uneconomical to equip and maintain establishments for the sole purpose of building such tools.

Machinery for building in the most efficient way the ever-increasing sizes of tools the market demands, would involve an investment far in excess of that which would predicate an equitable return. The machine-tool builder therefore in many instances has to use average large-shop equipment to produce tools of a larger size than any he has in his establishment. This condition requires considerable attention from the designer, who must plan the large units of the machine so that they may be handled by existing equipment and at the same time not suffer in their value as a part of the big machine tool.

Limitations Imposed on the Designer

Large patterns are bulky in storage and expensive in maintenance—to such an extent that in many cases the designer must try to adapt them to a variety of uses. It frequently pays to make a mold from a larger pattern and to stop it off with cores, rather than make a new pattern for the job. The time required to make new large patterns for a machine might affect delivery dates seriously and cause the loss of sales. The designer must bear all of this in mind, and also consider the feasibility and desirability of compromise in shaping the large units.

Another factor entering into the design and construction is the limiting sizes of parts that can be conveniently shipped. Bridge and tunnel clearances on the railroads limit the dimensions of parts that can be shipped as a unit. Machine tools must be made so that after having been assembled, tested, and corrected where necessary to an accuracy seldom matched in other mechanisms, they may be taken down, shipped, reassembled, and reproduced after these operations the same degree of accuracy as when under test.

The quality of machine tools for finishing is dependent on sound design backed up by expert foundry and machine work; and all of these factors must rest on the foundation of experience—not only that of the individual but that which lies in the records of an establishment. The grade of mechanic required in building these big tools is much higher than the average, the valuable men being those who have had a number of years of experience in this class of work. Detailed planning and instruction can rarely be applied in such work, and therefore the individual experience of the men, as well as of the foremen, has an appreciable effect on the character of work produced.

In the drafting room, as has been noted, there must be a thorough knowledge of shop conditions, shipping conditions, and of the difficulties encountered in previous experience in building the big machines. In the pattern shop and foundry there must be knowledge of the action of the molten metal in cooling, which will enable the patternmaker and the foundryman to gage with some degree of certainty the eccentricities of the metal in large castings so that those delivered to the machine shop will be sound, the bearing surfaces will show a good close-grained material, free from sand or casting defects, and the finished surfaces will have such hardness as will produce good wearing qualities and at the same time will not be too hard to machine satisfactorily without undue trouble with the cutting tools.

A large casting must be designed so that as far as possible the various sections will balance each other in cooling. Lack of balance in a long casting, for instance, if not properly compensated, will cause it to distort in cooling, often to such an extent that the amount of finish allowed in the pattern shop is of no use. There are some cases, however, where it is necessary to use unbalanced sections. In these cases experience teaches how much the mold should be distorted to offset the natural tendency of the casting. Big castings for machine tools require the handling of large quantities of molten

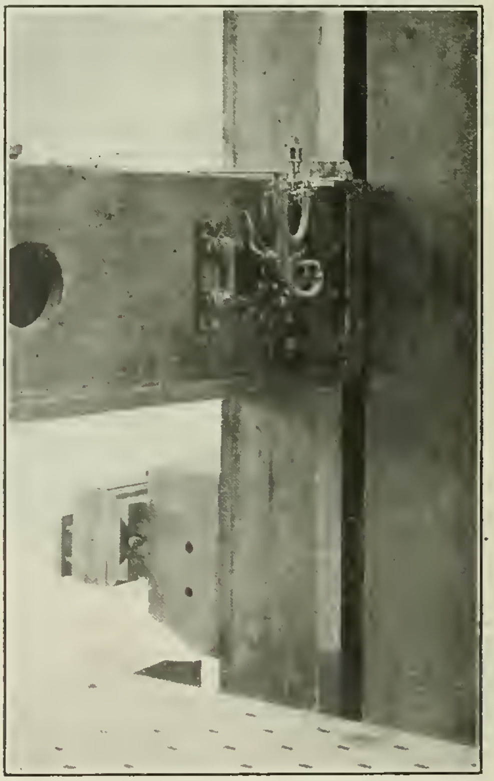

Fig. 3 Pneumatic Device for Clamping Planer Crossrail

metal in the very short time that can be allowed for pouring even the largest of castings. Interrupted flow of metal in pouring a large casting may, in fact will, if it occurs, detract from the value of the casting.

In order to produce a good close-grained material on the wearing surfaces of the machine, it has been found desirable and practical, using a high-silicon iron, to cool these surfaces quickly by casting them against chill blocks. The metal produced in this way is not what is known commercially as chilled iron. It is easily machined and not extremely brittle. While it is common knowledge that this method is desirable and practical, some years of experience as to size of chills and analysis of metal are essential in the making of large castings in order that satisfactory and consistent results may be obtained.

In the machine shop the castings must be properly handled to produce accuracy. All castings as they come from the foundry contain a great number of internal stresses. When some of these stresses are released in machining, others that they have been balancing are also released and produce distortion. It is therefore necessary that these large castings should be rough-machined in the proper sequence of operations and that enough time between be given for the stresses to work themselves out before final conditioning.

One of the disturbing factors in the construction of large machine tools is the variation in temperature between night and day and between floor temperatures and temperatures which exist at a height of, say, 25 ft. above the floor. For instance, in testing the alignment of the housings or uprights on large machine tools, variation in temperature will cause uprights to move from one side of a plumb line to the other in comparatively short time. Due allowance for variation in temperature, timing of the tests and inspection, during the course of erection, to fall under proper conditions, are very necessary in building these machines, particularly as such an upright must be plumb to within very close to a thousandth of an inch in its whole length.

The main bearings on large machine tools must be accurately fitted. To do this conveniently, where possible the bearings are capped and bushed and each bearing scraped to fit its individual shaft. The shaft bearings are ground. In fitting the shafts to the bearings on large machine tools, shoulders are turned on the shafts to suit. Measurements from the stands and housings after they are set up and bolted to place, are transferred to the shafts with proper allowances for running clearance. A properly designed bearing, if improperly fitted during erection, may in a very short time of running develop such trouble that the design of the bearing may be questioned and throw discredit on the machine performance.

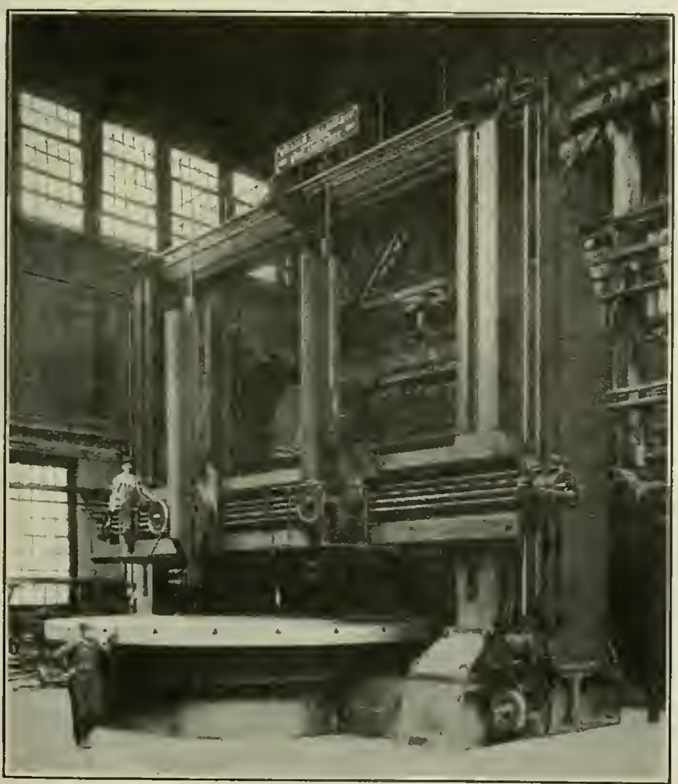

Fig. 4 25-Ft. Boring and Turning Mill with 10-Ft. Stroke of Tool

(The crossrail here is so deep vertically to meet requirements that the reinforcing arch girder is omitted satisfactorily. Total weight of machine, 373,130 lb.)

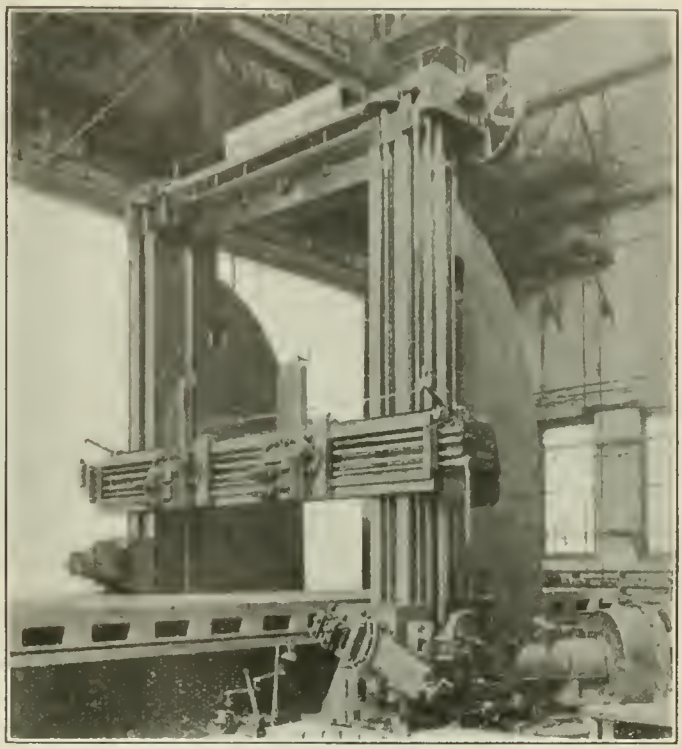

Fig. 5 12-Ft. Planing Machine

(As in the mill of Fig. 4, the crossrail is so deep vertically that a reinforcing arch girder is not needed.)

All of the main bearings in high-grade machine tools are bushed in order that (1) the best possible kind of metal may be provided for the bearing surface, and so that (2) in case of accidental cutting or scarring or wearing in service the bearing may be renewed by replacing an old bushing with a new one. In order that replacement may be properly effected the bushings are first bored and then turned on a mandrel so that concentricity of their inner and outer surfaces may result. This insures that a replaced bushing will restore correct alignment. The practice of boring bushings after they have been fastened in the stand is bad, and not tolerated by reputable builders.

Illustrations of Problems Confronting the Designer of Large Machine Tools

A detailed discussion of design and construction as applied to any one tool, to be complete, would take up more space than is available for all of this paper. However, one or two specific cases may be taken to illustrate some of the outstanding points.

Fig. 1 will give an idea of the proportions of a large boring and turning mill. To appreciate the size, comparison may be made with the medium-sized boring mill set on the work table of the large mill. The small mill shown swings 100 in. between the uprights or housings; the large mill swings 35 ft. and has a maximum clearance between the work table and the underside of tool heads of 18 ft. The rams at whose lower ends the cutting tools are carried have a stroke of 7 ft. The weights of some of the large castings are as follows: bed, 98,000 lb.; table, 73,000 lb.; crosshead bar, 66,000 lb.; total weight of machine, 429,200 lb.

The main problems confronting the designer in this instance were that the machine was to carry on the table work weighing up to 75 tons, bore a true hole 7 ft. long, and face and turn accurately. The accuracy required in the bore will probably not permit over 0.002 in. variation in round or in parallel in the length of 7 ft. To obtain the requisite accuracy the guides on the crossrail on which the tool heads move must be very close to a perfect parallel to the annular bearing surface on top of the bed. Obviously the tendency

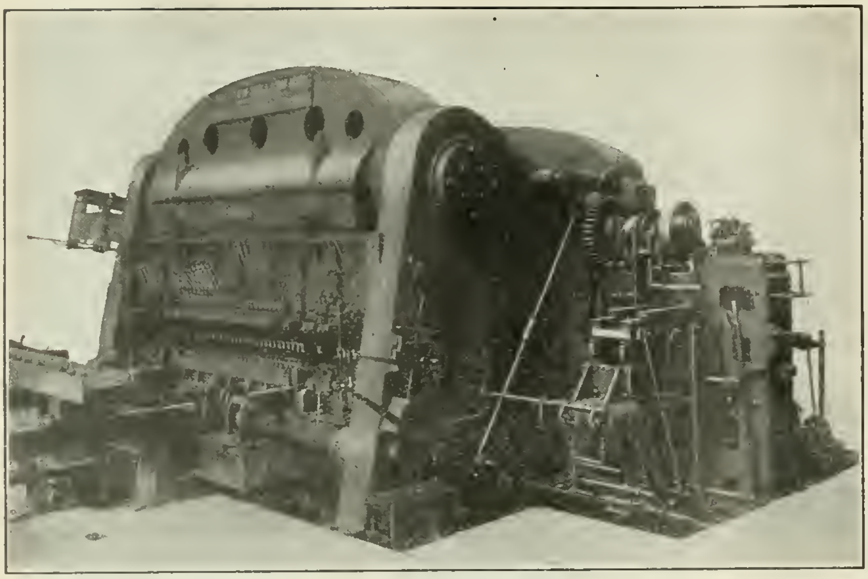

Fig. 6 Multiple Punching Machine, Operated Automatically from a Punched Paper Templet

(Used for duplicating layouts and very accurate in spacing. One of these machines has punched 59,600 holes in 9 hours. It may be broadly classed as a large machine tool.)

of a beam suspended on screws 36 ft. from center to center is to deflect somewhat, due to its own weight and the weight of the tool heads. To remove the sag in the crossrail, a separate casting in the form of an arched girder is bolted to the top of the crosshead bar. The arched girder is mounted between abutments at the two ends of the crossrail, in between the uprights and in a vertical plane as near to the front edge of the crossrail as saddle clearances permit.

Rigid Support for Cutting Tool

Another problem confronting the designer is that of supporting the cutting tool in a sufficiently rigid manner to take reasonably heavy boring cuts when the tool is extended, say, 7 ft. to 10 ft. below the bearing. This puts a bending as well as a twisting strain upon the tool bar, and a twisting and bending strain upon the crossrail. To resist these forces in the crossrail, the rail is made of a box construction. In the machine shown in Fig. 1 this box is a continuous section the full distance between the two uprights and is clamped at the back edge of this extended section to the uprights, at both sides. It is much easier to design a sufficiently rigid crossrail along these lines than in the case where the curved-back crossrail is used, in which the box section reinforcing the front of the rail starts from nothing just inside of the uprights and swells to its maximum dimension, horizontally, in the middle of the machine. With this latter construction the entire torsional strain is transferred to each end of the rail through the comparatively light section, while with the extended back the strain on the light section of rail which passes in front of the uprights is relieved considerably by the clamps securely holding the back edge of the crossrail to the uprights.

Fig. 2 shows a large planing machine erected in the shops of one of the large electrical manufacturing companies. A conception of the proportions of this machine can be formed by comparison with its surroundings and with the height of the workman standing on the table. It is made with a table to plane work 36 ft. long. The overall length of the bed is 65 ft. 8 in. The clearance between the housings is 16 ft. 2 in. and the distance from the table to the underside of the crossrail is 13 ft. 4 in. These figures fix the limits for the size of the work that can be handled on it. The bed weighs 123,400 lb. and the table (38 ft. 6 in. long) 151,000 lb., the total weight of the machine being 412,340 lb.

On a machine of this type the outstanding considerations are as follows: It must be so constructed that it will produce flat and parallel surfaces throughout its complete working range. The parallel accuracy is of course controlled to a great extent by the foundations upon which the machine is installed. Settling of foundations can very easily throw a long bed out of line to an extent that will affect this requirement. Where accurate work is required from a planer, the bed should be tested, for level and straight, at short periods, for some time after installation and thereafter at such periods as may be indicated by the character of the output of the machine. In the builder's shop, however, the machine must be set up so that it will plane flat and parallel within extreme limits of a few thousandths of an inch.

The same problem confronts the designer in this case as in that of the boring mill, namely, the design and construction of the rail on which the planing toolholders are carried. As the planers so far built have not reached the width between the uprights required on boring mills, it has not been necessary to make the crossrails of as heavy a section as on the boring mills; but the same considerations, on a reduced scale, indicate the desirability of the use of the arched girder to eliminate the initial deflection of the rail.

Planer Reciprocating Mechanism

Another feature of great importance is the question of adequate mechanism whereby the heavy table, and heavy work carried on the table, may be reciprocated at desirable speeds. The planing machine cuts in one direction. The two-direction-cutting planer came into and passed out of existence some years ago. The return stroke of the platen and work is therefore lost time, and must be reduced to the smallest possible amount in efficient production. The time required at each end of the stroke during which the planer must be slowed down, stopped, and reversed is another important item in production. A planer of this size can conceivably be used on a job requiring a stroke of 2 ft. in which the table loading is very high, say, 90 to 100 tons. Imagine the problem of reciprocating this heavy load, in addition to that of the table, backward and forward, cutting on one stroke and coming back to the cutting position on the other. The shock upon the mechanism and upon the fastenings holding the work to the table is obviously one that must be handled carefully. Up to the present time the table-driving mechanism of a planer has assumed two distinct forms. The one more commonly

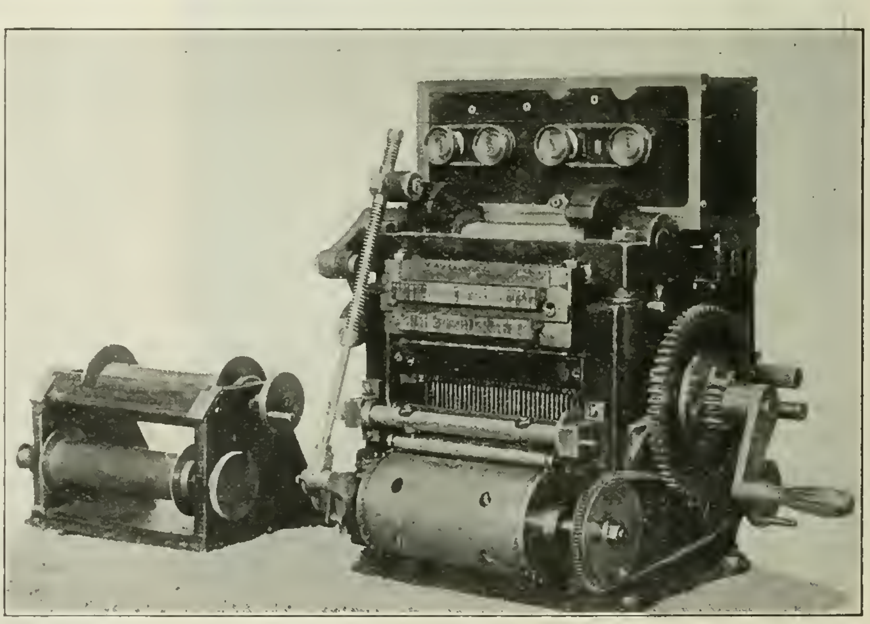

Fig. 7 Mechanism for Punching Paper Templates Used in Automatic Punching Machine Shown in Fig. 6. The Punched Template is Checked on the Rolls Shown at the Left

used is the obvious one and therefore the oldest, wherein the driving mechanism consists of a train of spur gears, reducing the speed from the power means to the proper speed of the work table or platen. These gears are sometimes modified to herringbone types. The power is delivered in all cases of recognized design through a rack bolted or clamped to the underside of the platen. The other type of drive, a recognized form for more than fifty years, is that known to the trade as the "Sellers" drive. The pinion which engages the rack is a helical pinion, commonly called "spiral pinion," the teeth being wrapped around the pinion in the form of a helix. The pinion is mounted on a shaft which extends diagonally through the bed, emerging at the back of the right-hand upright, and to which the necessary reducing gears are applied. This latter form of drive, while more difficult to produce, has an advantage in the fewer reductions necessary to translate the speed from the driving means to the table. This is for the reason that a spiral pinion can be made with four or five teeth, and of a diameter large enough to key upon the driving shaft. In this drive, when properly designed, there are at all times portions of four teeth engaged with the rack. In the case of the spur-geared drive it is difficult, even with a large driving gear with a great number of teeth, to get more than one tooth in positive action at all times. It can be readily seen that with a five-tooth pinion driving into the rack, as compared to at least a twelve-tooth pinion driving through an idler into the rack, a gearing reduction equivalent to more than two to one is introduced.

Coming back to the shock of reversal of the planer platen, the designer using a drive in which the pressure is distributed over four teeth of the rack has an easier problem to solve than one in which one tooth only is counted on to take the shock.

In the planing machine in particular, the designers and builders have to thank the electrical engineers for the best solution, so far, of the problem of reversing driving means. A reversing motor having direct connection to the driving gear of the planer has been developed in capacities up to 75 hp. and both it and the control have been found to stand up successfully under the strain of continuous reversal.

The electric control of the variable-speed d.c. motor has had considerable influence upon the design of machine tools in the last twenty-five years. The facility with which speeds can be changed within the range of the motor, in the case of a drive; and the ease with which one can use remote control on motors for the adjustments, has eliminated many mechanical complications and made possible greater simplicity of design.

Pneumatic Clamping Device

Compressed air is used for some of the operations which in the smaller and earlier machine tools were performed manually. A notable instance of this is found in these same large boring and turning mills and planers. Rigidity is essential to the satisfactory performance in cutting and the crossrail of a mill or planer must be firmly clamped in position during the cutting operation. For this purpose adequate clamps are provided to the inside and outside of the housings. When it is desired to change the distance between the platen or work table and the crossrail, these clamping bolts must be released, and tightened again after setting. On a high, wide machine these bolts are in inconvenient positions for the operator to reach. To obviate this, pneumatic clamping devices are arranged so that the operator from a position on the floor can, by moving a small air valve, control either of the required operations. Fig. 3 shows one of these air-operated clamps at the back edge of an extended-back crossrail. Similar devices are located at the three other clamping points. A cylinder operates two clamps, each one acting to resist the pressure required to set up or unlock its mate. The pneumatic cylinder functions through mechanism which, when clamped, stays in that condition until positively unlocked. It is unnecessary to maintain pressure in the cylinder during the periods between adjustments. The mechanism in the pneumatic clamping devices consists in some cases of screws operating through levers with knife edges to multiply the clamping pressure, the screws being operated by levers. The clamping cylinder is connected to one of the levers, and the end of the piston connected to the mating lever. The cylinder is suspended between the two and acts as an equalizing as well as a pressure means.

Boring mills and planers have been selected from which to draw the few examples given, as being the two outstanding largest types of surface-finishing machine tools constructed up to the present time. Indications are that still larger planers and boring mills will be built in the near future than have been built before.

Automatic Punching Machine

There are other large machine tools in which developments of equal importance with those mentioned have taken place, and their design and construction offer many interesting problems. In figure 6 one such tool is illustrated. This machine is classed as a large machine tool, was designed and built by machine tool builders, yet it might be just as appropriately classified under the title of "automatic machinery." It has been distinctively named by its users the "pianola punch," this name being derived from the fact that its operation is entirely controlled by a punched paper template on a roll, similar to those used in player pianos. Compressed air controlled by the holes in the paper template, operates all of the selective mechanisms.

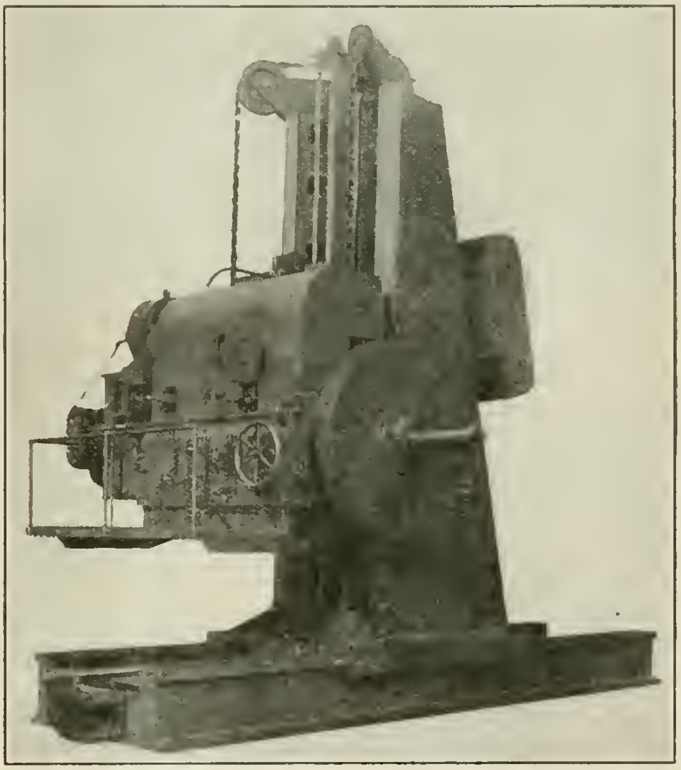

Fig. 8 Floor Boring, Drilling, and Milling Machine

(A large tool capable of handling the work of a boring mill or planer and often used for boring and surfacing castings for which a planer or boring mill of sufficient size is not available.)

The machine is of the lever type. The punches are carried on a crossbeam and arranged so that their cross-spacing may be adjusted to suit required conditions. Each punch holder is complete with a pneumatic gag-block for throwing its individual punch into or out of engagement. Spacing mechanism is provided for feeding the work through the machine in any multiple of $^1/_{16}$ in. The template which controls all of the functions of the machine is punched and proof read in some office department, brought to the machine, the work clamped in position and machine set in motion. No further attention is needed until the operation of punching the plate or angles, or both, as the case may be, is complete. Then the punch will automatically stop. Innumerable reproductions may be made from the original template, and made with great accuracy. As many as eight plates, separately punched, have been piled one upon the other and the holes registered so closely that rivet-size iron could be put through all of the plates, in any hole. The mechanism for punching and checking the paper templates is shown in Fig. 7.

The discussion on Large Machine Tools might be made to fill up almost an unlimited space; but it would seem as if the foregoing will suffice to broadly outline the general character of the work of designing and constructing large machine tools.

The Efficiency of the Scotch Marine Boiler

Results of Coal- and Oil-Burning Tests Made by the U. S. Shipping Board and the Bureau of Mines Showing the High Combined Efficiencies of Boiler, Superheater and Air Heater That Are Obtainable with Careful Operation

By C. J. JEFFERSON,[1] NEW YORK, N. Y.

THE following brief account of the tests run on a Scotch marine boiler by the U. S. Shipping Board in conjunction with the Bureau of Mines has been written with the idea of presenting to the marine world a few facts and figures in regard to the possible efficiencies and capacities that may be obtained with the Scotch marine boiler, provided it is operated with the same care in supervision as that given to the average efficient stationary plant.

From the analysis of the logs of approximately 250 vessels, it is apparent that the average merchant marine cargo carrier develops approximately 60 to 65 per cent efficiency in her boiler plant when oil-fired and that these values are from 55 to 60 per cent for coal-fired boilers. This same condition holds true for the average stationary plant of less than 1000 boiler hp., as has been shown by several analyses made at various times of boiler tests conducted on this type of plant.

The time has come, however, when better results must be obtained. The Diesel engine is rapidly entering the marine field and the steam-driven vessel must develop its maximum efficiency if it hopes to be able to sail in competition with the motorship, even after making all allowances for the relative difference in the first cost for installation.

Moreover, the merchant marine of the United States has established a higher standard of living for its operating personnel than its competitors. This higher standard means increased cost of operation, and this increased cost must be met by increased efficiency of performance.

The first essential in obtaining higher efficiencies is to educate the operating personnel to the point where they appreciate what higher efficiencies mean, how to use the instruments necessary for determining the efficiency of combustion, and how to correct faulty combustion and thereby build up boiler efficiency.

For this purpose the U. S. Navy has now opened a school at the Philadelphia Navy Yard for the benefit of the U. S. Merchant Marine, where a short and intensive course is given in the theory and practice of fuel-oil burning. Candidates for this school must be American citizens holding merchant marine licenses as second assistant or higher.

The tests which are outlined below were conducted by the U. S. Shipping Board in order that reliable and accurate data might be obtained as to the possible efficiency and capacity of the Scotch marine boiler, which is one of the oldest types of boilers in service and which has been accepted as a good, reliable servant without due regard being paid to its possible efficiency.

The Bureau of Mines was especially interested in making the thermodynamic survey of the boiler by means of thermocouple readings, gas analyses, etc., to determine the effects of combustion by the water-cooled furnace. Its findings are now being prepared by Mr. Mumford of the Bureau of Mines and his associates who worked with him and the author in carrying out these tests.

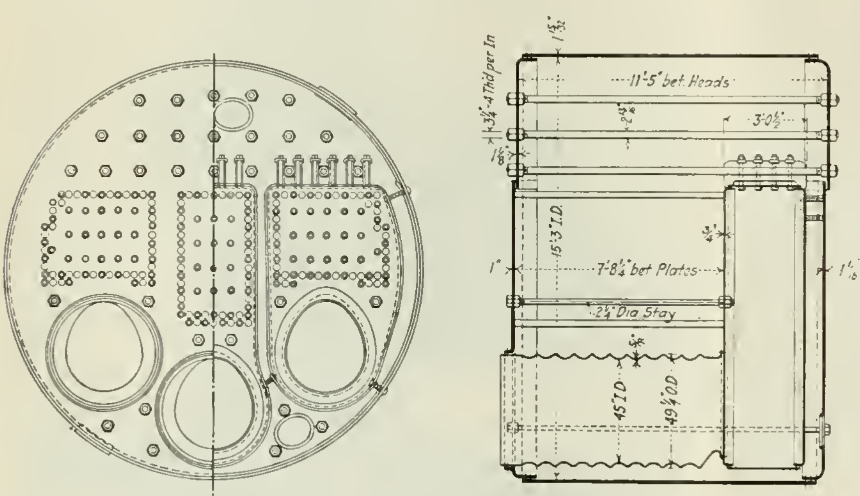

Fig. 1 General Arrangement of Scotch Marine Boiler Tested

The boiler selected for the test purposes was a single-ended, three-furnace, separate-combustion-chamber type, having 2777 sq. ft. of heating surface with coal fire and 3022 sq. ft. with oil fire. The boiler was fitted with a Foster waste-heat superheater having 774 sq. ft. of heating surface and which was placed within the gas pass above the smokebox. Above this superheater was an air heater having 1220 sq. ft. of heating surface which heated the air supply to the Howden fronts when running forced draft. Fig. 1 shows the general arrangement of the boiler and Fig. 2 that of the superheater.

Tests were divided into four distinct groups, namely, hand-fired coal, pulverized coal, forced-draft oil fire, and induced-draft oil fire. The pulverized-coal experiments were conducted to the point where it was demonstrated that this type of firing is not feasible for marine service of the Scotch boiler, as the limited size and water-cooled feature of the furnaces and combustion chambers prevented operating at ratings which were sufficiently high to meet the demand made by the average marine boiler plant.

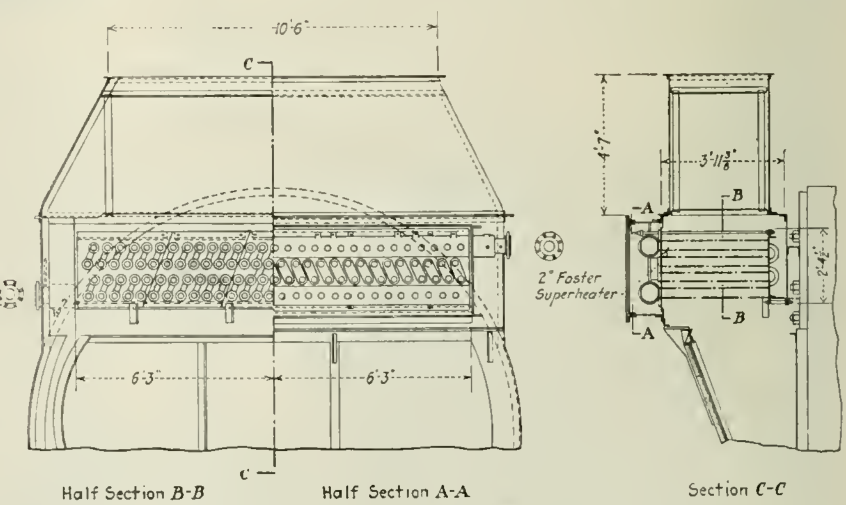

Fig. 2 Superheater Used with Scotch Marine Boiler Tested

Fig. 3 shows the boiler fitted for the hand-fired coal-burning test. In this figure the smokebox, ashpit, and fire doors are shown wide open as it was taken immediately after thorough cleaning of the

fire side of the boiler in preparation for the test. Four of the coal-burning tests which show typical results are given in Table 1. These tests are selected as representing results covering a combustion range of from 13.07 lb. to 30.9 lb. of coal per hour per square foot of grate surface. It will be noted that the plant efficiency including boiler, superheater, and air heater ranges from 73.9 to 77.9 per cent. All of these tests were run under forced-draft operating conditions.

The forced-draft oil-burning tests were conducted using Dahl,

the Todd, and the Enco burners. This latter burner, Fig. 6, was originated at the Philadelphia Navy Yard Fuel Oil Test Plant, and its adaptation for use in Scotch boiler service was developed during these tests.

The ratings obtained in these induced-draft tests were limited by the amount of available draft as the height of stack above the center of furnace was only 40 ft., and this draft was augmented by a ½-in. steam nozzle. The combined effect of the stack and nozzle produced an 0.9-in. draft at the base of the stack. Table 3 gives the data of four representative tests covering a range of from 0.233 to 0.513 lb. of oil per hour per square foot of heating surface and showing efficiencies ranging from 80.6 to 82.9 per cent. Fig. 8 gives the average efficiency values obtained from all of the tests of this class.

In comparing Figs. 7 and 8, the fact must be kept in mind that

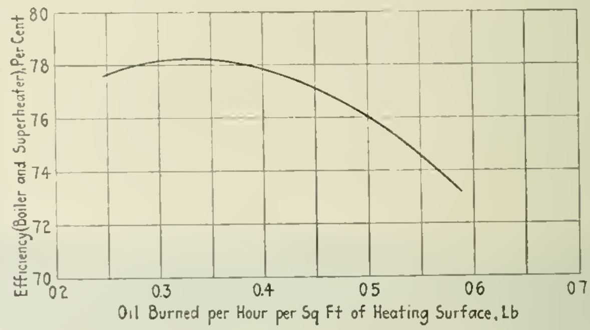

Fig. 7 Average Combined Efficiency Values Obtained in the Forced-Draft Oil-Burning Tests

(1002.46 × lb. oil per sq. ft. of heating surface = oil per burner.)

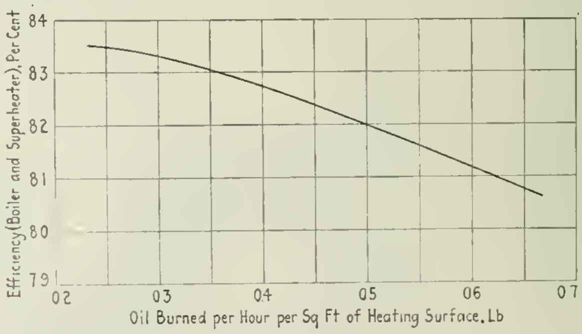

Fig. 8 Average Combined Efficiency Values Obtained in the Induced-Draft Tests

(1002.46 × lb. oil per sq. ft. of heating surface = oil per burner.)

the induced-draft tests did not have the help of the air heater in building up furnace efficiency.

From the foregoing data it will be seen that the Scotch marine boiler is capable of efficiencies considerably in excess of the average operating values obtained, and it is, therefore, a matter of simple calculation to show what considerable fuel savings are possible when reasonable supervision is shown on the part of the operating force.

Effect of Pulsations on Flow of Gases

By HORACE JUDD,[1] and DONAL B. PHELEY,[2] COLUMBUS, OHIO

The movement of gases and liquids when calculated by the existing hydraulic formulas presupposes a steady or continuous flow of the fluid. Anything which causes this flow to proceed in puffs, waves, or pulsations will result, by the action of metering devices, in errors often of great magnitude which generally do not admit of any adjustment, or of any definite knowledge of the amount of the error.

The present paper discusses work undertaken under the joint direction of the Engineering Experiment Station of the Ohio State University and the Research Sub-Committee on Fluid Meters of The American Society of Mechanical Engineers, which had for its object (1) the study of the nature of the pulsation and (2) the discovery of some practical means of reducing or eliminating the pulsation or of compensating for its effects on the devices used for measuring fluid flow. The investigation was confined to the venturi meter, the orifice, the flange nozzle meter, and the pitot meter, using air flow from a small compressor discharging into a 3-in. line. It is believed, however, that the basic principles established by the experiments are fundamental for pulsating-flow conditions for gas, steam, and water as well as for air, and also for other sizes and kinds of installations.

ONE of the most disturbing factors encountered in recent years in the metering of air, gas, steam, and water, especially in connection with all forms of power engineering, has been that due to turbulent or pulsating flow. This has not been confined to any one class or type of meter, but is present to a more or less degree with all forms of metering devices.

The measurement of gases and liquids when calculated by the existing hydraulic formulas presupposes a steady or continuous flow of the fluid. Anything which causes this flow to proceed in puffs, waves, or pulsations will result, by the action of metering devices, in errors often of great magnitude which generally do not admit of any adjustment, or of any definite knowledge of the amount of the error.

The work described in the present paper was undertaken under the joint direction of the Engineering Experiment Station of The Ohio State University, and the Research Sub-Committee on Fluid Meters of The American Society of Mechanical Engineers. A sub-committee of the Fluid Meters Committee consisting of A. R. Dodge, H. N. Packard, and H. Judd was selected to take direct charge of the research work.

Purpose of the Investigation

The object of the investigation as outlined by the sub-committee in direct charge was twofold:

a To study the nature of the pulsation

b To discover some practical means of reducing or eliminating the pulsation, or of compensating for its effects on the devices used for measuring fluid flow.

For convenience, flow meters have been classified in two main divisions which may be called (1) positive meters, and (2) inferential meters. The domestic gas, or water, meter is an example of the first class. It is a displacement meter in which an actual volume of gas is introduced into a container of known size, and the quantity thus measured is registered on the meter.

In commercial installations of even moderate size, inferential meters are used almost entirely. In meters of this class some function of the quantity of fluid passing a given cross-section of pipe is measured and from this observation the actual flow is deduced or "inferred." This method can be made to give accurate results under steady-flow conditions, but when the flow is pulsating the accuracy of the measurement is seriously affected, if, indeed, not entirely destroyed.

Three general cases may be mentioned where this problem is of great importance: (1) The measurement of natural gas, both entering and leaving a compressor station where reciprocating compressors are used; (2) the measurement of air both entering and leaving large reciprocating air compressors, or blowing engines; and (3) the measurement of steam supplied to reciprocating steam engines. The steam flow is pulsating in character because the engine cuts off the steam supply during a considerable part of each stroke. In each of these cases the flow of the fluid has a regular, comparatively rapid, rhythmical pulsation, which occasions serious errors in measurement, especially where the measuring element is of the inferential type.

Similar pulsating conditions are present in water flow where reciprocating pumps are used. The problem, however, is more easily solved by the proper use of air chambers and surge tanks. Water hammer in pipe lines from whatever cause bears a striking similarity to the pulsating effect produced by an air-compressor valve.

The authors have confined their investigations to inferential meters. These meter elements as selected are the venturi meter, the orifice meter, the flange nozzle meter, and the pitot meter. Furthermore, they have been limited to air flow from a small compressor discharging into a 3-in. line; and hence their findings, strictly speaking, would be applicable only to installations of similar character. However, it would seem highly probable that the basic principles established by these experiments would be fundamental for pulsating-flow conditions for gas, steam, and water as well as for air, and also for other sizes and kinds of installations.

Equipment Employed in the Investigation

The experimental work was carried on in the Mechanical Engineering Laboratories of the Ohio State University, and was begun in May, 1920. The essential elements for carrying on the project were: (1) a disturbing element to produce the pulsating flow; (2) a quieting element, or elements, to eliminate or modify the pulsations; and (3) a measuring element, to indicate constant flow conditions and also to indicate the effect of the pulsating flow.

Disturbing Elements. Fig. 1 shows the general layout of the apparatus, at the extreme left hand of which is located the air compressor C, a 9-in. by 9-in. single-stage, single-acting, gas engine-driven machine running at 293 r.p.m. This supplied air to a line about 120 ft. in total length of which 50 ft. was made up of $2^1/_2$-in. pipe containing several short lengths and fittings. The remaining 70 ft. comprised the 3-in. test line of straight continuous length. This test line was at first made up of standard 3-in. black pipe of commercial quality; later 24 ft. of 3-in. brass pipe was substituted for that portion of the test line preceding the meter and extending 3 ft. below the meter section. (See Fig. 1, B.)

This air supply with its full pulsating effect could be admitted directly to the test line or could be first discharged through a large tank before entering the test line. A second disturbing element for producing pulsations artificially is shown at I, Fig. 1, the butterfly-valve interrupter. This butterfly valve could be driven at speeds ranging from 180 r.p.m. to 800 r.p.m., producing thereby a variation in the number of pulsations per second.

Quieting Elements. Considerable study was made of this essential feature and many trials were made to satisfy the authors that they were securing pulsationless flow where and when needed. The tank T, Fig. 1, was used to quiet the pulsation before the meter station, M, was reached. This was a 48-in. vertical tank of 200 cu. ft. capacity. Air could be admitted either at the bottom or at the top and released from the tank through the internal pipe which reached nearly to the top. This tank when fitted with $1^1/_4$-in. orifices at top and bottom made it possible to get air flow free from pulsations before the test meters were reached.

A second quieting tank was inserted at Q, Fig. 1, at a point 8 ft. below the meter station. This was necessary in order to secure pulsationless flow at the orifice head for the purpose of establishing standard flow conditions. This tank was selected almost by chance and afterward was proved by test to be of sufficient capacity to eliminate practically all of the effect of the pulsating flow, and with

Contributed by the Research Committee and presented at the Annual Meeting, New York, December 4 to 7, 1922, of The American Society of Mechanical Engineers. Abridged. All papers are subject to revision.

the insertion of a $1\frac{1}{4}$ in. orifice at the exit from the tank the authors were entirely successful in securing pulsationless-flow conditions.

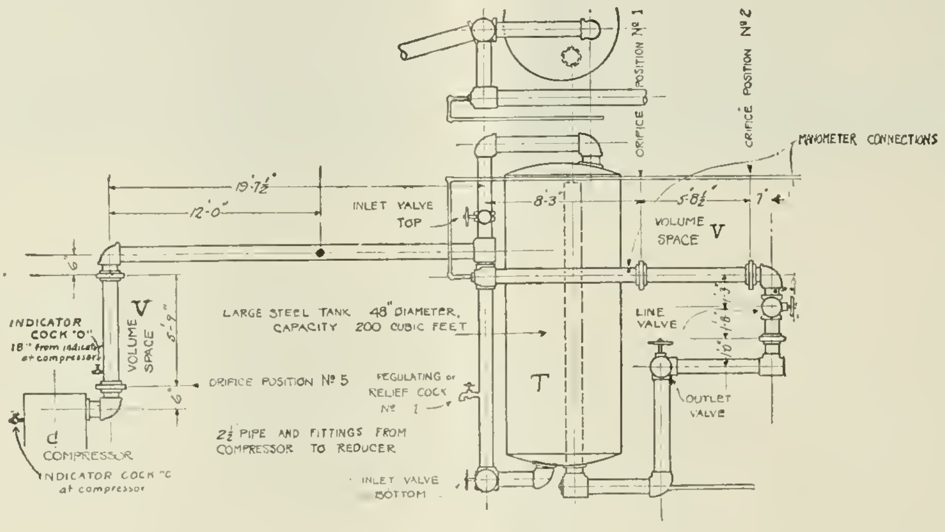
There are two positions marked, V, Fig. 1, one near the compressor and one just beyond the large quieting tank, where volumes of different sizes were inserted for the purpose of studying their quieting effect. Because the term volume seems to apply better the authors have perverted the word "volume" from a term meaning capacity to a special designation, and have used it altogether to denote the various tanks of different dimensions which have been used as quieting elements. Most of these volumes were used in the second volume space, V, beyond the large quieting tank.

The line valve near the entrance to the 3-in. test line was used as a quieting element when employed as a throttling device. Both a gate valve and a globe valve and in some cases orifices were thus used as throttling devices.

The combination of throttling with volumes constitute the muffler type of quieting device. Fig. 3, shows at *B* an S-section pipe-flange muffler which was also inserted in the line at the second volume station. This muffler is located in a by-pass in front of the line which runs directly from the compressor. All the volumes used as quieting devices were placed in direct line, but later it was found that the by-pass position answered just as well for the muffler or the other quieting devices. Fig. 3 shows sectional views of the pipe-flange muffler and also other forms of mufflers, including two funnel mufflers. A form of pulsating bag was also used as a quieting volume and was connected to the compressor line in a way similar to an air chamber on a reciprocating pump. Another device used was a system of revolving fans or baffles.

Measuring Elements. Under this heading will be taken up in order: (1) the orifice-head meter, (2) meter elements used, and (3) manometers used.

Orifice-Head Meter. It was recognized at the outset that one of the indispensable features was an accurate method of measuring the discharge of the pipe, or (its equivalent) an accurate means of indicating the velocity of the air in the pipe. This was effected



Left-Hand Portion

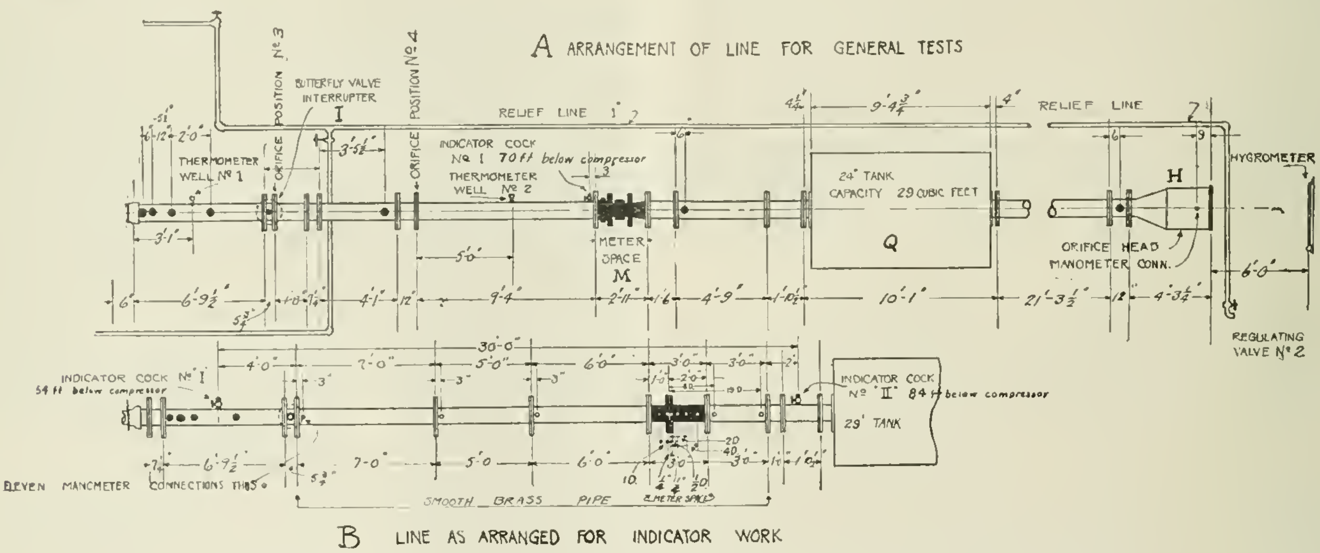


Fig. 1 General Layout of Apparatus, Right-Hand Portion (Left Hand Portion Above)

by means of an orifice head at the end of the pipe line, Fig. 1, *H*. Its outer diameter is 9 in. for a distance of 2 ft., followed by a tapered section to meet the 3-in. line. This is given a taper of 7 deg., and was so chosen as being the limiting angle for preventing as far as possible the swirling and eddying of the air as it passes into the orifice head from the line. Seven holes, reamed to $1\frac{1}{8}$ in., were provided in the head plate ($\frac{3}{16}$ in. thick), although during the tests not more than five were used at one time. In general the capacity of the compressor was reached with four holes open with a standard static discharge head of 0.9 in. of water at the orifice head. The orifice head was calibrated by discharging air through it from the calibrated tank *T* under a constant static head at the orifice head.

The orifice head was also checked against a second orifice to show how uniformly the air was distributed in its cross-section. All possible combinations of the orifices including single orifices and 5-hole orifices with and without the center orifice gave a variation not exceeding one-tenth of one per cent. This established uniform flow conditions in the orifice head regardless of the number of orifices that were open in the head plate.

Meter Elements Used. The point of insertion of the meter elements in the line, Fig. 1, *M*, was about 70 ft. from the compressor, 50 ft. above the orifice head, and 25 ft. from the entrance to the 3-in. test line.

The venturi meter was a standard unit with 3-in. entry and 1-in. throat. It is shown in sectional view at *A* in Fig. 2.

The orifice meter was made up of a flanged section of 3-in. brass pipe of the same length, 35 in., as the venturi section. The orifice flange, *B*, Fig. 2, was placed 12 in. from the upstream end and was counterbored to receive the set of orifice plates and to center them accurately. The downstream side of the hole in each plate was chamfered to $\frac{1}{32}$ in. in thickness.

The flange nozzle meter was made by inserting in the orifice-meter section a special-shaped rounded-edge orifice with projecting cylindrical end.

Two forms of pitot tips were used. The hatchet-edge static tip

(pitot No. 1) with 1/8-in. side openings is used with an accompanying open-ended impact tip with 5/16-in. opening. Both tubes are made of 1/4-in. seamless brass tubing. Also a modified form of pitot tip (pitot No. 2) was used having 3/16-in. brass tubing and an impact or leading opening facing the direction of flow and a static or trailing opening directly opposite. The diameter of each opening is 1/8 in.

Manometers Used. As far as possible the simpler forms of manometers were used. The vertical U-tube water manometer, Fig. 2, *D*, was used with the venturi meter, and part of the time with the orifice meter and flange nozzle meter, and also for the static line pressure. Where the readings had to be magnified, use was made of a 6-in. inclined one-leg reservoir oil manometer, 5 to 1 magnification (Fig. 2, *C*). For certain other readings an inclined *U*-tube oil manometer and a vertical *U*-tube two-liquid manometer were used.

A Foxboro differential mercury recording gage, Fig. 2, *E*, was used to make comparisons with the water manometer used with the venturi meter. The flow conditions were maintained and checked at the orifice head by means of an Ellison inclined gage of 1 in. range and 10 to 1 magnification.

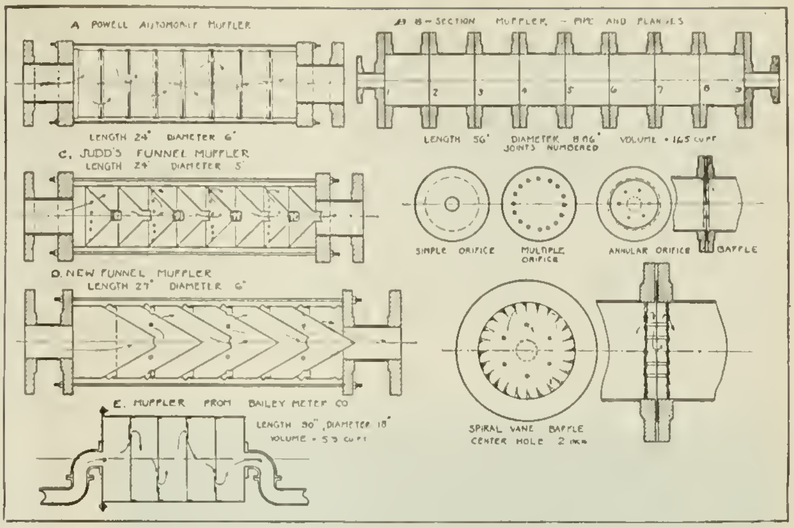

Fig. 3 Muffler Devices

Nature of the Pulsation

The first knowledge of the nature of the pulsation was gained through the use of a "photopulsometer," made and loaned to the authors by Mr. H. N. Packard of the Cutler-Hammer Co., Milwaukee, Wis. In this instrument a pitot tube with one leading and one trailing tip set with the opening in line on a vertical diameter was inserted in the center of the pipe. The leading or impact tip communicated with the under side of a diaphragm chamber. The trailing or static tip led to the upper side of the diaphragm chamber. The mica diaphragm, 0.011 in. thick, would therefore respond to changes in velocity of the air in the line as they occurred. These vibrations were directly transmitted to a mirror hung in jeweled bearings and by means of a beam of light could be thrown on a photographic film giving a diagram proportional to the velocity. By means of a pendulum beating quarter- and half-seconds a chronographic record could also be made as shown on most of the films by the breaks in the diagrams. A great many films were taken in this manner under a number of different running conditions and it proved to be a valuable method for providing a permanent record of the state of the flowing air in the line, either under violent pulsations due to various disturbing factors or for more steady flow due to the effect of certain quieting factors, as well as a record of the state of flow when under steady or pulsationless-flow conditions.

Velocity Diagrams. Figs. 4, 5 and 6, give records of the velocity changes at the center of the pipe line at various points and under various flow conditions. The maximum effect of the pulsation in the open line direct from the compressor is shown in Fig. 4. There is little or no quieting effect due to a length of pipe equal to 183 diameters.

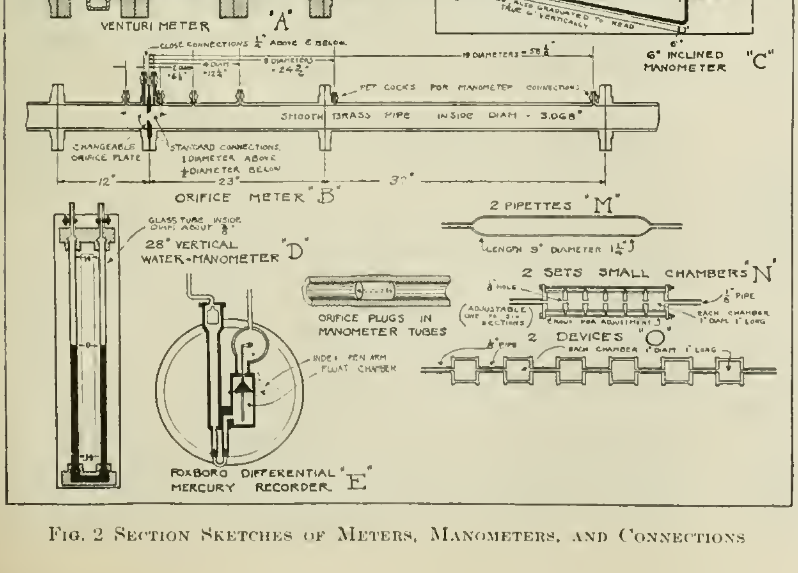

Fig. 2 Section Sketches of Meters, Manometers, and Connections

The large tank *T* was tried as a quieting chamber, when connected similar to an air chamber to a pump. However, it was found to be worthless as a quieting device. This substantiates the authors' later experience that, to be effective, tanks, or volumes, should be inserted in the line so that the air may pass through them axially.

One of the methods for eliminating pulsations is throttling by means of some kind of obstruction in the line such as a valve or an orifice. Diagram (*a*), Fig. 5, is taken for maximum pulsations direct from compressor. The diagrams appear to go below the zero pressure line, but when the secondary pulsations due to the natural period of vibration of the diaphragm are considered, it will be seen that the true diagrams approach but do not go below the zero line. Diagram (*b*) shows the quieting effect of an orifice when the pulsation has been reduced to the condition of pulsationless flow.

Effect of Pulsation of the Static Pressure in the Line. On starting the compressor it seemed frequently that the first impulse traveled much faster than the actual velocity of the air. To test this out and also to study the effect of pulsation on the static pressure in the line, two Crosby indicators were attached to the line, one on the compressor cylinder (Fig. 1, *C*), and the other 70 ft. distant (Fig. 1, *A*, No. 1 indicator) near the meter space. Diagrams were taken and two important features were brought out: (1) The pulsation in the pipe produced a much greater pressure effect than that imparted to the velocity of flow; (2) when simultaneous diagrams for a single stroke were recorded it was found that the suction stroke of the compressor corresponded to the pressure stroke in the line. This seemed to indicate that the pulsation required about the time of a compressor revolution to travel a distance of 70 ft. in the pipe. For a speed of 291 r.p.m. this would mean about 0.1 sec. for 1/2 revolution, or a pulsation velocity of 700 ft. per sec.

The Velocity of the Pulsation. The results obtained in determining the velocity of pulsation from the simultaneous sets of indicator diagrams for points located 30 ft. apart established three significant facts:

a That, although the authors' method shows results varying from the maximum to the minimum through a wide range, yet in no case does the velocity of pulsation so determined approach anywhere near the velocity of the flowing air.

b That, for a variation of velocity of flowing air ranging from zero to 27 ft. per sec., the velocity of pulsation was found to be independent of the velocity of the air.

c That the total average for 148 computations gave 1090 ft. per sec. as the velocity of pulsation. The velocity of

sound in dry air at 32 deg. fahr. and 29.92 in. barometer is 1083 ft. per sec. The velocity of pulsation in all probability is equal to that of sound in air.

For the average velocity of pulsation equal to 1090 ft. and for 4.88 pulsations per second, the pressure wave length as shown on the diagrams would be 223 ft.

Since the velocity of the pulsation is independent of the velocity of the flowing air and is evidently equal to the velocity of sound in air, it seems quite reasonable to conclude that the pulsation is a pressure change in the form of a wave front resembling a sound wave of low frequency. It seems also highly probable that these pulsations are similar in character to the pulsations set up by water hammer in a pipe line, since they also travel with the velocity of sound in water.

Some additional knowledge of the nature of the pulsation was

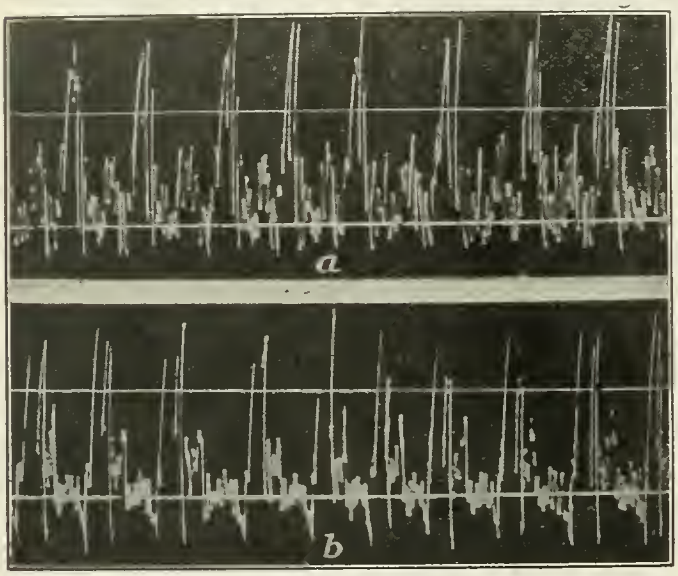

Fig. 4 Showing Maximum Effect of Pulsations at Different Points on the Line—No Quieting Effect Due to Increase in Length of Line ((*a*) Maximum pulsation in line 50 ft. below compressor. (*b*) Do., 111 ft. below compressor.)

gained by noting its effect on manometers. Where a manometer was used to measure a differential head at a meter, the following effects were consistently present:

a For pulsationless flow the reading was very constant, the only variation being a slight long period surge due to appreciable variations in the compressor speed.

b For pulsating flow this surge was magnified greatly.

c For pulsating flow there is also a rapid vibration of the water column corresponding to the pulsations and depending in amplitude upon the local conditions at the manometer.

d The most significant characteristic of the readings for pulsating flow was the large increase over that for pulsationless flow. This increase was present for every type of manometer, meter and gage tried. It varied from a few per cent to several hundred per cent under extreme conditions.

The Elimination of the Pulsation

The problem of the elimination of the pulsation, or of the effects due to the pulsation, suggested two methods of attack: (1) Modification of the existing metering devices so that the recorded flow would be unaffected whether the flow be steady or in pulsations; and (2) the use of devices which would correct or eliminate the pulsations before the flowing fluid reached the meter.

The first of these suggested schemes was taken up to some extent in the study of the modification of manometer connection. The second suggestion, that of pulsation elimination, received the major part of the authors' attention. Of the five quieting devices used, the pulsating bag and the revolving fan operated by the air flow were studied by means of the photopulsometer. The use of throttling devices, the insertion of tanks, volumes or equalizing chambers in the line and a combination of the two devices, forming the so-called "muffler," comprise the remaining three quieting and eliminating devices. These five schemes, it is believed, cover nearly all, if not all, of the practical schemes which might be used for this purpose.

Modification of Manometer Connections at the Meter. The first attempt to reduce the error of pulsation by this means was by throttling the manometer connections. It was found that throttling has no appreciable effect in reducing the error until the opening has been reduced to less than 0.07 in. diameter, and that even for an obstruction so small as nearly to close the opening the percentage of error is not reduced to within practical limits. The surge, or pulsation, of the water column was completely destroyed, so that the effect is quite analogous to that of the steam gage when throttled. This indicates that while throttling a pressure gage does not affect its reading, it has no beneficial effect in reducing the error due to pulsation.

The efficient quieting effect of volumes when used in the test line suggested the possibility that small volumes inserted in the tubes leading to the manometers might serve to reduce the pulsation before the meter was reached.

Several tests were made using the orifice meter and the 6-in. inclined gage with volumes of different sizes in one or both of the manometer connections. The results of these tests show that the use of volumes in the manometer connections does not give so favorable results as the method of throttling. There is only about 15 per cent reduction in the error for the 70 per cent orifice meter.

It was thought, also, that the point of attachment of the manometer connection might have some influence on the error due to pulsation. With the orifice meter comparisons were made with the manometer connected (1) close to the orifice and (2) at a distance of one pipe diameter above the orifice and at points below the orifice ranging from $^1/_2$ diameter to 19 diameters.

Tests made show that for all orifices including the 80 per cent

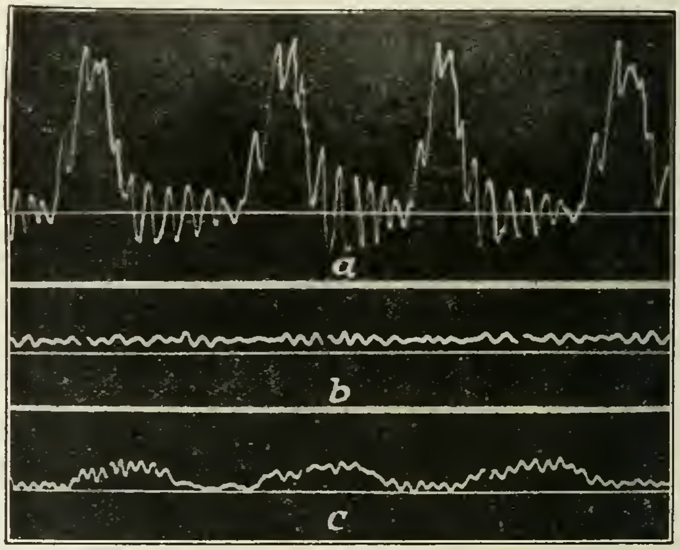

Fig. 5 Showing Quieting Effect of Throttling by Means of an Orifice ((*a*) 80 ft. below compressor, maximum pulsation in line. (*b*) 10 ft. below throttling orifice, pulsation destroyed. (*c*) 4 ft. above interrupter, 3.5 pulsations per sec.)

orifice the error at the standard points of correction is greater than that for points near the orifice which averages 96.3 per cent of the error at the standard points of correction. For points farther distant from the orifice there is a tendency for the error first to increase and then to decrease as the 19 diameters point is approaching, in all covering a total range of 20 per cent error.

Effect of Type of Manometer Used. The error in measuring pulsating flow seemed to depend to some degree upon the type of manometer used to register the head, even if all other conditions of the line and meter were identical.

It may be stated that all manometers properly graduated will give the same head readings for pulsationless flow. But when the flow is pulsating, the ratio of its reading to the true reading will differ somewhat according to the variations mentioned above. A mercury manometer will probably show an error less than that of a water manometer and the latter less than one using mineral oil. A manometer with small tubes is likely to read higher than one

with a larger set of tubes, but this is merely a tendency. If the tubes are too small the capillary effect can be noted; and if they are too large, or if they end in a reservoir, the doubtful effect due to a "volume" will be introduced. The inclined leg of a manometer under some conditions may even cause less "surge" effect. The presence of a check value or damping device between the two manometer legs or chambers, or a float to actuate the recording arm, may reduce the error.

Maximum Percentage of Error Produced by Pulsation. The results obtained show that the less the obstruction to the flow of the air, the greater the percentage of error due to pulsation; also, the greater the restoration of pressure after passing the meter, the greater will be the error. The reason for this relation appears to be that, since the pulsation is a form of pressure energy, that type of meter unit which in itself most completely dissipates the pulsation energy will show the least percentage of error.

Distribution of Pulsation as Shown by Traverse. The pipe was traversed by both types of pitot tubes for maximum pulsation conditions. The results when plotted show by both traverses that error due to the pulsating flow is least at the center of the pipe. There is a slight tendency for the point of minimum error to be located a little to one side of the center of the pipe. It is not known just how much the pitot tubes themselves are influenced by their approach to the wall of the pipe.

Quieting Effect of a Revolving Fan Section. The revolving fan apparently has some merit as a quieting device, but is of questionable practical value.

The Effect of the Pulsating Bag as a Quieting Device is shown by Fig. 6. It is felt that the special design of such a device would be needed to cover the requirement of each individual installation in order to correct or eliminate the pulsating error.

Elimination of Pulsation by Throttling. The experiments carried on with the various devices for eliminating or modifying the pulsation led to the conclusion that the solution of the problem depended entirely on the absorption of the energy of the pulsation propagated as a pressure wave closely resembling a sound wave of low frequency. Whatever the device used, its value in killing the pulsation will be measured by its ability to absorb, or dissipate, this energy of pulsation.

The general effect of throttling is to reduce the error rapidly by means of a pressure drop up to 4 in. of mercury. The use of a greater pressure drop causes the error to be reduced more gradually. In most cases the error is not reducible below 1 to 3 per cent, even with a sacrifice of a drop of 12 in. mercury. The manner of throttling is immaterial whether by gate or globe valve or by an orifice.

Elimination of Pulsation by the Use of Volumes. Tanks, or volume capacities, or "volumes," as the authors have chosen to call them, were used in the line for the purpose of quieting the pulsation. These volumes were inserted in the line so that the direction of flow through them was along the axis of the volume. They were all cylindrical in shape and with the exception of the 8-in. and the 48-in. volumes were made of thin sheet metal, No. 24 gage. It is evident from the results obtained that a volume is also a practical means of eliminating the pulsation. The chief question is, whether in large installations volumes of sufficient size would be of practical use.

Effect of Varying the Shape of Volume was also studied. In a general way a volume is probably more efficient when it is of relatively large diameter.

Elimination of Pulsation by Combining Throttling with Volumes. Since the pulsation could be nearly if not quite eliminated either by the use of throttling devices or by the use of volumes alone, the natural conclusion was that some combination of the two schemes might be discovered which would give satisfactory results without the objectionable large pressure drop or the excessive size of the volume. A series of runs was made, while the various volumes were in the line, where orifices of various sizes were placed at the entrance and exit of the volumes. The venturi and the orifice meters were used in these tests. It was found that it was possible with a volume of several cubic feet, combined with a pressure drop of about two inches of mercury, to reduce the error to a small figure, even for a meter having a large maximum error.

The Muffler as a Quieting Device. Following the experiments with the volumes and orifices combined as a means of eliminating the pulsation, the idea was further developed by the combination of a volume with several orifices; or in other words, the adaptation of the principle of the automobile muffler to the problem of pulsating flow. It was found that the effectiveness of any single type of muffler, aside from its value as a volume alone, depends entirely upon the amount of throttling produced and very little upon the design and arrangement of its baffle work.

Conclusions

The conclusions reached as a result of the investigation may be summarized as follows:

A Nature of Pulsations:

a Pulsations in a pipe line, originating from a reciprocating system, or a similarly disturbing system, consist of sudden changes both in the velocity and in the pressure of the fluid.

b The pressure change is the most apparent and is probably the greatest factor in producing errors in metering devices.

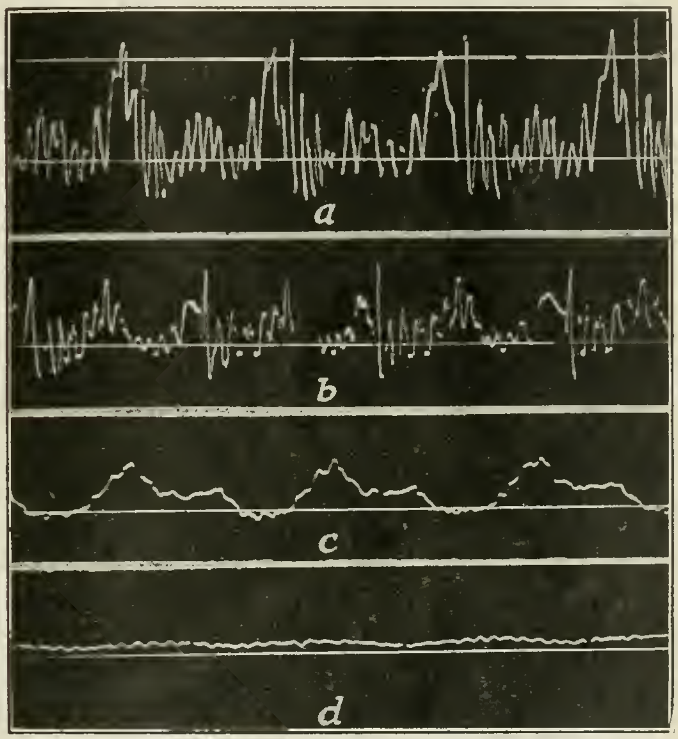

Fig. 6 Showing Quieting Effect of Pulsating Bag

(*a*) 54 ft. below compressor; maximum pulsation in line.
(*b*) 54 ft. below compressor; pulsating bag attached to quiet pulsations.
(*c*) 88 ft. below compressor; shows slight quieting effect of the 12-in. volume.
(*d*) 117 ft. below compressor; shows complete quieting effect of the 24-in. volume.

c The pressure change is in the form of a wave front resembling a traveling sound wave of low frequency.

d The pressure wave travels in the pipe with the velocity of sound.

e The velocity of the pulsation is independent of the velocity, or quantity, of fluid flowing.

f Pulsations in air flow are similar to the compression waves set up by water hammer. Both travel at the velocity of sound in the fluid and are independent of the velocity of flow.

g The effect of this pulsation on a flow meter is to increase its reading, often causing an error of great magnitude. The magnitude of this error depends upon the frequency of pulsation, nominal static pressure of the fluid, type of meter used and adjacent fixtures in the pipe line.

h With orifice meters and flange nozzle meters the pulsating error increases as the diameter of the orifice, or nozzle, approaches the diameter of the pipe.

i The throttling or modification of the manometer connections to the meter does not appreciably reduce the error.

j The point of attachment of manometer connection has no great effect on the error due to pulsating flow.

k The pulsation error at the center of the pipe is 35 per cent less than that at the wall of the pipe.

l A meter on a "dead-end" connection will usually show a positive error of considerable magnitude.

m The pulsation must be eliminated or greatly reduced in order to have the meter read without objectionable error.

B Practical Elimination of Pulsations:

n Because of the high velocity of the pulsation, an excessive length of pipe line would be necessary to destroy the pulsation.

o Throttling is effective but requires a pressure drop of 6 in. of mercury to reduce the error to 5 per cent.

p Abrupt volume enlargements in the pipe line will eliminate the error, if of sufficient capacity. A volume capacity of 20 cu. ft. is required for an error within 2 per cent.

q Generally speaking, for the same capacity, a volume of relatively large diameter is more effective than one of small diameter.

r No relation was found between the compressor displacement and the capacity of the volume chambers.

s The combination of throttling with volumes forming the "muffler" device probably is the most effective device for the mechanical elimination of pulsations.

t The pulsating bag, or diaphragm, and the fan, or revolving baffles, are partially successful in eliminating the pulsations, but their installation is thought to offer serious practical objections.

u The effectiveness of any of these quieting devices seems to depend upon their ability to dissipate or change the energy of pulsation which is effected chiefly through a drop in pressure.

v The device which will destroy the pulsating energy with the least obstruction to the flow of the fluid is the most desirable.

w The effectiveness of the meter element itself in quieting the pulsation depends upon the degree of restoration of the pressure beyond the meter. The greater the percentage of restoration, the higher the percentage of error shown for any given type of meter.

C Adjustment of Error of Pulsation:

x It is probably not feasible to correct any meter by means of a correction factor owing to the disturbing effects which may arise from slight changes in the installation and running conditions.

y The experimental establishment of a pulsating correction factor and its relation as shown in the formula proposed in the complete paper is not considered feasible with our present experimental knowledge of the laws of pulsating flow.

z It seems probable that each installation where pulsating flow is present would present its own peculiar problem for which an individual study and consideration of the existing conditions would be necessary for a satisfactory solution.

The complete paper contains additional illustrations of apparatus, indicator and photopulsometer diagrams, tables giving the data obtained in the investigation, and a bibliography of the subject. It also discusses the possibility of adjustment of errors at considerable length.

Discussion[1]

H. N. Packard,[2] who opened the discussion, said that he did not agree that the pressure change was the greatest factor in producing errors in metering devices. For instance, imagine a cylinder and piston to be discharging through a short length of pipe, including a pitot tube, into a large volume such as a gasometer. In the meter section no appreciable static pressure increase could be measured, but a very appreciable variation in rate of flow must occur with the consequent error of meter reading. As practically all meter installations were fairly close to the pulsation-producing piston, he believed the trouble caused was mostly due to actual instantaneous flow variations through the metering device.

The statement was made that at least a 6-in. mercury pressure drop was required to reduce pulsations to a practical limit. Did the authors consider this a general statement or applicable only to their test conditions? It would appear to him to be a function of the density of the fluid, its velocity and the pulsation wave form (magnitude of pulsation) if made as a general statement.

He was still of the opinion that there was some relation between the piston displacement and volume of a quieting receiver. Taking the two absurd extremes of a volume equal to piston displacement and an infinite volume, in one case it was known that no effect would be produced and in the other that perfect quieting of pulsations would occur. He believed that the quantity of fluid discharged per stroke, the number of strokes per minute, and the volume and diameter between the source of pulsations and the meter determined the pulsation effect at the meter, at least with elastic media such as gases.

On dead-end error tests he believed that there was an actual displacement of gas back and forth in the meter, this flow effect being due to the elasticity of the gas which was alternately compressed and expanded in the dead-end volume.

J. M. Spitzglass[1] wrote that prior to the advance of Professor Judd's experimental work on pulsating flow there was an idea prevalent that the error in the measurement was due mainly to the magnifying effect of the differential column, reading the average height and the corresponding square root of this average instead of the average of the instantaneous square roots which were the equivalent of the varying flow.

With the development of the flow meter, his company had sought to eliminate this error by making the meter respond electrically to the instantaneous instead of the average height of the differential column. This provision was thought to eliminate the part of the error which the authors of the paper designated as the "effect of the type of manometer used." They soon discovered that there was a much larger error due to the "harmonic" effect of the pulsations in the flow. Still, in all their observations with reciprocating flow this error had seldom exceeded 25 per cent under any circumstances. Furthermore, this error could be easily eliminated by moderate restrictions in the form of additional orifice plates on either side of the differential medium.

The effect of pulsation, according to Mr. Spitzglass' understanding of the investigation, was shown to be rather in the nature of an additional term than a factor in the algebraic expression of the flow for a given meter.

R. J. S. Pigott[2] submitted a written discussion in which he said that the problem of pulsating flow was largely an acoustic one. All the data went to show that the variability of the conditions was due to the fact that the acoustic conditions in the pipe differed with every installation, and it was hard to see how pulsating flow could be stopped in every case until a study was made of the phenomena from an acoustic standpoint.

One of the earliest problems in the opinion of the members of the Fluid Meters Committee had been that of either providing correction for the effect of pulsating flow upon the indications yielded by the flow-meter mechanism, or to so reduce the pulsations as to render their effect insignificant. The net result of research had definitely confirmed the belief that any type of meter operating on a difference of head which was proportioned to the square of velocity would register high on pulsating flow. The other belief, that it was very difficult, if not impossible, to provide suitable correction factors for the readings of the meter, was also very largely confirmed. The problem, therefore, was mainly reduced to providing commercially practicable means for suppressing pulsations to a point where they would not have a marked effect in the registration of the meter.

The experimental work so far carried out had indicated that it was feasible to accomplish this end by means of a combination of throttling with enlargement of volume. The scope of the experimental work had not been large enough as yet to definitely establish the amount of throttling and the amount of volume enlargement required for any particular case, and it was probable that the variations in velocity and size of lines would render an exact solution for any specific case difficult.

The first report of the Fluid Meters Committee was to have been produced for the Annual Meeting but the amount of work to be done both in editing the report and preparing for printing was

[1] These extracts from the discussion deal more particularly with those portions of the paper appearing in the preceding abridgment.

too much to permit publication at that time. This report would cover the matter of installation very fully, as well as the theory and accuracy of the devices employed. It was to be hoped that it would provide for the designers and users of flow meters a complete summary of information available on the subject. Hitherto there had been no single source from which this information could be obtained, and it had been scattered through three or four hundred different publications.

John L. Hodgson[1] wrote that in his opinion, the results obtained from the elaborate researches described in the paper might have been very much greater had a careful analysis been made beforehand of the ways in which pulsating flows caused errors in meters which were based upon the measurement of a differential pressure. By making such an analysis he had found it possible to reach wider and more general conclusions than the authors and at the expense of far less experimental work. Some of the most important of these conclusions could be summarized as follows:

A pulsating air flow might be considered to consist of:

a A "pressure variation" which was transmitted with the velocity of the fluid in the pipe, plus the velocity of the sound in the fluid proper to the particular size and roughness of pipe used, and the nearness to the source of pulsation of the point where the velocity was measured.

b A "velocity variation" during which the whole of the air in the pipe was accelerated or retarded. The fluid at a point distant from the source of pulsation did not, however, change its velocity until the impulse, transmitted with the velocity stated under *a*, reached it.

Both these pressure and velocity variations caused errors in the meter, but in quite different ways.

The error due to the pressure variation occurred when the pressure pipes leading to the meter had different coefficients of discharge for inflows and outflows, and when the capacity in the meter on the two sides of the water or mercury column were different. It was then possible to obtain an actual difference of pressure on the two sides of the meter by the pressure variation alone and when there was no velocity variation at all in the pipe.

The error due to the pressure variation might easily be brought down to a very small amount by using pressure connections which had equal coefficients of discharge on both directions, and by keeping the capacities in the meter about equal.

There remained the error due to velocity variation, which was the real source of trouble. It could be shown by calculation that for certain wave forms this "velocity variation" might produce errors of several hundred per cent.

The error due to this cause could be calculated or determined by calibration for any particular conditions; but as it varied with the rate of flow, and the wave form, and the product of the specific volume and the absolute pressure of the fluid, and the loss of pressure in, and the capacity of the pipe line, it was best reduced to a small amount rather than allowed for.

The only way to reduce it was to smooth out the wave form of the "velocity variation" at the metering point. This could be done in many ways, the simplest of which (not mentioned by the authors) was to insert a capacity *and* a throttling device between the source of pulsation and the metering point. If the meter itself offered sufficient resistance it might form the throttling device; if it did not, an additional throttling device might be added. The capacity should be placed between the source of pulsation and the meter, and the additional throttling device, if any, should be placed on the downstream side of the meter.

In their closure the authors, replying to Mr. Packard, wrote that they could readily see that his type of meter would not be greatly affected, if any, by the pressure changes, even though the static pressure gage might read higher due to the pulsation. They would also conclude from their investigation that his meter would be less affected by the pulsation because the effect on the velocity head seemed to show much less error than that produced in meters depending on the pressure drop readings.

In regard to the effect produced by the static pulsation, they had failed to convey the proper meaning. The change or effect on static pressure produced by the pulsation was much greater than the effect produced on the velocity head. This pulsation, like sound, seemed to be propagated as a pressure wave and the effect produced on any measuring device, especially where difference in pressure head was used, was much greater than the effect recorded on the velocity diagrams from the photopulsometer. Hence, the conclusion that the "pressure change" was the greatest disturbing factor was drawn. This they believed to be born out in their work.

It seemed apparent that the pulsation (assuming its propagation as a pressure wave), was transmitted in the pipe by means of the air (either flowing or quiet) as a medium; and that with the dead-end meter connection the pulsation surged back and forth independent of the air which itself might also have some slight movement back and forth. This transmission of pulsation in the dead-end line would seem to be similar in this respect to the surge of pressure in a water line due to water hammer, which was very much greater in magnitude as compared with the effect due to velocity.

The conclusions given in the summary were made with reference to the installation which the authors had tested; also the reference to the throttling effects of a 6-in. mercury pressure drop considered their test conditions only, and should be modified much according to Mr. Packard's suggestion.

Referring to the relation to piston displacement of the volume of a quieting cylinder, it was probably true that *some* relation existed, but it had seemed to them that it would take such an extended investigation to establish anything approaching a law, as to render the solution impracticable.

In the dead-end meter installation, they agreed with Mr. Packard that there was an actual forward and back flow of the fluid due to the elasticity of the gas; but it was also true, they thought, that the pulsation in the form of the compression wave traveled forward in undiminished amplitude and returned in more or less diminished amplitude, depending on the length, shape, and volume of the dead-end connection.

Mr. Spitzglass stated in his discussion that the authors in finding the percentage of error due to pulsating flow had compared "a variable quantity, the pressure pulsations, on the basis of another and more variable quantity, the velocity pressure of the meter."

The error due to pulsating flow was based on the velocity, or quantity of flow, or its proportional equivalent the square root of the pressure difference through the meter element for pulsationless flow. For the four types of meters used the velocity head was equal to or proportional to the drop, or pressure difference, through the meter element. From whatever cause the pulsating flow might have been produced it was quite evident that its effect would have to be determined from the reading on the meter manometer.

It appeared to the authors, therefore, that while the pressure pulsation seemed to be the greatest factor in the error due to pulsating flow it was the velocity head reading that was observed on the meter. In their opinion it was the velocity-head readings as shown by the meter for both conditions of flow that should be compared. In fact, they were at a loss to know of any other way of establishing the percentage of error.

As pointed out in the paper and as further emphasized by Mr. Pigott, the authors believed that very little could be done to establish suitable correction factors for meters operating under pulsating flow and that the solution of the problem was reached when some suitable means were provided which would reduce the pulsations to a negligible point. The adaptation of the "muffler" device was apparently the most effective mechanical device for reducing the pulsations. However, further study and experimentation were necessary to establish the proper combination of throttling and volume space for static pressures and pulsating conditions approaching those in general practice.

Mr. Hodgson took exception to certain conclusions in the paper, in some cases justly so, and in others due apparently to a wrong interpretation. He pointed out the importance of having equal spaces in the manometer connections of the meter and in the case of the photopulsometer equal spaces above and below the diaphragm. The authors also recognized the importance of this and so far as possible all manometer connections were made of equal length, although this relation could not be maintained while the manometers were in use.

It was conceivable that the pressure pulsations might be lessened,

Some Engineering Aspects of the Design of Musical Instruments

By WILLIAM BRAID WHITE,[1] CHICAGO, ILL.

The object of this paper is to propound and answer two principal questions, namely, to what extent may the problems of producing musical tone by means of musical instruments be considered as engineering problems, and how far engineering principles and practices can be expected to work improvements in the efficiency of the most important musical instruments and in the economy and exactness of their manufacture. The major portion of the paper is devoted to the consideration of the specific problems presented in the manufacture of pianofortes.

ENGINEERING principles and practices are not at present inevitable concomitants of the making of musical instruments. Nevertheless it can be shown that musical-instrument manufacturing involves in all branches problems familiar to the mechanical engineer; and that if the principles of mechanical engineering were more generally adopted as the foundation of such manufacture, vast improvements would in due course be achieved.

Most of the present paper is devoted to a consideration of the specific problems presented by the manufacture of pianofortes, with some passing observations on player-pianos and organs. The first-named instruments occupy a position not only the most prominent in the music industries, but also the most favorable for the introduction and application of scientific ideas. Along with them, it is true, ought to be placed the various wind instruments of brass and wood, but these as yet are more important artistically than industrially; while the bowed instruments of the violin family are not practical subjects for scientific investigation from the engineering standpoint, or at least will not be such until their manufacture has reached the level of large-quantity production. Nor need there be, for the purposes of this paper, any consideration of the comparatively unimportant instruments of percussion and other minor contributors to the modern orchestra.

It is evident that any musical instrument whatsoever depends upon the recognition of, and obedience to, those laws of physics known as the laws of acoustics. Therefore it can easily be understood that scientific methods, based upon exact calculation, should form the foundation of musical-instrument building. In a word, musical-instrument building is one of the mechanical arts.

The modern pianoforte factory compares favorably with all other woodworking plants in respect to the adoption of machinery for cutting and finishing lumber and for fabricating it into wooden structures. But in regard to the tonal elements in pianoforte making, scientific reformation is imperatively needed and the present discussion is therefore confined to this phase of the problem.

The tone-producing elements in the pianoforte consist, first, of steel wires which are struck by "hammers" made of wood covered with felt. These hammers are swung on centers to which their shanks are pinned, and they move against the strings under the impulse of the musician's fingers conveyed through an elaborate system of levers, known technically as "the action." There are eighty-eight "unisons" or "notes," each consisting of two or three wires tuned to the same pitch. and each with its own hammer, its own system of levers, and its own finger lever or "key." With the rapid development of pianoforte playing since the early part of the nineteenth century, the indifferently drawn thin wires previously used had soon to be superseded by heavier material. The introduction of cast-steel wire, however, caused additional strains, which necessitated solider and stronger framework. Thus arose the now universal practice of carrying the strings of the pianoforte upon a frame or plate of cast iron. Herein lies the central engineering question of pianoforte making.

Another important tone-producing element of the pianoforte is the "soundboard." This is a sheet of spruce wood, built up from selected strips of the lumber into a square or wing-shaped table, according as it is to be used for a vertical (upright) or horizontal (grand) instrument. The strings pass over this resonance table and are put in contact with it by means of wooden bridges on which they rest, and which determine their vibrating lengths. Considering that spruce is a soft and not very durable wood and that the sheet must not generally exceed $^3/_8$ in. in thickness, it is evident that a rather heavy duty is placed upon a very slight structure in the carrying of the downward pressure of the stretched wires.

In practice the stretched wire is looped at one end over a hitch pin and then crosses the wooden bridge which connects it with the wooden soundboard. It then is stepped off at another bridge called the bearing bridge, from which it passes around the tuning pin.

Basic Conditions of the Problem

Now let the following facts be noted: First, the number of these strings or wires is about 230 in the standard pianoforte. The ten lowest (counting from the bass upward in pitch), which are also the longest, run one to a unison. The next twenty-five or so (differences exist among individual makes) run two, and the remainder, three to the unison. The tension exerted by all these wires when tuned to the standard pitch is usually not less than 35,000 or more than 50,000 lb., variations being due mainly to the individual ideas of various manufacturers as to the advantages of this or that degree of tension.

Second, the highest of these unisons (in pitch) utilizes strings each about two inches in length. At distances of an octave the string lengths are multiplied in the ratio 1:1.875, so that the increase in length from unison to unison (12 to the octave) is approximately in the ratio 1:1.054. Thus, in the largest instruments, the so-called concert grands of about nine feet overall length, the lowest bass string may be 8 ft. long. These length ratios represent the best contemporary practice, but are not necessarily binding.

Now a length of 8 ft. for the longest string on a pianoforte of this size does not, of course, represent a correct proportion, since there are seven octaves of tones. In fact, at certain points in the design of each style of pianoforte it is necessary to check the progressive lengthening of the strings, which would otherwise begin to exceed the length of the instrument, and instead to lay out each succeeding unison on the plan of increasing the weight of the wire so as to make up for the inability to increase the length as much as would otherwise be necessary. These overweighted strings are usually known as the "bass strings" or the covered strings, and form a distinct section of the design, though in a tonal sense closely related to the remaining unisons.

Third, the limitations of the human hand prescribe a total width of 48 in. for the keyboard, which is equivalent to the width of 52 white keys. The black keys are interpolated at intervals between and behind the finger plates of the white ones. Hence the entire layout of the strings, with all the arrangements for their support, must be contained in a structure which, in the largest grand pianoforte, may be as much as 60 in. wide at the keyboard end, and as much as 9 ft. long. In a small vertical (upright) instrument, the extreme width may not be more than 53 in. and the height 48 in. An ordinary grand of small domestic size will be perhaps 54 in. wide and 63 in. long.

The chief engineering problem in pianoforte design is to produce a supporting structure which will withstand the tension of the strings and provide complete stability under any normal condition of temperature or atmosphere, so that the strings will not slacken or tighten into an out-of-tune condition, and so that the soundboard shall be free to vibrate and to perform its duties as a general amplifier of the sounds set up by the vibrating strings.

Fig. 1 shows the string plan, with the bass or covered strings crossed over and above the others in order to secure the greatest

Abridgment of paper contributed by the Forest Products Division for presentation at the Annual Meeting, New York, December 4 to 7, 1922, of The American Society of Mechanical Engineers. All papers are subject to revision.

possible length. This is the sort of design which would be adopted for a small horizontal piano of apartment or domestic size, and is typical of present-day practice.

Tension Figures Calculated

The scale is divided into four divisions, and the strings in each have an approximate total tension as shown in Fig. 1. Assuming that the scale has been designed so that the average tension per string is 150 lb. in the three treble sections and 160 lb. in the bass section, and that there are three strings per unison to the three treble sections, then the tensions will be (proceeding from right to left): Upper treble division, 17 unisons, 7,650 lb.; middle treble division, 18 unisons, 8,100 lb.; lower treble division, 25 unisons, 11,250 lb.; which gives for the treble divisions a total tension of 27,000 lb. while for the bass section of 28 unisons of covered strings at 160 lb. per string, 18 of which are two to the unison and 10 one to the unison, we have 7,360 lb., making a complete total for the scale of 34,360 lb.

In regard to the problem of the supporting structure, the idea of a solid iron casting across which the strings shall be stretched and which shall take up their pull without putting any undue strain on the wooden soundboard, has been generally adopted since the middle of the nineteenth century. In general, the iron frames, or

marked 1 and 4 and one almost perpendicular marked 6. Struts 7 and 8 delimit the extreme treble section.

Now in most cases of current practice the struts are cast in rectangular section and are always deeper than they are wide. The cross-section of No. 3 is usually about 1.75 sq. in. in area. The cross-sectional area of the lower or hitch-pin end of the same strut is always less, owing mainly to the need for crossing it over the wooden string bridge with necessary clearance; 1.25 sq. in. is the area usually employed for the cross-section for No. 2.

The limiting strut at the lower end of the lower treble is usually designed at about 1.75 sq. in. for the part designated No. 1 and 1 sq. in. for No. 4.

Strut No. 5, limiting the upper end of the bass section, is often made with a cross-sectional area of 1.25 sq. in. and Nos. 6, 7, and 8 might be put down at an average of 1.25 sq. in. each.

It is evident that if a modified T- or I-bar construction were used, the cross-sections could be considerably smaller and the plate a good deal lighter. It is also plain that there is a torsional movement and a bending movement caused by the upward pull of the string as it crosses over the bearing bar near the tuning pin and is pressed downward under the agraffe or pressure bar, by means of which it is limited at the tuning-pin end and held tight against slippage when in tune. Fig. 3 shows the nature of this bearing.

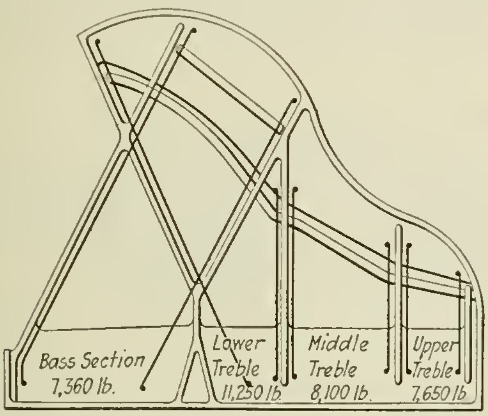

Fig. 1 String Plan and Iron Frame of a Grand Piano

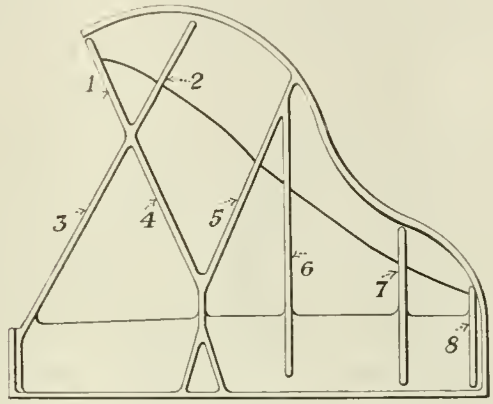

Fig. 2 Strut System in the Iron Frame of a Grand Piano

"plates," as the supporting structures are commonly called, are often far too heavy and the iron is frequently not well distributed. When they crack, as they sometimes do after the strings are first pulled up into tune, the first expedient is usually to thicken the broken member. A great deal of time, labor, and expense would of course be saved in these cases if the plate had been from the first designed by a competent engineer who could have calculated the stresses and strains and designed the tension, shear, and compression members accordingly. The relation of the strings to such a structure is incidentally shown in Fig. 1.

These iron frames, cast in one piece, fulfil two main objects: they support the tension of the strings and limit the tone-emitting lengths of these strings at the ends nearest to the tuning pins, while affording hitching places for them at the other ends. They thus consist in principle of three parts, namely, a tuning-pin plate, through which the tuning pins are driven and which is under a shear strain; a hitch-pin plate at the other end which contains the hitch pins on which the ends of the strings are fastened; and a series of compression members or struts which serve to keep the two plates at the proper distance from each other when the strings are under tension, at the same time preventing the structure from buckling. Fig. 1 shows the hitch-pin plate at the top, and the tuning-pin plate at the bottom.

Description of Supporting Structure

Fig. 2 shows the outline of a supporting structure designed to take up the strains described in the case discussed in connection with Fig. 1. It will be seen that for the bass section two struts are used, one of which has been numbered 2 and 3 and the other one 5. In the tenor or lower treble section there is one long diagonal strut

This torsional strain, and the upward pull as well, make it necessary of course to stiffen the struts rather more than would be necessary if they were to be used solely as compression members.

It should now be clear that the problem of designing the supporting structure of the pianoforte does merit the attention of engineers. In one sense of the term, the frame or plate may be deemed analogous to a truss bridge, with the differences that the load does not change rapidly and that the vibrations set up are relatively insignificant as regards any effect upon the stability of the structure.

The great need is economy of material, of resisting power, and of design, to the end that the weight of metal may be reduced, the appearance improved, the standing-in-tune qualities maintained, and duplications of the original pattern be rendered accurate and facile. It is probable also that better engineering practice would produce marked economies in the cost of production and vastly improve the general tonal standard, by securing greater uniformity and accuracy in the foundational structure of the instrument.

Acoustical Side of Tone Production

The design of the iron plate leads to a question of quite equal importance, namely, the acoustical design of the tone-producing elements or strings. Musical sounds are distinguished one from another by their pitch, relative intensity (loudness), and color or quality. The latter property, which distinguishes the sounds of one instrument from the sounds of the same pitch produced by another, exists for each family of instruments in varying degrees. Pianofortes differ among themselves greatly in quality. Some emit tones which may be described as "rounder," "fuller," or more "mellow," or again "brighter," than those of others. The differ-

ences depend upon a variety of conditions, among the most important of which are:

1 Thickness of the wire
2 Density and molecular structure of the wire
3 Tension at which the wire is stretched
4 Nature of the material with which the wire is struck
5 Point of the string at which contact takes place
6 Velocity of the hammer which strikes the blow, which is of course a function of the finger impulse upon the key.

Basis of Uniform Tone Quality

To secure tone quality as nearly as possible uniform from end to end the designer of a pianoforte should secure substantially uniform tension in each string from end to end of the scale, and an accurately graduated progression in length and weight of strings from the extreme treble to the lowest bass. The practical obstacles in the way of the attainment of this ideal are: (1) the limited number of available thicknesses of wire, (2) the limits placed upon the available lengths of pianofortes, (3) the limits beyond which bass strings cannot be loaded without destroying their tonal efficiency, (4) the fact that music wire vibrates most readily and efficiently for musical purposes at a tension equal to about one-half of its breaking strain, and (5) the uneveness of the felt used in making hammers.

To find the tension T in pounds at which a given string must be stretched so as to emit a sound of given pitch in vibrations per second the formula $T = P^2L^2M/675{,}000$ may be used, in which T is the tension required, L the length in inches, M the weight in grains (avoirdupois) per inch, and P the pitch in vibrations per second.

The design of the bass section is rather more complicated than that of the treble because the lengths cannot be determined at pleasure, but are strictly limited by the size of the pianoforte. In fact, the only rule is to make the bass strings as long as the instrument will allow, and then to calculate the weight each should have in order to give the required tension. It is better, practically speaking, to make the bass tensions a little higher, say 160 lb. per string. With this knowledge, together with the pitch in vibrations per second of each unison and the predetermined string length, the weight can be calculated from tables which have been worked out by the American Steel & Wire Co. From these same tables the nearest combination of core (steel) and covering (steel or copper) to give that weight of wire may be read off.

This is the general acoustical problem in regard to the strings themselves. The design of the supporting structure, however, can never be scientific until the string plan is just as scientific. Uniform tension properly graduated length, and carefully calculated weight are thus essential to the higher possibilities of pianoforte manufacture.

The Wooden Framework

In connection with the foundational structure there is one element which has not yet been touched upon, and which, although it is a matter of woodworking, nevertheless demands engineering attention. The strings are stretched across a soundboard and supported by the iron plate; but this plate and this soundboard must themselves be supported at their margins. The necessary support is given by a framework of wood to which, in the upright, the tuning-pin block, the soundboard, and the iron plate are fastened, and to which also are attached the sides and key bed of the instrument. In the horizontal instrument the curved or wing-shaped case, built up of veneers and bent into shape in a continuous rim around a caul, is braced by a system of beams, on which are laid the soundboard and the iron plate. Questions of stress and strain calculation naturally enter into the design of these.

Engineering Qualities of the Touch Mechanism

The practical engineer, looking at the constructional features of the pianoforte, will discover two other elements affording opportunities for improvement, namely, the touch mechanism and the stringing system. The train of delicate levers which conveys to the hammer the slightest or the boldest movement of the finger upon the balanced key lever consists of small pieces of wood pivoted on german-silver pins centered in bearings bushed with a very thick woven special cloth. Contact points are faced with buckskin or felt. There is no lubrication, and yet the total resistance to be overcome by the finger never exceeds 2.5 oz. and is usually less than this. Probably the action is the last part of the pianoforte which need engage the attention of the engineer, since it is the one part to which engineering principles have already been successfully applied.

Parallel observations may be made concerning the system of stringing. This relates to the methods commonly used to fasten the tuning pins so as to enable them to bear the torsion of the strings wrapped around them, while allowing the tension to be increased or decreased at will for tuning. The common method is to use a slim steel pin about 0.3125 in. in diameter, almost uniform in thickness from end to end, furnished with an extremely fine thread and turned into a hole drilled in a plank or block made up of cross-banded maple veneers. The total length of the pin does not exceed 2.5 in. of which about 1.75 in. is driven into the block. Many methods have been suggested and tried, successfully from the mechanical point of view, of which the object has always been to substitute a mechanical system for the crude wood block and frictionally held pin. But trade prejudice has always prevented their adoption.

Present Position of Musical Pneumatics

The rise during the last twenty years of mechanisms for playing the piano either entirely automatically or under personal control through the agency of perforated tune sheets known as music rolls,

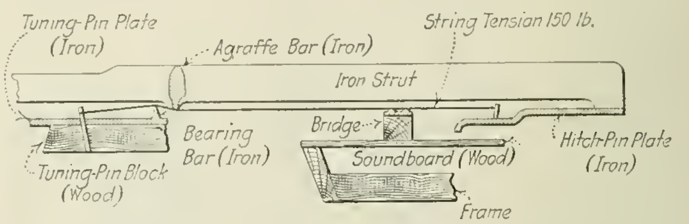

Fig. 3 Showing Method of Holding Strings Tight Against Slippage

introduces a new and fascinating set of engineering questions. These mechanisms employ, in all their forms, the pressure of atmospheric air against subnormal air pressures induced in closed chambers. That is to say, they are vacuum machines. The engineering problems they practically present may be grouped under three headings, namely, the production of the vacuum power, the prevention of leakage, and the design of the moving parts. In all these features many improvements are greatly needed. The present piano-player mechanisms are relatively crudely put together, depending upon glued-up plywood panels, rubber tubes connected with metal nipples cemented into wooden boards with shellac, and other similar devices which are clumsy, bulky, and very hard to standardize. The production of an all-metal action has been attempted, and with some success, but in practice the industry prefers to use wood, rubber hose and rubberized cloth, leather, and glue.

Problems of the Organ

The other great and complex musical instrument is of course the organ. In its many shapes, whether designed for ecclesiastical purposes, for the theater or for the home, it represents a vast complication of pipes, chests, electric contacts and cables, electromagnets, blowing engines and stop mechanisms. Unfortunately, however, the opportunities for engineering improvement are confined to the following points:

1 Blowing engine
2 Construction of the chests on which the pipes are set, with special reference to the possible use of concrete and metal in place of wood in order to eliminate the influence of temperature and atmosphere
3 Improvement in the electric mechanism which opens the pallets under the pipes when keys are depressed. Such improvement is mainly needed in order to promote durability and reliability

4 Interchangeability and standardization of parts.

These questions of interchangeability and standardization of methods, parts, and designs are the burning questions in musical-instrument manufacture. The great instruments which have been discussed are highly organized and comprehend an immense variety of parts and processes. The pianoforte draws its materials from mine, foundry, forest, sawmill, varnish factory, the sheep's back, the wire-drawing mill, from the elephant's tusks and from the sap of the caoutchouc tree.

The annual output of pianofortes is probably not to be valued on the basis of wholesale prices at more than $60,000,000 in an ordinarily good year. The industry needs, and would respond to, energetic and practical treatment from the standpoint of approved engineering practice.

Discussion at the Forest Products Session

AT THE Forest Products Session of the Annual Meeting of the Society, the following papers were presented: Some Engineering Aspects of the Design of Musical Instruments, by W. B. White; Lumber Dry Kilns, by Thomas D. Perry; Lumber Standardization, by F. F. Murray; New Factors Which Are Influencing Woodworking Machinery Design, by S. Madsen; and Control of Lumber Cutting Waste and Production, by C. M. Bigelow. The following abridged account comprises the discussion of the papers of this session that have already been published in Mechanical Engineering.

Discussion of Paper by Mr. White

Thomas D. Perry[1] opened the discussion of Mr. White's paper by asking the author if scientific investigations had been made of the resonance qualities of different woods used in the manufacture of musical instruments.

Mr. White replied that Dr. Miller, of the Case School of Applied Science, had made many valuable investigations during the past twenty years on the vibration of wood. He said that it would be highly desirable to know more about the behavior of a steel wire with reference to wood vibration and the effect on the vibration of wood of processes of preparing the wood for use.

Frederick F. Murray,[2] who said he was interested in the subject from the standpoint of the standardization of lumber, asked if wood as raw material was treated in the piano industries on the same basis that steel was treated in other industries.

Mr. White replied that the piano industry had grown from small beginnings 150 years ago until today it was including many machine and duplicate processes. The industry was still divided into a few branches, and in each of these the skilled workman did every operation belonging properly thereto. As long as such conditions existed, he said, it would not be possible to get standardization and interchangeability in the industry.

Mr. Murray said that in the furniture industry specialization had resulted in departments devoted to the manufacture of a single type of furniture, such as tables or chairs. In such shops the present standard classification of lumber was inadequate, and there was great waste resulting from piecework in shops operating on a production basis.

Mr. White spoke of the changes in the piano industry resulting from the demand for small grand pianos of the apartment size and for self-playing pianos. In all important shops, he said, there was a general standardization and a virtual interchangeability of parts. On the other hand, he said, the piano industry was essentially an art industry and the problem to be solved combined the ideals of art and production.

Mr. Murray said that standardization as he was interested in it did not mean a standardization of product nor an attempt to conform public taste to a standardized product, but dealt with the standardization of the raw material which would still admit of the most complicated fabrication. The purpose of such standardization was to eliminate the waste which now existed because of the lack of it.

[1] Grand Rapids Veneer Wks., Grand Rapids, Mich. Assoc-Mem. A.S.M.E.

[2] Hardwood Mfrs. Inst., Chicago, Ill. Jun. A.S.M.E.

Discussion of Paper by Thomas D. Perry

The discussion of Mr. Perry's paper on Lumber Dry Kilns[1] was opened by Kenneth Redman[2] who wrote that the paper inferred that the blower or forced-circulation type of kiln was suitable only for the drying of thin stock, or veneer. As a matter of fact, he wrote, the fan type of kiln was today meeting with its most marked success in the drying of extremely heavy stock which heretofor it had not been possible to dry in the pipe-coil kiln without the liability of enormous losses in the drying process. An examination of some of the fundamental facts to be considered in drying lumber would clearly show why this was possible.

Mr. Redman heartily agreed with Mr. Perry that the ideal way to dry lumber was to keep the surface pores open and to draw the moisture out of the wood at the rate that the moisture could transfuse from the center to the surface. In order to secure the maximum rate of such transfusion it was necessary to keep the outer pores of the wood open, and his experience confirmed the theory that the passing of comparatively large volumes of air so conditioned that each cubic foot would absorb only one or two grains of moisture, was by far the most speedy and economical. In other words, the fan type of kiln did not attempt to completely saturate the air, thus causing it to cool, become heavy and drop, and in this way create a circulation.

This feature of the pipe-coil kiln, regardless of its particular type, depended upon the varying density of the air in order to stimulate circulation, and consequently the drying power of moisture deficit varied directly with the length of time that the air remained in contact with the lumber. The air should be kept in contact with the lumber for as short a period as is commercially practicable so that each individual board in the pile of lumber might be subjected to air of practically the same drying power. The shorter the air travel, the more uniformly dry would be the lumber.

The principal duty of air in any drying process was to act as a conductor of heat which was transferred to the material to be dried, thus causing moisture to vaporize and then to be carried away. It was much more efficient to move air by means of a fan than to depend upon the heating and cooling effect of air.

A. A. Cutler[3] wrote in part that it would be unfair to a person wishing information on lumber kilns to let the author's statements concerning blower kilns go unchallenged. It was impossible, he wrote, to dry lumber at an even rate or in the least time unless the speed of air circulation in the kiln was rapid enough to bring each cubic foot of air in the piles back to the conditioning point before it had lost enough of its heat energy or increased its relative humidity to the point where its drying capacity was appreciably less than when it started on its circuit of drying, and nothing but a rapid circulation would accomplish this. The prevention of "interstrain" was simply a matter of conditioning the air entering the lumber piles.

If the circulation was sluggish and slow as in gravity circulation kilns, it would start to rise in the line of least resistance until the upper part of the compartment had been filled with air of the same or nearly the same temperature. Then it would gradually steep into the spaces between the lumber. As soon as it became cooler, by reason of having taken on some moisture, it would fall slowly until it got into a level of equal temperature or less humidity, where it would remain until by gradual change of kiln condition it reached the outlets at the bottom as in the case of Mr. Perry's recommended type of kiln. Hot air going up outside the pile and cold air coming down inside surely would not dry lumber evenly.

High temperatures and high relative humidities would reduce the moisture content of lumber by vaporization of moisture without creating any surface strains, but these two conditions could not be created evenly through piles of lumber without rapid circulation, and rapid circulation could not be created by anything less than a blower.

Mr. Perry had mentioned an actual operation schedule tested by practice of reducing one-inch oak from 35 to 5 per cent moisture content in 16 days. A properly constructed kiln of the blower type could do this same feat in eight days and this difference in drying

[1] Published in Mechanical Engineering, February, 1923, p. 110.

[3] Cutler Desk Co., Buffalo, N. Y.

time was due to being able to maintain ideal drying conditions all the time in all parts of the piles.

The idea of steaming lumber in the initial drying stages, of course, did tend to even up any difference in moisture contents between the outside and inside of the lumber, but it had a very much greater value in heating the lumber to the kiln temperature. Except under conditions of 100 per cent relative humidity, the temperature of the lumber was always lower than the kiln temperature in proportion to the speed of drying. The employment of high humidities occasionally during the drying would speed up the drying time, but only in rapidly circulating kilns could this be done evenly through the piles. Within the ordinary range of kiln temperatures no damage could be done if the humidity was maintained at or near 100 per cent, but damage might be done when the humidity was reduced too rapidly. Again, it became obvious that control of humidity was very important, but how could it be accurately controlled if the circulation was so slow that widely different conditions must be created in one part of the pile of lumber before the air in another part would move out. In a blower kiln, with a speed of fourteen changes of air per minute between layers of lumber, the humidity and temperature would not have a greater difference than five per cent and five degrees, respectively.

Mr. Perry's assumption that blower kilns created too rapid surface drying was not in accordance with the facts. There might be some that did, but there were certainly others that did not, and association of rapid circulation with "too rapid surface drying" was unfair. It must be perfectly obvious that the drying rate was determined by temperature and relative humidity and that these two, so far as the conditions inside the piles were concerned, were controlled by the speed of movement of the conditioned air. Therefore, the rate of surface drying was under better control in a blower kiln than in a gravity circulating kiln.

Burritt A. Parks[1] wrote that he would like very much to have the discussion bring out more explicitly the relative advantages of the blower type and ventilated type of kilns. Among the advantages claimed for the former type were the following:

1 If the kiln is properly loaded, using end-piled trucks, a more uniform circulation of the air was obtained across both surfaces of the lumber, resulting in more rapid and uniform drying.

2 With practically all the air being recirculated, the temperature and humidity throughout the kiln were more uniform and more readily controlled.

3 Rapidity of circulation under absolute control, where a steam-engine-driven fan was used, making it possible to control kiln conditions in accordance with stock to be dried.

Some of the ventilated and condenser-type kiln advocates claimed great advantages for their kilns over the blower type on account of no power being required. This had always appealed to him as "sales talk" as the exhaust steam from a steam engine, used to drive the fan, could be used in the heating coils with a loss of only 10 to 15 per cent of its heat value in passing through the engine.

In answer to the discussers advocating the blower type of kiln, Mr. Perry said that it was obvious that there was no hope of his agreeing with them or of their agreeing with him, but he would like to call attention to two fundamentals which Mr. Redman and Mr. Cutler had not fully comprehended: First, that the maintenance of high humidity in rapidly moving air was exceedingly difficult and rarely accomplished, and second, that he knew of no means whereby a cubic foot of air would absorb only two or three grains of moisture and no more. It was his experience that the air would absorb more moisture than was desirable.

H. L. Henderson[2] asked the author what effect the periods of steaming and stewing had on the lumber. He also asked if the drying schedules put out by various kiln companies were based on moisture deficit in relation to the kind of wood being dried or if they had been worked out by experiment for a particular type of kiln.

Mr. Perry answered that very few data on the use of moisture-deficit curves for drying had been published. He believed this to be a wonderful field for the further development of scientific methods of drying. The steaming period was one which produced a complete saturation of the lumber, a complete steaming at the temperature of the room. As the process was completed there occurred another which might be better termed a cooking period, which was a preparation for the more active removal of moisture during the drying period.

[1] Byron E. Parks & Son, Grand Rapids, Mich. Mem. A.S.M.E.
[2] N. Y. State College of Forestry, Syracuse, N. Y.

Anthony S. Hill[1] asked how it was possible to know that every piece of wood in every pile had been thoroughly steamed until its center was warmed.

Mr. Perry answered that the variable elements to be controlled in a dry kiln were humidity, circulation, and temperature. Nearly every dry kiln, he said, had means for the control of humidity by the admission of water or steam to the atmosphere of the kiln. Circulation was, of course, quite clearly related to temperature and would depend on the difference in temperature inside and outside the kiln if it were of the accelerated-draft type, so that circulation and temperature had to be controlled in relation to each other. Personally he was an ardent advocate of steaming lumber. He referred to the boiling of a potato as a means of removing water from it as being in a way analogous to this process in the drying of lumber.

A. A. Hemlen said that the author had pointed out that surface moisture could be removed at almost any reasonable speed.

If it was not known how fast water could be removed from a cell without destroying it, however, the surface of the drying problem had not been scratched, he affirmed.

Mr. Perry admitted that there was much about lumber drying which was not known. The practical rule-of-thumb measure was injury to the wood, and it was known that unless a uniformity of moisture content was preserved, injury would result.

T. Cassidy said that in his plant in which the very finest woods were dried, there were kilns of almost every type, and that with good operators and careful operation, good results could be obtained in any one of them. It was a question for engineers to settle, he said, which drying method would bring about the best results in the shortest time.

R. B. Wolf[2] who acted as chairman of the meeting, asked if there was a practical method of controlling humidity conditions in a kiln.

Mr. Hill said that humidity control instruments were available, but Mr. Murray pointed out that an automatic control by such instruments was difficult if not impossible.

In closing the discussion, Mr. Perry spoke of the need of research and development in the field of lumber drying.

Proposed Classification of Oil Engines

In a paper on High-Speed Oil Engines, which was read by J. L. Chaloner before the Institution of Automobile Engineers in London, on February 15, and abstracted in *The Engineer* of February 23 (p. 202), the author said that while it has been suggested that there are too many types of oil engines to permit of a simple classification, nevertheless a detailed study of the many designs brings out the fact that they are in almost every case a modification of some fundamental principle or a combination of two or more such principles.

"Otto" has fallen into obscurity, "hot-bulb" requires qualification, "Diesel" is perplexing and inaccurate, "semi-Diesel" lacks precision, "cold-starting" is misleading, "high-compression" may refer to oil or gasoline engines, "crude oil" shows misrepresentation, and "refined oil" confesses a deficiency. Yet all the existing types can be allocated in accordance with definite ranges of pressure—whether compression pressure or maximum pressure is immaterial—and methods of fuel injection. When including high-speed engines the problems of nomenclature are certainly somewhat more complicated, because there is the tendency of the "constant-volume" and "constant-pressure" cycles to merge into each other. Mr. Chaloner accordingly suggests a system of classification of liquid-fuel internal-combustion engines under the headings (1) Gas Injection, (2) Air Injection, and (3) Mechanical Injection, each of which comprise (*a*) low-pressure, (*b*) medium-pressure, and (*c*) high-pressure engines.

The Airship for Long-Haul Heavy-Traffic Service

By RALPH H. UPSON,[1] DETROIT, MICH.

The factors upon which the value of the airship as a carrier depends form the subject of this paper. The airship is compared with other carriers, especially the steamship, and questions of speed, route, cost of transport, and time value are considered. Design and construction methods are discussed, as are also the problems of stability, dynamic lift, mooring, and fire risk. It is not the intention of the author to treat the subject in detail, but rather to indicate the possibilities of the airship for commercial traffic and to point out the chief problems toward which the engineer should direct his attention.

COMPARING airships with other common carriers, the most closely related is the steamship, of which the airship is a logical namesake. The fundamental difference is simply one of size and weight—the boat being "inflated" with air and other materials, the airship with hydrogen or other light gas. Take any boat which floats in the water, and enlarge its linear dimensions roughly ten times, *keeping the total weight the same;* it will then float in the air and may be called an airship. But just here is where the first big problem, that of structural weight, is met. For if in this example a similar design of structure throughout is assumed, it is clear that the airship hull must be made ten times as heavy to retain the same strength as its prototype, the boat, without even considering the l/r requirements of the compression members. At this rate the airship would not even "lift" itself, and this seemingly damning fact is perfectly true as far as it goes. But fortunately its effect may be modified or even reversed by other factors which may be utilized for cutting down the structural weight.

All the opportunities for lightening the hull structure must be taken advantage of to achieve a good weight-carrying efficiency. The first of these is the possibility of arranging the loading of an airship so that tension stresses predominate in its structure, whereas compression stresses must naturally predominate in a steamship. If properly utilized, this is a great factor in the final result. In a typical Zeppelin airship, for example, about 35 per cent of the hull structure is fabric, and about 12 per cent is high-tensile wire with an effective strength two to three times that of the most efficient compression girders. Recent improvements in the shape and arrangement of the hull permit a still higher proportion of tension elements.

Next, there is a big advantage in the fact that an airship is entirely immersed in the elastic fluid in which it floats, which insures a practically uniform buoyancy throughout. The effect is modified somewhat by vagrant currents, sudden gusts, and aerodynamic instability (which will be described later), but on the whole an airship in flight is subject to outside forces much less in magnitude and at the same time more positively determinable than those affecting a steamship in a heavy sea.

It is not only in engineering methods but in materials themselves that great advances have been and are still to be made. The first light-weight, heavy-duty gas engine was developed for airship use. In metallurgy the whole development of the remarkable alloys of aluminum for structural use owes its inception to the needs of airship design. A whole paper might well be devoted to duralumin, which seems destined to replace much of the steel now used in bridges, boats, railroad cars and all other structures where lightness is an appreciable factor.

But the greatest basic factor favoring airships still remains in the consideration of *resistance to propulsion.* Given a steamship and an airship of equal gross weight and equal speed, the latter will require only about one-tenth the horsepower of the former. Or, expressed in other terms, for an equal horsepower the airship will go over twice as fast; or assuming equal power efficiency for the two types, the steamship must be of a tonnage roughly 1000 times greater. This little-known fact is the airship's real reason for existence, for it is utilized not to save power but to gain speed. A speed of 60 m.p.h. for example, which is practically impossible for a displacement type of boat, is attained by the average airship with the greatest ease. Eighty-three miles per hour has been reached and 100 miles is simply a matter of design.

Until a very few years ago this great advantage existed only in theory. Before the war the greatest speed was in the neighborhood of 40 m.p.h., in a "ship" whose structural weight was about two-thirds of the total. The airship seemed a dead issue as far as any real commercial transportation was concerned. Now, however, we are taking almost full advantage of the theoretical resistance while avoiding almost entirely the disadvantage of extra weight.

In respect to size the airship is affected in much the same way as the steamship. The weights of various parts of an airship structure vary all the way up to the fourth power of the linear dimensions. Hence beyond a certain point there is an actual increase in the structural weight per unit displacement. Considerations of power and fuel consumption, however, bring the range of economical size far beyond that of greatest structural efficiency. This is because the resistance, for equal speeds, varies as not quite the square of the linear dimensions.

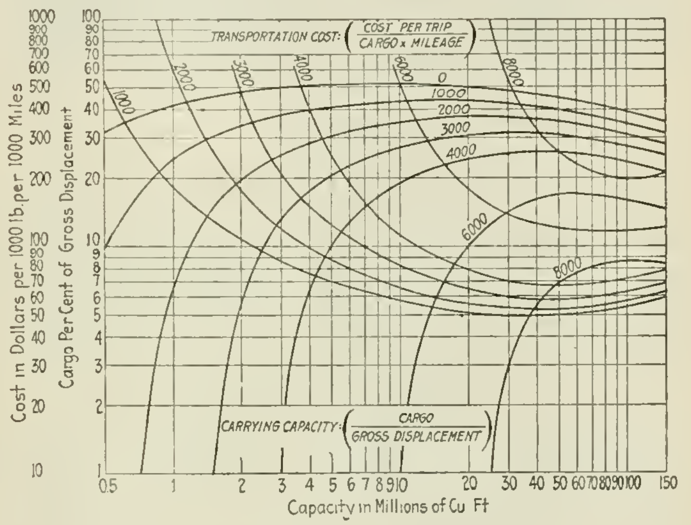

Fig. 1 Effect of Size on Airships of Similar Design, Assuming an Average Air Speed of 70 Miles per Hour

All the above factors have been taken into account in computing the data for Fig. 1, which shows the effect of size alone on freight service over routes of different lengths. The curves that are concave downward show the net cargo weight as a percentage of the gross displacement weight, the figures on the curves themselves referring to the length of route in statute miles. The other set of curves (concave upward) shows the cost of transport in dollars per 1000 lb. per 1000 miles for the different routes marked. Note especially the range of sizes marked at the bottom in *millions of cubic feet.* Remember that the largest airship in existence today has a capacity of 2,500,000 cu. ft. and see how much further we have to go to use even to fair advantage this one item of size.

But this takes care of only three of the prime factors or variables entering into the consideration of a commercial airship line. Altogether there are five: namely, size, speed, route, cost of transport, and time value. The latter is the value of time, or of saving time, per unit of passengers or cargo carried. Taking the simpler case of freight (including mail and express), if time has any value it has a money value per hour on any unit weight of the cargo carried. This may be due to its intrinsic value, to perishability, news value, or other qualities. Let us take an assumed example. In a shipment of 1000 lb. of California fruit destined for the eastern states, an average of 20 per cent spoils during the trip. The remainder commands a price of 15 cents per pound. Suppose now that a saving of 40 hr. on the trip cuts the perishability in half and the fruit, being

[1] Chief engineer, Aircraft Development Corporation. Contributing editor, *Aviation.*

Contributed by the Aeronautic Division and presented at the Annual Meeting, New York, December 4 to 7, 1922, of The American Society of Mechanical Engineers. Slightly Abridged. All papers are subject to revision.

fresher, sells for 5 cents a pound more. Here we have a total saving of $60 or a time value of $1.50 per 1000 lb. per hr.

Taking everything into account on a basis of present values, it seems probable that anything having a time value of $1 or more per 1000 lb. per hr. ($2 per ton-hour) can be shipped more economically by air than by rail, or about half of this figure in the case of shipping by water. This is assuming in each case the speed and size of unit best suited to the quality of goods carried.

Fig. 2 shows on a similar basis the comparison between all the available means of transportation. Here the speed is taken as net, with allowance for average stops, delays, time required to get in and out of terminals, and to load and unload. The shaded areas represent the respective economic fields to be served by steamship,

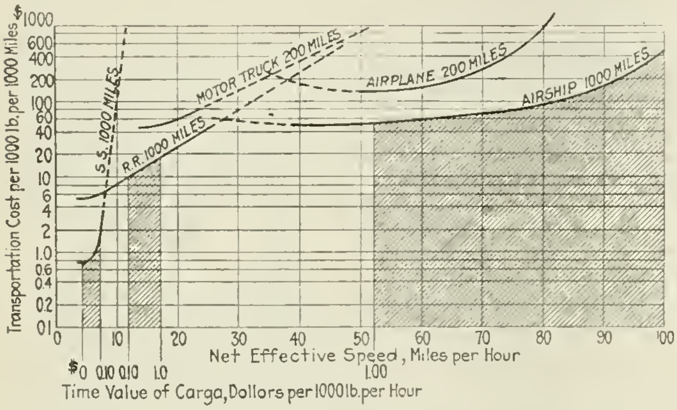

Fig. 2 Transportation Diagram Showing Economic Relations Between Different Carriers

railroad, and airship, which may be termed primary transportation units. The secondary units, motor truck and airplane, are not directly comparable with the others because their value lies in various special features peculiar to themselves. The airplane, for example, can combine high speed with small size and a comparatively short route, conditions which cannot be met by the airship.[1]

Design and Construction Methods

All lighter-than-air construction has developed from the free balloon as the basic type. Today there are five other more or less recognized types as follows:

- The kite balloon, which is the modern type of captive observation balloon
- The "blimp," a rather vague term usually applied to a small non-rigid airship with a single engine
- The non-rigid airship
- The semi-rigid airship
- The rigid airship.

The last three are only relative terms as all of them have much in common. For example, a non-rigid airship is usually stiffened as the nose in semi-rigid fashion. The usual "semi-rigid" ship is really rigid in principle, but its rigid structural parts are mainly concentrated in a keel at the bottom of the envelope instead of being partially distributed around it as in the Zeppelin "rigid." Again, it must not be thought that there is any appreciable difference in the rigidity of these different types in flight. The nomenclature merely has reference to the method of producing the necessary rigidity, the fundamental principles being the same for all.

Fig. 3 shows the Zeppelin type of construction, which is the only one so far used for the largest sizes. This consists of a sort of cage into which is put a series of large gas cells, the whole structure being covered by an outer fabric envelope. Here the non-rigid principle still exists but is confined to relatively small spaces between girders. The amount and distribution of structural elements is simply a matter of design based on the requirements to be fulfilled.

The design in general divides into two main parts: First, the aerodynamic design, in which the relations of speed, power, controllability and all external forces are worked out and correlated; second, the static design which takes care of all internal stresses and deformations, and distribution of lift and load. Calculations wherever possible are based on known laws and previous experience. But as an airship is so large and costly, and in so rapid a state of development, it is very important to have some way of checking calculations, for every new design, by experiments on models.

Problems Yet to be Solved

There are many problems connected with the control of airships which are as yet imperfectly solved. Quite contrary to what might be judged from general appearances, an airship in motion is naturally very unstable. It is not that it is subject to any sudden diving or loss of balance, for the mere mass of a large ship is enough to prevent that. Its instability is one of direction, i.e., it tends to keep on turning (either horizontally or vertically) in any direction in which it starts. Fig. 4 shows why. The air reaction or resistance at zero angle of course acts along the axis of the hull. But let the wind hit the model at even a small angle to its axis and a remarkable change occurs. The reaction is now much larger; its line of action is at a considerable angle to the wind stream, and crosses the axis far in advance of the hull itself, i.e., the hull is now acted on by a force which does not even touch it.

This instability may be made less serious by the mounting of fixed fin surfaces in the rear, but it is usually impracticable to attain complete stability in this way; so that we must still depend to a large extent on the rudders and elevators. The function of these is then not so much to turn as to keep from turning; in fact, a gradual turn requires the rudder to be held in just the opposite direction to prevent turning too sharply, and often to hold a given angle with the horizontal requires an elevator action opposite to what might be casually supposed. The development of satisfactory stabilizing means would take considerable strain off the pilot, make for a straighter flight path, minimize unpleasant motions, and facilitate mooring.

Another feature that may be appreciated by reference to Fig. 4

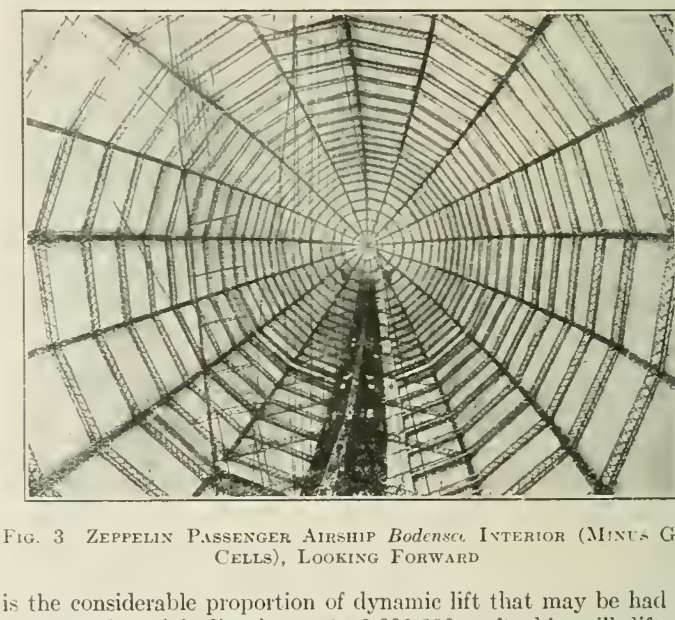

Fig. 3 Zeppelin Passenger Airship *Bodensee* Interior (Minus Gas Cells), Looking Forward

is the considerable proportion of dynamic lift that may be had at small angles of inclination. A 2,000,000-cu-ft. ship will lift in this way an *excess* load of 3 tons or more at full power. The lift is there—there is no doubt about that—but the problem is how to utilize it. An enormous airship cannot be started by running it along the ground like an airplane. It would be as easy to put wheels on an ocean steamship and run it on land. But some method of taking on the extra load and carrying it safely after the airship gets under way is at least a possibility and should be carefully investigated.

The way this dynamic lift functions now is generally in a reversed direction. The ship starts up approximately balanced, but changes in altitude and temperature are sure soon to cause variations in the lift which are compensated for by use of the elevators. These changes are not usually serious for a high-powered ship, but it is decidedly otherwise as regards the gradual consumption of fuel on a long trip. This is compensated at first by tilting the ship down

[1] Aerial Transportation of the Immediate Future, *S.A.E. Journal*, June, 1921, p. 593.

to get a negative dynamic lift, but eventually it becomes excessive even for straight flight and far more than is possible to land with. Then there are only two alternatives, either to let out gas or take on ballast. The latter, where possible, is the safer and cheaper. Two devices for this purpose are being developed at the present time; one is a trailing pump for taking water up from the ocean or other body of water; the other is an apparatus for condensing the moisture out of the engine exhausts. By the latter method more water can be collected than the original weight of the fuel, but the condensing apparatus so far developed is clumsy, heavy, and not entirely satisfactory. Another idea that has been used with some success is to burn the surplus hydrogen in the engines, thereby getting a reserve of fuel. This is a valuable recourse for emergencies, but hardly a substitute for the taking on of ballast, whose principal object is to prevent using up the gas reserve.

Another problem largely aerodynamic in character is the mooring and housing of a large airship. The resistance of a ship set approximately crosswise to the wind is commonly 30 to 40 times the amount of the head-on resistance. Hence the main principle of mooring in the open is to keep the nose headed constantly into the wind. In this position it will easily withstand any wind that blows.

The "mooring mast" as used in England, in which the wind itself is supposed to keep the ship in proper alignment, is not entirely satisfactory. In the first place, it takes great skill to bring an ordinary unstable ship up to a mast at all without breaking something. Then, even after it is moored fast, the ship will yaw through a considerable angle, putting corresponding strains on the structure. In a vertical plane the wind stays fairly near horizontal, but the ship does not, owing to the unavoidable changes in lift and trim. Furthermore, the ship is in a very inconvenient position for loading, unloading, inspection, and repair. But the most permanently serious problem of all those concerned with outside mooring may well be that of snow. A heavy snowfall without much wind would soon pile up a dangerous weight on the huge surface of the envelope and fins. Without other provisions for taking care of such a situation, the safest thing to do would be to cast loose and fly south with the birds!

Finally, any exposed mooring with the present rather perishable envelope fabric may be said to be an extravagence rather than an economy for any regular operation. Nevertheless, with metal envelope and other improvements the author believes that the time is not very far distant when an airship will remain in the open as a matter of course and only be brought into a hangar as a steamship is put into drydock, i.e., for general overhauling and special repairs.

Fire Risk

In addition to such problems, which range all the way from details to general construction, there is the fire risk, which seems to be the one considerable danger in airship operation.

It may be said at the start that the danger from fire is no doubt greatly exaggerated by many people mainly due to the accidents which befell the *R. 38* and the *Roma*. For airships there are no data by which we can estimate the risk on a percentage basis, for no regular passenger on an airship line has ever been lost, and no airship, aside from military and experimental ones, has ever burned

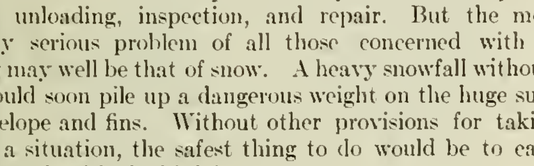

Fig. 4 Air Reactions on a Stream-Line Hull for Varying Angles of Pitch and Yaw

(Figures refer to inclination of wind stream relative to axis of hull.)

in the air. The Zeppelin passenger ships have carried approximately 40,000 passengers a distance of over 3,000,000 passenger-miles with never a fatality or serious injury. Nevertheless, the fire danger obviously exists and everything possible must be done to eliminate it.

In a present-day airship there are three principal inflammable elements: hydrogen, gasoline, and fabric. All three have possible substitutes, the most available being helium, heavy fuel oil, and metal, respectively.

The use of helium removes the largest bulk of inflammable material, but it is a mistake to suppose that the fire risk can be eliminated by this means alone. Hydrogen will not explode unless mixed with air, but it will burn if ignited by some outside agency at a point where it meets the air. For example, suppose a gasoline fire in one of the cars spreads to the envelope and ultimately reaches the gas. If the gas is hydrogen it will of course burn as it rushes out, at the same time rapidly accelerating the burning of the envelope. This is what happened to the front half of the *R. 38* after it broke in two. The use of helium would have been no insurance against the outer envelope burning away, and with it enough of the inner fabric to liberate all the gas; but the action would undoubtedly have been enough slower in that case to have saved many lives.

To eliminate the gasoline hazard, as well as to provide more economical fuel, there are several promising developments of heavy-oil engines now in process. This type of engine should be specially suited to airship work, which requires constant running for long periods of time.

To make the airship structure itself fire-resisting, the most feasible means seems to lie in a more extended use of duralumin. An all-metal envelope promises not only protection against fire but great improvement in durability and other desirable qualities as well. The metal ship of the future, especially if provided with heavy-oil engines, will be virtually fireproof as far as commercial service is concerned. It can thus be independent of the use of helium, which is rare, expensive, and deficient in lift. For military purposes, however, all three of the above-mentioned safeguards would be desirable.

Conclusion

To sum up the situation in general, it may be said that the improved airship will be definitely available for commercial traffic over either land or water in rough proportion to the extent to which the following conditions exist:

- Length of route (should be 500 miles or more)
- Density of traffic (at least 200 passengers or 50 tons of goods per trip)
- Time-value of pay load (passengers' time worth \$6000 per year or more; goods \$2 per ton-hour)
- Favorable meteorological conditions (no definite minimum).

The New York-Chicago route, which is so favorable in other respects, is the very worst in the country from a weather standpoint. A thorough analysis of this route by the Zeppelin Company shows the following results for present means and methods. A nightly 12-hr. service in both directions can be maintained 100 per cent on time for a season of six months. For the full year, however, the on-time trips would be cut to about 93 per cent. (An average of 4 per cent of the trips would probably be postponed or cancelled by advance notice, to enable prospective passengers to go by train if they so desired.)

A 60-hr. (average) transatlantic service could be maintained practically the year round.

The technical requirements of such a service are fairly clear, but the business side of it presents one of the hardest problems that have ever come up. In any other kind of transportation men have had the privilege of starting out with small units which, under favorable conditions, could at least pay their own way. With airships, however, it is necessary to choose between the frying pan and the fire. Either we must start with a comparatively small unit and a certainty of losing money on it or take a chance with large units on which we may lose a great deal more before they can be made profitable. It is indeed a great temptation to spend the larger amount of capital for what may look like good profits from the start. But it must be remembered that it is a new enterprise, entirely untried in this country; ships of the necessary size and construction have never yet been built; the whole system of safe and economical operation must be developed; and conjointly, the public must be educated to use the service. It is a maze of interreacting factors like the stresses in an airship hull itself, but much more indeterminate, and should certainly be as frankly recognized. A single ship of the smallest practical size (which is quite large and costly enough) to try out a given route will be well worth what it costs if it contributes but a small percentage to the "success insurance" of the larger enterprise.

Hydraulic-Transmission Variable-Speed Drive for Machine Tools and Manufacturing Processes

By WALTER FERRIS,[1] MILWAUKEE, WIS.

"Hydraulic transmission" has been in course of development as a variable-speed drive for twenty-five years, and has often been applied to gun control, turret control and steering gears on naval vessels during the past fifteen years. Its accuracy and flexibility of speed control, mechanical efficiency, durability of mechanism, and ability to stand abusive accelerating and stalling loads without overheating are well established, yet this type of drive has never attained extensive introduction in the industries, where its most extensive field seems to lie.

The author describes and illustrates a number of applications of the "Oilgear" to machine-tool driving, broaching, hydraulic presses, etc. This device is based on the same principles as earlier hydraulic transmissions, but has been developed from the beginning (in 1909) with a view to industrial requirements first, and automotive and marine applications afterward. The results obtained in practice during the past five years would apparently indicate that this method opens a field in which great improvements in machine-tool design may be made.

THIS paper is a report of progress made in applying "hydraulic transmission" variable-speed drive to machine tools and ordinary manufacturing processes, as distinguished from its previous applications to gun control and other naval work. In undertaking to develop a type of hydraulic transmission which should be commercially available, the designers of the device described later have purposely avoided the obvious field offered by the automobile, choosing instead the wide field of machine-shop drives and general manufacturing purposes. In this field the rigid requirements of extreme lightness and compactness do not apply, while the need of a satisfactory drive which will give any desired speed is just as great as in the automobile.

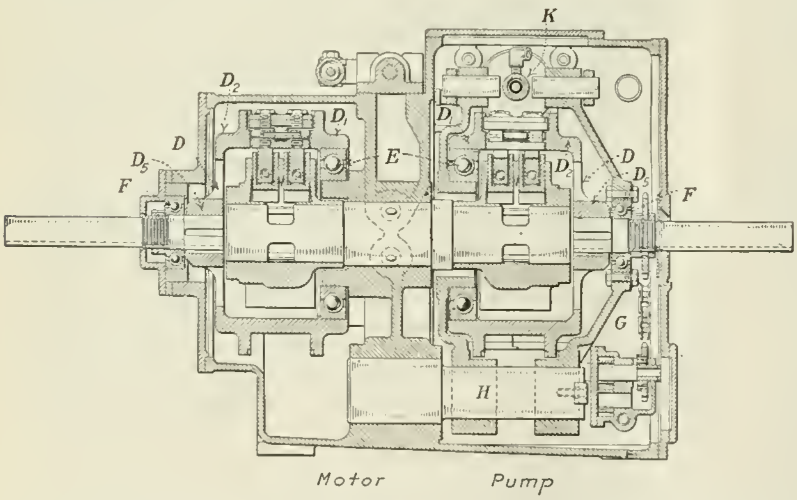

Fig. 1 Oilgear Hydraulic-Transmission Variable-Speed Drive, Longitudinal Section

Every hydraulic transmission comprises a pump, a motor, and a liquid circuit connecting them. For the driving of machines in machine shops and for general manufacturing we may add the conditions that the pump shall be a plunger pump, that it shall have a sufficient number of plungers to give a practically uniform flow, and that the stroke shall be adjustable at the will of the operator. Also, the only power-transmitting liquid herein considered is oil.

The various types of variable-speed hydraulic transmissions all employ multi-cylinder plunger pumps, and may be divided according to the arrangement of their plunger groups into axial and radial machines. Axial machines have cylinders arranged like the chamber of a revolver, parallel to and surrounding the drive shaft. Radial machines have cylinders arranged like the spokes of a wheel. In all cases there is an oil circuit having high-pressure ports and a conduit leading from pump to motor, and low-pressure ports and conduit from motor back to pump. In all cases several pump plungers are acting at once in communication with the high-pressure port, and several others in communication with the low-pressure port. This feature gives a uniform flow of oil. Some machines run with all working parts submerged in oil, and some with "empty case" and an oil sump below the level of the working parts. All have one member carrying a group of cylinders and another member operating the plungers in those cylinders, with the plunger stroke variable by the operator.

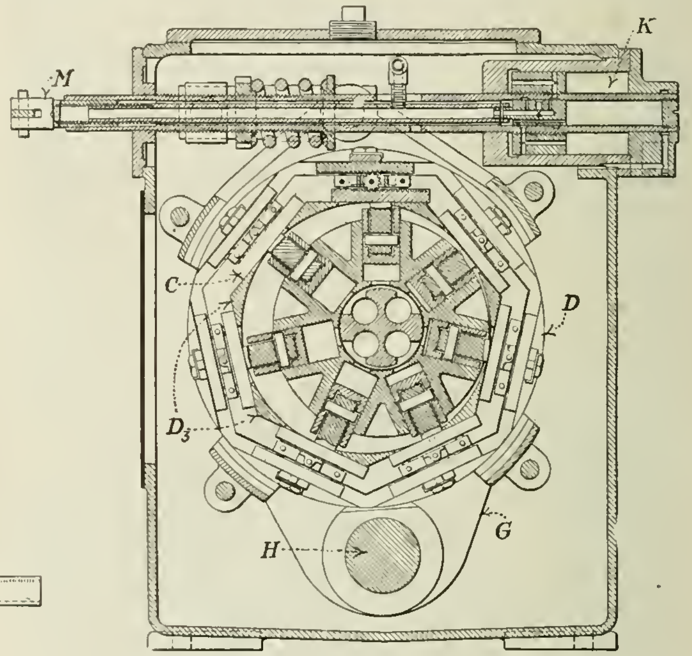

Fig. 2 Transverse Section Through Center of Pump

Design of the Oilgear

The Oilgear machine is of the radial type, its arrangement being shown in the longitudinal section (Fig. 1) of a unit containing both pump and motor mounted on a double-ended pintle and the transverse section (Fig. 2) through the center of the pump.

Fig. 3 shows the unit with two handhole covers removed, through which all of the plungers in both pump and motor can be withdrawn for examination if required. To remove a plunger it is only necessary to slide out a reaction plate A (Fig. 4) which is plainly visible through the open handhole, after which the roller-bearing cage B is removed and the crosshead with the attached plunger or plungers may then be withdrawn. It will be seen that each driver D (Figs. 1, 2, and 4) comprises two complete rings or flanges D_1 and D_2, integrally united by seven posts or bars D_3. Flange D_2 also carries hub D_5 into which the shaft is pressed, and the entire revolving driver D is supported on ball bearings E and F.

In the case of the pump these ball bearings are carried by a swinging cradle G (Figs. 1 and 2), which can be swung to the right or left around a stub or pivot shaft H. This serves to change the stroke along an arc of large radius, in place of the rectilinear slide used in the other radial machines. Figs. 4 gives details showing the plunger and crosshead unit with roller bearing, reaction plate, etc., in their relation to the driver. The thrust of the Oilgear plunger is

[1] Vice-president, The Oilgear Co. Mem. A.S.M.E.

Contributed by the Machine Shop Division and presented at the Annual Meeting, New York, December 4 to 7, 1922, of The American Society of Mechanical Engineers. Abridged. All papers are subject to revision.

delivered directly against the crosshead C, and thence through a roller bearing B to a corresponding reaction plate or roller path A carried by the driver D. There are no wristpins or rubbing bearings of any kind. The pressure on the plunger is limited only by the capacity of the roller bearing, which also reduces the friction almost to zero. The pins C_3 (Fig. 4) are not wristpins, but merely loose retaining pins to hold the parts together until the assembly

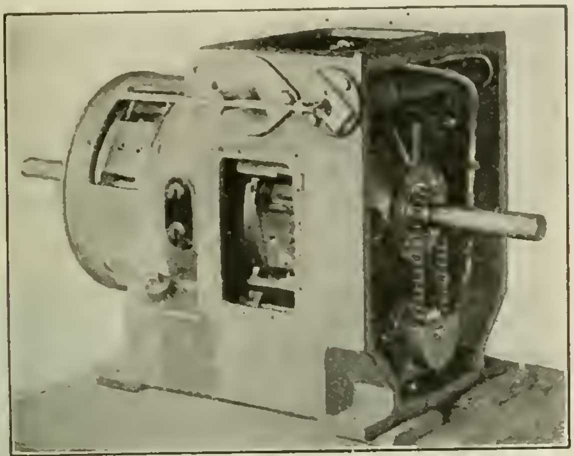

Fig. 3 Oilgear Machine with Handhole Covers Removed

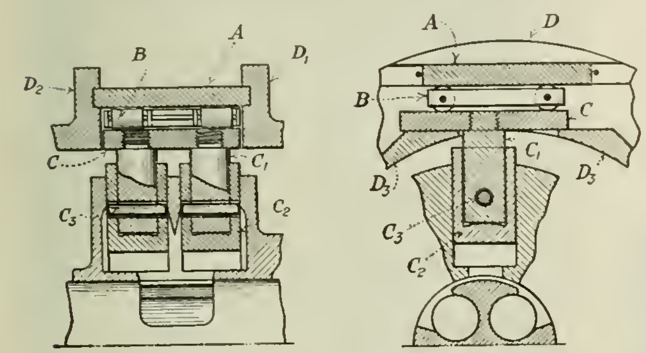

Fig. 4 Details of Plunger and Crosshead Unit

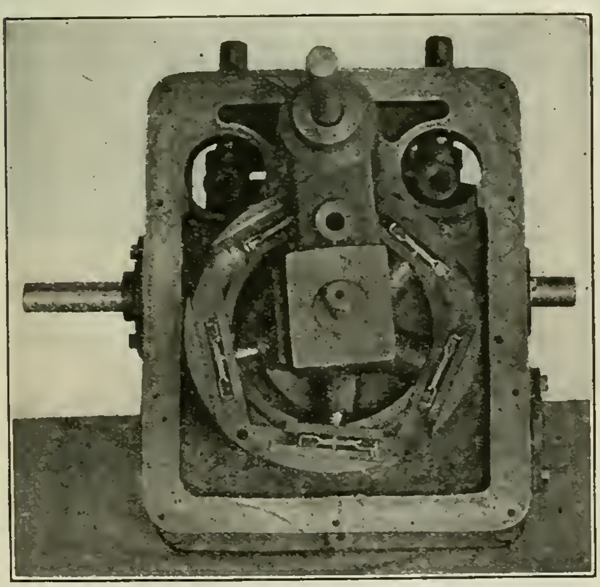

Fig. 6 Variable-Delivery Portion of QC Control Pump

is complete. All angular thrusts and side friction on plungers are eliminated. Figs. 1 and 2 also show the hydraulic stroke-changing mechanism K controlled by the pilot-valve stem M.

This paper is not intended to give a full discussion of the theory of the Oilgear, which in most points is similar to that of other hydraulic transmissions, but it is necessary to describe one special form before passing on to the applications. Fig. 5 shows a small Oilgear known as the QC control pump, connected to an ordinary double-acting cylinder operated thereby. Figs. 6 and 7 show the interior construction and working parts of the pump. The casing shown contains the pump only, the cylinder in Fig. 5 acting as the motor. This is in effect a hydraulic press, and it will be alluded to in that connection in a number of the applications subsequently described.

This control pump comprises the combination of a small variable-delivery pump, Fig. 6, with a large constant-delivery pump (the gear pump, shown at K in Fig. 7, and occupying the lower part of the unit) combined with it in the same casing and operated by the same drive and control. The machine also contains a distributing valve (J, Fig. 7) which is connected to the operator's handle on top of the case (Fig. 5). This handle may be moved from its central or zero position 90 deg. in either direction. During about

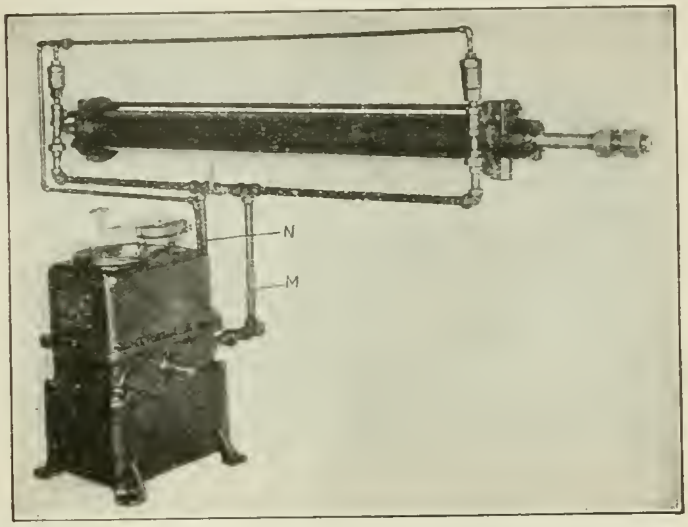

Fig. 5 QC Control Pump, in Casing, Connected to Double-Acting Cylinder

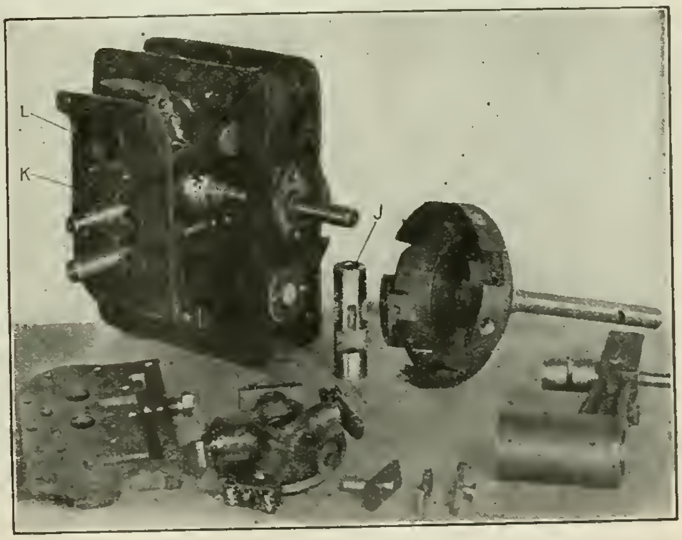

Fig. 7 Lower Part of QC Control Pump

60 deg. in either direction of this travel the effect is to change gradually the stroke of the variable-delivery pump, Fig. 6, thereby pumping more or less oil and moving the piston in the hydraulic cylinder shown in Fig. 5 either to the right or left very accurately, and faster or slower as the operator desires.

When the handle, Fig. 5, is turned 90 deg. either to the right or left to the extreme position, the distributing valve J, revolving in a ported sleeve L, Fig. 7, cuts out the variable-delivery pump from the main pipes M and N, Fig. 5, and connects the large gear pump K, Fig. 7, to these mains, thus driving the piston to the right or left with a very much faster movement. This serves to give a rapid traverse to a lathe carriage or boring-mill ram which may

be operated by this feed; or, in other cases, to the ram of a hydraulic press.

In a preceding paragraph the Oilgear hydraulic transmission was described as a combined unit in a case containing both pump and motor. Also the Oilgear control pump has been described, as made in a separate casing, for operating detached direct-acting pushing cylinders. It can also be used to operate detached rotary motors, such as the one shown disassembled in Fig. 8, which is adapted to drive the feed motions of machine tools, etc. Note the few and simple working parts, all made by ordinary machine-shop processes.

Machine-Tool Feed Applications

The principal elements are the QC control pump, shown in Figs.

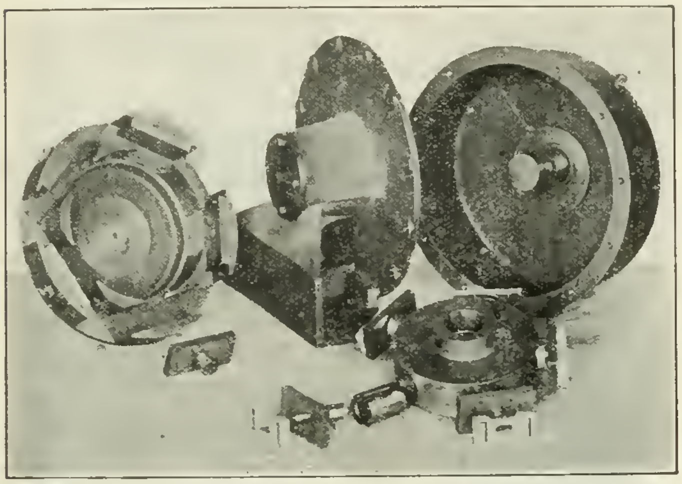

Fig. 8 Disassembled View of Detached Rotary Motor Controlled by Oilgear Hydraulic Transmission

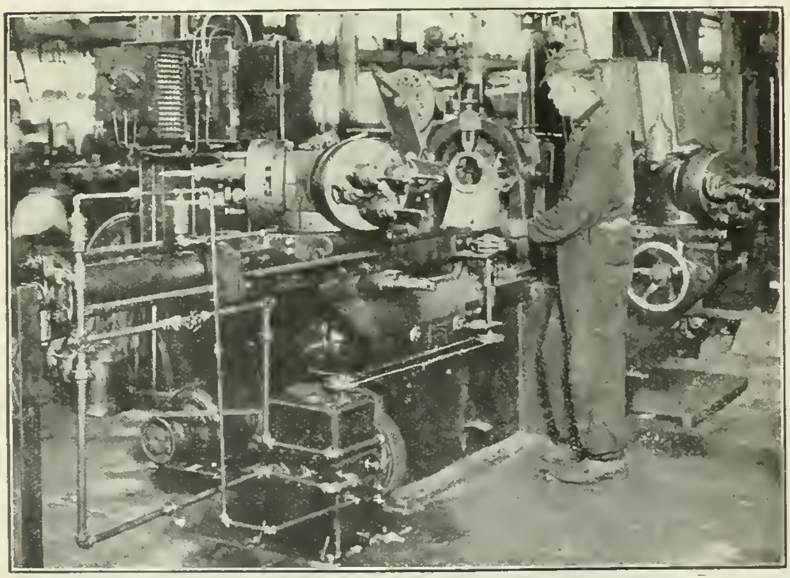

Fig. 9 Special Turret Machine Equipped with Hydraulic Feed

5 to 7, inclusive, connected to a feeding motor for driving a machine-tool carriage or ram, either a direct-acting pushing cylinder as shown in Fig. 5 or a rotary motor as shown in Fig. 8.

In either case the motor is located with reference to the feed mechanism to be driven. The direct-acting feeding cylinder is always to be preferred when it can be used, because of its well-nigh perfect steadiness of operation and the great range of feeding and rapid traverse speeds which can be satisfactorily obtained. For instance, a 4-in. piston may be driven by the variable-stroke pump of Fig. 6 at feeds of $^3/_8$ in. per min. or less, while the rapid-traverse pump (K, Fig. 7) will move the piston at 14 or 15 ft. per min.—a speed ratio of about 450 to 1.

Assuming that a rotary feeding motor can be driven at 1000 r.p.m. for rapid traverse movements, the same speed ratio would require it to turn steadily at $2^1/_4$ r.p.m. when pulling a heavy feeding cut. This range is more than such a motor will satisfactorily handle. In addition, the efficiency of the direct-acting cylinder is much greater, and mechanism is saved.

The application of Oilgear feed has so far been carried out only on already existing machine tools, but several feed installations have been in continuous operation on high-production work for periods of from one to two years, and in no case has there been the slightest wear of the plungers or other working parts.

Fig. 9 shows the application to a special turret machine producing gas-engine beds.

Hydraulic-Press Applications

While the above-described control pump was primarily designed for a machine-tool feed, its properties have proved highly desirable in hydraulic-press work. Such a press, of 25 tons capacity, is shown in Fig. 10. It may be driven from any constant-speed source of power, such as lineshaft or constant-speed motor. Rapid

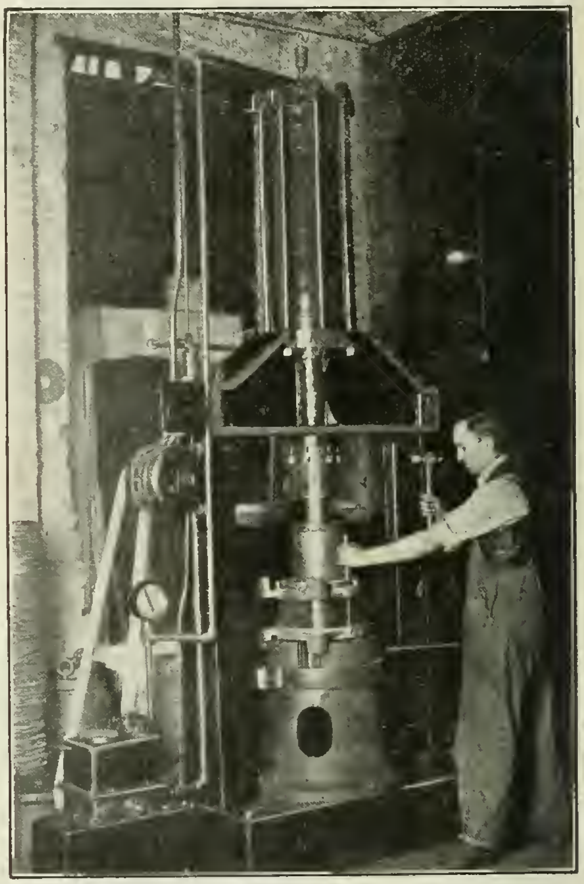

Fig. 10 Hydraulic Press Operated by Oilgear Pump

traverse of the ram is furnished, at a speed of about 40 in. per min. downward and 60 in. per min. upward. While pressing, any speed of the ram up to about 7 in. per min. is available, and the control is so delicate that when the ram is absolutely stalled against a shoulder the pressure gage can be maintained at any desired point. Many other presses driven by Oilgear pumps and having similar operating characteristics are in use.

Broaching. An important application of the direct-acting cylinder is the ordinary broaching process. A horizontal hydraulic broaching machine shown in the complete paper is driven by a 10–15 hp. Oilgear pump. The pulling cylinder is 6 in. in bore, and is double-acting. The piston rod is attached directly to the sliding head which pulls the broach. The reversing tappets are engaged by the sliding crosshead at either end of its stroke as in a planer, and are connected to the pilot valve of the hydraulic reverse gear in the Oilgear pump. The connection to the pilot valve is from a vertical rockshaft whose angle of swing is limited by two adjusting screws, thus controlling the stroke of the pump separately during the pulling and return strokes of the broaching machine and permitting any desired speed up to a maximum of 360 in. (30 ft.) per min.

In the ordinary method of pulling the broaches by screws the usual speed is less than 5 ft. per min., and the hydraulic broaching machine therefore gives a great increase of output, probably averaging 100 per cent. The comparison between the screw and the hydraulic broaching methods may be approximately given by the statement that on the average one hydraulic machine and operator will replace two screw machines and two operators and require about the same amount of power.

Vertical Push-Broaching Presses. The vertical semi-automatic manufacturing press is a further illustration of the adaptability of hydraulic drive to produce machine tools exactly adapted for the work in hand. This press is equipped with an automatic stroke-control gear and is driven by a 5-hp. Oilgear variable-stroke pump known as the Type W. The length of stroke, and hence the speed of the ram, is set by the location of the adjustable tappets. The typical working cycle consists of a downward rapid-traverse stroke at any desired speed through any desired distance, followed by a working stroke at a different speed through any additional distance, automatically reversing and returning to the top position at the completion of the stroke. The ram may be set either for full stroke or for as short a stroke as will be sufficient for the work in hand, and this stroke may be taken near the upper position of the ram or at any other point within its total range. If the entire downward stroke is a working stroke, the rapid approach stroke may be omitted, the entire stroke being set at the required working speed.

Straightening Presses. Equipped in this way this press is available for various vertical broaching and forcing operations. When desired the press may be operated by the QC control pump shown in Fig. 5 and used as a sensitive straightening press. When so equipped, the operator can move the ram by thousandths of an inch if desired, and apply pressure accurately by the pressure gage.

Hydraulic Riveting. A third and even more striking application of such a press is its use as a hydraulic riveter. In this case it is equipped with a pump known as the Type WE, which differs from the Type W only in the method of controlling the stroke. The Type WE pump, is so arranged as to always pump a maximum quantity of oil when the pressure is below a certain point, say, 900 lb. per sq. in. As the pressure rises the pump automatically reduces its rate of delivery until at a predetermined maximum of, say, 1000 lb. per sq. in. the delivery ceases altogether except for the small quantity required to maintain the maximum pressure in the delivery pipe.

When this kind of a control is used the pump is connected to the riveter through a four-way piston valve. The operator handles the press or riveter by operating the piston valve and the pump functions exactly like an accumulator, except that the oil pump only develops sufficient pressure at any instant to overcome the actual resistance of the ram. When the ram is stalled against a rivet or other dead stop the power consumption ceases and the pump runs idle except with sufficient delivery to maintain the pressure.

Such a plant in effect is a portable accumulator plant operating at an overall efficiency of 85 per cent or more, and adapted to be driven from any convenient source of power such as a lineshaft or small electric motor. It requires but from one-eighth to one-sixth the power needed to operate an air riveter, and its use will frequently avoid increasing air-compressor capacity.

Rotary Machine-Tool Drive

The most obvious field in the machine shop for the variable-speed hydraulic transmission is in the main drives of the machine tools themselves. On the other hand, it is the most difficult part of the field to develop, because of the required changes in designs and patterns, but still more because of the high state of development attained by the direct-current electric motor on variable-speed work. Nevertheless, the hydraulic variable-speed drive has several important advantages even over the best electric variable-speed drive, including the outstanding advantages of offering a means of obtaining a perfect speed variation from an alternating-current motor. These may be stated as follows:

a More perfect control of speed
b No coasting when the power is shut off
c No peak loads drawn from the line, and no heating of the hydraulic drive
d Low maintenance and minimum of attention required.

In equipping the average machine tool with hydraulic drive, some saving will be obtained from the omission of a number of gear changes, etc., now required, and a further saving from the fact that all the machines of a certain kind and size will be identical, no matter what the source of power used to drive them. That is, a lathe headstock equipped for hydraulic drive would have a single receiving pulley or shaft to be driven at, say, 600 or 800 r.p.m. It might be driven either from a lineshaft, from an alternating-current motor, from a direct-current motor, or from a gas engine. If such a machine tool came on the second-hand market it would be equally available for installation anywhere.

The mechanism and advantages of hydraulic feed have already been touched upon. Its introduction into new machine tools will be somewhat modified if it is carried out in connection with the use of hydraulic drive for the same tools. In any case the use of the hydraulic method on any machine tool opens the way for the use of hydraulically operated friction clutches to effect gear changes, and also for the replacement of the ordinary air chuck by hydraulically operated chucks. This has already been done experimentally and with complete success. The hydraulic chuck has advantages over the air chuck in consuming much less power, having no tendency to dry out the cup leathers and thus fail to operate, and in moving only sufficiently to release and grip the work instead of making the entire stroke whenever operated.

All of the applications described in the preceding paragraphs have been actually made, and most of them have been in use a sufficient length of time to prove that they are successful practically. Many important fields are not yet touched, although the properties of the Oilgear mechanism seem perfectly adapted to their requirements. Among these are planer drive and other reciprocating movements, cranes and hoists, and elevators.

Discussion

In opening the discussion, J. J. Crain[1] said that the concern with which he was connected had been manufacturing hydraulic transmissions of the same general nature as the one described by the author for about 15 years, and had built about 2000 of them, most of which had gone to the United States Navy, where they were used for turning turrets, elevating guns, hoisting ammunition, etc. All of the present capital ships used this device exclusively for these purposes. The author was very modest in his claims of the performance of this type of apparatus. Before hydraulic transmissions were used in the Navy, most of the high-grade control was effected by the Ward-Leonard system and while this gave very fine control, it was not comparable to what could be obtained from a variable-stroke pump.

His company's associates in England had built about the same number of machines, but had gone more exclusively into commercial work. The real problem in wide commercial application was the financial one. It was an expensive machine. It had to be built accurately and of high-grade material, and to convince a man to pay for it it was necessary to show him that it would produce annual savings which would warrant the investment.

The author seemed to have attacked the most difficult part of the problem first, and with no little success. The control given was without question practically perfect and there was practically no discussion on that point; rather, it was what price could the man who used it afford to pay?

The noise increased with the larger units, that being one of the limitations to the size that could be employed.

Mr. Crain said that he had not found very much difference in efficiency between the large units and the small units, the efficiency lying between 82 and 85 per cent at full speed and full power.

Charles M. Manly,[2] referring to an efficiency curve given in the complete paper, said that it was a curve of efficiency at constant torque and not at constant horsepower. In tests which he had made and presented to the Society[3] in 1911, the efficiency at constant horsepower had been shown to be greater than the effi-

Safety Engineering in the Compression of Gases

By A. D. RISTEEN,[1] HARTFORD, CONN.

The purpose of this paper is to outline a few of the chief hazards that are associated with the compression of some of the gases in common use in industry. Among the gases considered are air, oxygen, nitrogen, argon, carbon dioxide, hydrogen, acetylene, ammonia, and chlorine. The preparation, utilization, storage, or transportation of the gases, except when some of these items may happen to have an important bearing upon the actual operation of compression, are not discussed. As to the mechanical strength of the apparatus that is used to effect the compression, the paper deals only with the things that are likely to happen even when the apparatus itself is strong enough to withstand the stresses that are thrown upon it in the course of its normal operation.

COMPRESSED air, the first of the gases to be considered, is used for many different purposes and at many different pressures, but so far as safety is concerned it is sufficient to distinguish two main problems. First, we have to deal with cases in which the ultimate pressure desired does not exceed, say, 200 lb. per sq. in.; and second, the special case in which the compression must be pushed to perhaps 3000 lb. per sq. in. for the production of liquid air.

When the ultimate pressure is not greater than 75 lb., the compression is usually effected in a single operation; but it would seem better to adopt two-stage compression for pressures approaching or exceeding this limit. Three stages, at least, should be used for pressures in the neighborhood of 1000 lb., and to push the pressure from this point up to 3000 lb. a fourth stage or operation should be employed. It is advisable to use long-stroke compressors, with low piston speed, not only to avoid unnecessarily high temperatures, but also because less lubrication is needed.

Every now and then there is an explosion in connection with an air compressor, and the results are sometimes quite serious. Most of these explosions are probably associated more or less directly with the lubrication of the compressor cylinders, and with inefficient cooling of the air that is undergoing compression. In an ordinary compressor the temperature of the air rises considerably during the compression stroke, and it is of the utmost importance to keep this rise of temperature within reasonable bounds. A good deal can be accomplished in this direction by surrounding the cylinders with effective water jackets. The cooling water in these jackets should circulate actively and copiously, and thermometers should be provided to show the temperature at which the water is entering and leaving. To guard against stoppage of the flow of cooling water from any cause, it is also important to provide some positive means for showing that the circulation is free and plentiful at all times. It is advisable, for example, to have the discharge from each jacket located where it is plainly visible to the men working about the room.

It is not sufficient, however, to provide the compressor cylinders with water jackets. The air should be passed through a special cooler immediately after leaving the compressor and its temperature brought down near that of the surrounding atmosphere as quickly as practicable. Moreover, if the compression is effected in two or more stages, an intercooler between each stage and the next one should be provided, so that every cylinder will be supplied with air at a moderate and reasonable initial temperature. The use of efficient cooling devices tends not only to insure safety but also to lessen the cost of compression, because cooling reduces the pressure as well as the temperature.

In compressing air to moderate pressures the cylinders are lubricated with oil. Oil may also be used in the first stages of high-compression apparatus, though water is preferable for the final stages. The composition and physical characteristics of the oil should be carefully considered.

As a general rule, too much oil is used in lubricating the cylinders of air compressors. It takes considerable experience to determine just the right amount, and what is right with one machine or one grade of oil may not be right with another. In a general way, however, it is safe to say that the lubrication is ample if the cylinder walls are always coated with a slight film of oil. It is often assumed that the explosions that sometimes occur in connection with air compressors are due to the ignition of oil vapor or of oily mist. It would be hard to justify this theory. Whenever a compressor cylinder discharges the air that it contains, the oily vapor or spray that is present is discharged at the same time, and it is hard to see how a quantity sufficient to produce a serious explosion could accumulate. Moreover there are comparatively few explosions in which the initial break is in the compressor cylinder. More commonly the first rupture occurs in the discharge pipe or the receiver, and trouble at these points can be minimized, and perhaps entirely avoided, by (1) quick and efficient cooling of the air, (2) thorough drainage of the oil that tends to collect in the piping and receiver, and (3) careful attention to the discharge valves on the compression apparatus. Considerable quantities of oil are likely to accumulate in the discharge pipe and the receiver, and if either of these bursts, a large amount of hot oily spray is likely to be discharged into the air, and this may take fire either spontaneously or from some external source, with a bad oil-vapor explosion as the result. Suitable traps and drains must be provided to prevent the accumulation of the oil, and in this way the oil hazard can be largely or wholly removed.

If the exhaust valves of the compression apparatus are leaky, then upon the return stroke more or less of the compressed and heated air will find its way back into the cylinder, so that the temperature of the air in the cylinder upon the next compression stroke will reach a much higher point than the designer of the apparatus intended. Carbonaceous deposits, produced by the carbonization of the lubricating oil, often collect in considerable quantity in and around the exhaust valves, and these may sometimes take fire, or they may prevent the valves from closing tightly. Exhaust valves should be carefully watched for such deposits, and should be kept as clean and tight as possible.

Oxygen

Oxygen is compressed and shipped in vast quantities and is used in the greatest imaginable variety of ways. Before subjecting it to compression it is essential to know that the oxygen is pure, and especially to know that it is not contaminated with any other substance with which it could combine, either during compression or in the course of subsequent handling. For example, if it is prepared by the fractional distillation of liquid air, it is important to know that the air that was subjected to liquefaction was free from smoke particles, from organic dust of any kind, and from coal gas, acetylene, and every other substance of an oxidizable nature. If the oxygen was produced by the electrolysis of water, it is equally essential to know that it is not contaminated by hydrogen. It is easy enough to insure purity in all these respects, but the importance of not neglecting the necessary testing, and the purification operations when these prove to be needed, cannot be over emphasized.

In handling compressed oxygen it is supremely important to prevent the gas from coming in contact with oil or grease either during the compression or while the oxygen is being stored, transported, or utilized; and in view of the fact that many exceedingly serious accidents have occurred in consequence of neglecting this principle, the author wishes to emphasize the hazard just as strongly as he can. When a man talks with appropriate earnestness about the danger of allowing compressed oxygen to come in contact with oil, grease, or other combustible organic materials, it is easy for the uninitiated to believe that he is inspired by unreasonable timidity, but this is not the case. Those who have followed the history of oxygen compression are well aware that many accidents have occurred under conditions that thoughtful and experienced men

[1] Director of Technical Research and Safety Publication Work, Travelers Insurance Company and Travelers Indemnity Company. Mem. A.S.M.E.

Presented at a joint session of the American Society of Safety Engineers and the A.S.M.E. Safety Codes Committee at the Annual Meeting, New York, December 4 to 7, 1922, of The American Society of Mechanical Engineers. All papers are subject to revision.

would not have considered to be at all likely to produce trouble. The use of even a slight trace of oil in the compressor is exceedingly hazardous, not only on account of the danger of immediate combustion, but also because some part of the oil is bound to go over with the compressed gas; this will collect in the tanks or cylinders used for storage purposes, and sooner or later serious results will surely follow. It is probably safe to say that most of the accidents that have occurred in connection with compressed oxygen have been due to lack of appreciation of the importance of this thing. The trouble is not confined, of course, to the mere combustion of the oil itself. The metal parts of the apparatus will burn freely as soon as they become sufficiently heated by the ignition of the oil or grease, and the consequences may transcend imagination.

The only absolutely safe thing to use for the lubrication of an oxygen-compressor cylinder is *pure water*, which should be introduced into the suction pipe in the form of a visible spray. Under special conditions it may happen that pure water is not sufficient, and in a case of this kind it may be permissible to dissolve a little soap in it; but soap should not be used when water will suffice, and it should *never* be used without first proving, by actual analysis, that the particular supply to be dissolved contains no uncombined (or unsaponified) oil or grease. The packings used on the compressor must also be entirely free from oil, grease, or graphite. Packings made for this express purpose should always be employed.

The compression of oxygen is often, and perhaps usually, carried up to about 2000 lb. per sq. in., and it should be effected in not less than three stages. In speaking of the compression of air, the importance of prompt and effective *cooling* has been emphasized, and much greater attention should be paid to this point when compressing oxygen. The pump cylinders should be water-jacketed, the circulation of water should be positive and abundant, and the apparatus should be so designed that cessation or diminution of the flow of jacket water cannot escape immediate notice. The gas should also be passed through effective intercoolers between each compression stage and the one next following; and *immediately* after leaving the last cylinder of the compressor it must be passed through a final cooler, and brought down to the temperature of the surrounding atmosphere.

It is exceedingly unwise to introduce oxygen into receivers of any kind, unless these receivers are known to be perfectly clean internally and wholly free from oil, grease, and other combustible substances. The author would like to see some kind of a regulation established forbidding every oxygen manufacturer to fill any tanks other than his own. This principle is already followed, it is believed, by some and perhaps all of the larger manufacturers, but unfortunately it is not followed by everybody. Moreover, oxygen should never be compressed into containers that have been used for other gases. When a cylinder or tank has been previously used for holding compressed gases other than oxygen, there is likely to be an accumulation of oil upon its inner surface, because oil may have been used for cylinder lubrication in connection with the compression of these other gases, and it is hard to remove such oil thoroughly enough to make the tank safe for oxygen.

Nitrogen

Nitrogen gas has a far narrower range of application in the arts than oxygen, yet it is compressed and shipped to a certain extent. This gas was used during the war in the recoil cylinders of certain types of guns, and it has also been used to a limited extent for blanketing combustible liquids and for supplying a neutral atmosphere for other purposes, where the presence of a gas with active chemical properties would be objectionable. At the present time compressed nitrogen is supplied mainly, it is believed, for filling incandescent electric lamps, and in connection with the manufacture of automobile tires.

Nitrogen forms four-fifths of the bulk of the atmosphere, and as it is nearly inert in its elemental form the precautions that are recommended in connection with the compression of air are also adequate when compressing nitrogen. It should be noted, however, that the nitrogen that is used for filling electric-lamp bulbs must be free from hydrocarbons, and this means that when the gas is to be employed for this purpose it is not permissible to use oil for lubricating the compressor cylinders. Water should be used instead. For certain reasons, in fact, it is best to avoid oil altogether and to lubricate with water in all cases. This does not mean, however, that there is any danger of direct chemical action between the oil and the nitrogen.

Nitrogen is usually compressed to about 2000 lb. per sq. in., and the compression should be performed in three stages.

Argon

Argon, like helium and neon, has no chemical properties whatsoever. It forms no compounds and is absolutely inert under all circumstances. Hence it cannot produce fires or explosions. Moreover, it is not poisonous. It is obtained from liquid air, however, and when first separated from the air it is mingled with a large proportion of oxygen—the mixture usually containing about 65 per cent of oxygen and 35 of argon. When it is handled in this state it must therefore be treated like oxygen; but after it has been freed from the admixed oxygen it may be compressed under the same conditions as nitrogen. For shipment it is usually compressed to a pressure of 1800 or 2000 lb. per sq. in., in three stages.

Carbon Dioxide

This gas is compressed in large quantities and is used for the most varied purposes. As is well known, it will neither burn nor support combustion, and the author does not recall any chemical dangers which are likely to be encountered in its compression. It is not especially poisonous, but when a considerable quantity of it is mixed with the air that the workmen have to breathe, it replaces the life-giving oxygen to a corresponding extent, and this may mean that the air is not fit for respiration. The effects of carbon dioxide in this way are sometimes very insidious, especially as the pure gas is without odor or color; and it is therefore evident that special care should be taken to provide free and copious ventilation at all times in buildings in which carbon dioxide may escape, by leakage or otherwise.

Hydrogen

In connection with hydrogen and most of the other combustible gases (such as propane), the chief danger associated with compression probably consists in the likelihood of fire or explosion in case of leakage or of contamination with oxygen. If the hydrogen is prepared by the electrolysis of water, there is always a possibility that oxygen may be present in it in small amounts, and the gas should be carefully tested, either at short intervals or preferably by some continuous process, to make sure that the oxygen content is always well below 5 per cent. Small amounts of oxygen can be removed by passing the gas over palladium pumice, which causes the oxygen to combine in a quiet way with an equivalent quantity of hydrogen.

The danger of admixture with air or oxygen is not in any way restricted to hydrogen prepared by the electrolytic process. Air may leak into the suction pipe leading to the compressor, whatever the source of the hydrogen; and this, in fact, is one of the hazards that must be watched most carefully in handling this gas. The suction line may be fitted with test cocks or drainage valves, and when this is the case it is exceedingly important to keep them closed except when they are opened for legitimate purposes and at proper times. It is believed, moreover, that all such cocks and valves should be kept locked, and that the keys should be in the keeping of some designated, responsible man. To guard further against trouble from this source and from accidental leakage, the whole operation should be conducted so that there will be a positive pressure in the suction line *at all times*. Care should also be taken that the gasometer does not stick and that its seams are kept absolutely tight.

It is important to consider the possibility of leakage outward as well as inward. Hydrogen is usually compressed to a pressure of 1800 or 2000 lb. per sq. in., and at high pressures a good deal of gas will escape through a small hole in a short time. If hydrogen gets out into the room and is allowed to collect there, a serious explosion is likely to result. Every discoverable source of ignition should be carefully considered and safeguarded. Rigorous measures should be taken to prevent the men from smoking or using matches or other sources of open flame. The artificial lighting should be provided by incandescent electric lamps enclosed in

vapor-proof globes, and it is safest to mount these lamps outside of the windows, locating them so that they shine through the window glass into the interior. All electric wires should be run in closed conduits, and the fuses should invariably be outside of the region of possible danger. This applies also to switches, unless they are of a type which cannot produce an arc or flame. No electric motors should be used in rooms where hydrogen, propane, or any other combustible gas may escape in quantity, unless these motors are specially designed for this particular application, or else thoroughly ventilated by fresh, pure air from the outside of the building. And these various precautions should be observed not only where the hydrogen is compressed, but also wherever it is stored—either in gasometers or in cylinders. Finally, it is exceedingly important to provide abundant ventilation at all times to lessen the chance of fire or explosion in case the other precautions prove inadequate.

Left-handed threads are extensively used for fittings that are to be employed in connection with hydrogen, the purpose being to prevent the accidental connection of hydrogen lines or cylinders with pipe lines conveying other gases, and especially with those containing air or oxygen. It is to be regretted that in many plants the purpose of the left-handed thread is deliberately defeated by making use of devices known as "adapters." These are in effect right-and-left couplings, which are provided for the express purpose of making it possible to attach a cylinder with a left-handed thread to a pipe line having a right-handed thread.

Acetylene

No person should ever undertake to compress acetylene unless he fully understands the properties of the gas and knows exactly what it is permissible to do and what he must carefully avoid doing. This is not meant to imply that the compression of acetylene is a dangerous operation when it is performed under the direction of a properly qualified man, but is intended as a special note of warning to those who are tempted to compress the gas without first understanding its properties. Acetylene is an endothermic compound, and this formidable word has frightened a great many persons who do not understand its exact significance. It merely means that heat is absorbed (instead of emitted) when acetylene is formed from its constituent elements. Now it is well known that substances of this kind are likely to be more or less unstable under certain conditions, and acetylene is no exception to the rule; but the conditions under which the instability exists are well known, and it is only the man who does not understand them, or who is pleased to ignore them, who gets into trouble.

In compressing acetylene it is important to keep the temperature of the gas as low as practicable at all times. Expressed in more definite language, this means that the compression must be effected by a pump moving with a very low piston speed, and that it must be performed in not less than three stages. It also means that the pump cylinders should be kept as cool as practicable by a plentiful supply of water drawn from the coolest available source. The author cannot state any definite temperature at which the gas may become instable during the act of compression, and in fact it is doubted if anyone knows what that temperature might be. The only thing that we can say is, that if the operation is conducted as here described, there is apparently no danger from instability. It certainly is not safe, however, to *store* acetylene in otherwise empty cylinders, at the pressure at which the compressor pumps deliver it. There appears to be a time element involved here, and it is probable that a certain amount of polymerization gradually occurs in strongly compressed acetylene (except when it is stored in special receptacles containing suitable porous material charged with liquid acetone), so that in the course of time small quantities of other more sensitive substances are formed, which serve to lessen the stability. At all events, we know that acetylene should not be stored in an otherwise empty tank at a pressure of more than 15 lb. per sq. in. greater than the normal pressure of the atmosphere, and yet we know that explosions in the compression pumps, and in the delivery pipes leading from them, are exceedingly rare if the compression is effected as here described. In fact, the author knows of only one case of the sort, and this was precipitated by the breakage of a steel valve spring, which quite possibly struck a spark and thereby caused the development of a high temperature within the tiny space filled by the spark itself.

Oil may be used for lubricating the cylinders of acetylene-compressing pumps, but it should afterward be removed by passing the compressed gas through suitable separators as it leaves the compressor. And immediately upon leaving the oil separator the acetylene should be passed into the storage cylinders, which, as previously stated, must be filled with a special porous, solid material thoroughly impregnated by liquid acetone, which dissolves the acetylene and holds it safely in solution.

It should not be necessary to issue a warning against mixing other gases with acetylene in the storage tanks, or using acetylene storage cylinders for any purpose whatsoever, except for holding pure, unmixed acetylene (in addition to the safety filling).

Ethyl Chloride, Methyl Chloride, and Propane

These gases are used to some extent as refrigerating agents, but it does not appear desirable to discuss their compression in any detail. They are all inflammable, and hence must be handled with due regard to the possibility of fire and explosion. Propane (like butane) does not require lubrication in the compressor cylinder, because the substance itself affords sufficient lubrication. It is necessary, however, to lubricate the stuffing box of the compressor. There has been some difficulty in connection with the lubrication of cylinders in which the chlorides of ethyl and methyl are compressed. Castor oil has been used, but it is not very satisfactory. Glycerine is said to be much better, though still far from ideal. It is said that a new lubricant, consisting of ethylene and propylene glycol mixed with deflocculated graphite, and specially adapted to ethyl and methyl chlorides, and to propane, is now available.

In handling these and all other inflammable gases the various special precautions mentioned in connection with hydrogen should also be observed.

Ammonia

Liquefied ammonia is used in immense quantities in connection with refrigerating machinery, and although it perhaps cannot be called a poisonous gas in the narrow sense of the term, it is easily capable of producing unconsciousness and death when it is present in the air in any considerable amount. Similar remarks apply to sulphur dioxide gas, which is also used in refrigerating machinery as well as in various other applications. Both of these gases are freely soluble in water, and it is recommended that in all rooms in which they are handled an overhead sprinkling system be provided that is capable of discharging large volumes of water into the room in case of the accidental liberation of excessive quantities of either gas. A considerable part of the liberated gas would be absorbed by the down-rushing water, and even though the air might not be rendered respirable in this way, something would surely be gained in the way of checking the spread of the gas to other rooms. It is certainly important to provide free and abundant ventilation in and adequate means for quick exit from any room in which either gas may suddenly be liberated in quantity. These simple and evident precautions are often wholly disregarded in laying out plants in which ammonia or sulphur dioxide are handled or used.

Ammonia gas is usually pronounced incombustible and incapable of being exploded when mixed with atmospheric air, but research and experience have shown that this is not altogether true. A mixture of ammonia gas and air can be exploded if it contains from 16 to 27 per cent of ammonia, and some of the explosions that have occurred in our big refrigerating plants subsequent to the liberation of considerable quantities of ammonia may possibly have been due to the ignition of mixtures of this kind by means of the arc lamps which have in most cases been in use in rooms where these accidents have occurred.

In compressing ammonia another source of danger must be carefully considered. If the ammonia gas that is undergoing compression is allowed to become unduly hot, the ammonia that comes away from the compressor will contain a notable quantity of combustible gas that is distinctly different from ammonia. This may come in some measure from the decomposition of the oil that is used in lubricating the compressor cylinder, but it also contains free hydrogen, which appears to be produced by the actual dissociation (or breaking up) of the ammonia into its component gases, nitrogen and hydrogen. We used to think of ammonia as being exceedingly stable and incapable of dissociating in this way

to any sensible extent, but we now know that such is not the case. Dissociation occurs even at moderate temperatures, and it is likely to become quite significant when the temperature is high. To guard against the development of combustible decomposition products from the lubricating oil, it is important to use a special kind of oil which experience has proved to be well adapted to work of this kind; and to keep the dissociation of the ammonia itself within as low a limit as practicable, it is important to keep the gas as cool as possible by methods already outlined in connection with other gases. Finally, to guard against vapor explosions in case ammonia gas should escape into the air in considerable quantity, it is important to take the same precautions against ignition sources that have been suggested in connection with hydrogen.

Chlorine

Liquid chlorine is now shipped in vast quantities, for use in connection with bleaching, and for many other purposes. It has been greatly feared by the general public ever since it was used as a military gas in the war, but in time of peace this fear is hardly justifiable. Chlorine is exceedingly irritating, and it can produce unconsciousness and even death if inhaled in any considerable quantity. It has been well described as an "honest gas," however, the phrase meaning that it has no treacherous qualities. We always know exactly what it will do. In a manufacturing plant, or in a plant in which chlorine is compressed, immediate relief can be had, in case of leakage, by merely leaning out of an open window or going out of the room. It is not desired to underrate the dangers associated with handling liquid chlorine, yet it is only fair to say that they have been largely exaggerated. If a cylinder or a tank containing liquid chlorine bursts or springs a leak, for example, the evaporation that takes place rapidly chills the liquid still remaining in the tank, so that the evolution of gas is quickly and automatically checked, though not wholly stopped. Abundant ventilation is important in a chlorine plant and special attention should be given to the exits, so that if the gas becomes accidentally liberated in considerable quantity the men can pass out into the open air as quickly and directly as possible.

Chlorine must be carefully dried before compression, because if it is moist it will corrode the pump, piping, and tanks. Perfectly dry chlorine, on the other hand, has practically no action upon iron. The drying is effected by passing the gas through towers filled with pumice wet with concentrated sulphuric acid. In liquefying the gas by means of a compression pump the main difficulty to be overcome is keeping the piston gastight in the compression cylinder. A special form of packing is required for this purpose, and it should be designed and installed by some person who understands the necessities thoroughly. In one compression plant visited by the author there are seven sealing rings on the piston—six soft and hard packings of special chlorine-resisting material being used, while the middle space is filled with strong sulphuric acid which not only completes the seal but also serves to lubricate the cylinder. The pressure required in chlorine tanks is not high, as the vapor pressure of liquid chlorine is only about 120 lb. per sq. in., at 70 deg. fahr.; and even when a chlorine tank has been left standing in the sun for a considerable time, the pressure will hardly ever creep up as high as 160 lb. per sq. in. In liquefying this gas the compression is therefore performed in one operation. Tanks and other apparatus used in handling or storing chlorine must be clean and free from all other substances—solid, liquid, or gaseous—with which the chlorine might combine.

In conclusion, there is one general suggestion relating to safety-valves which applies to all gases. Some engineers discourage the use of safety valves on gas-compressing apparatus, partly because the escape of gas through them is a source of waste, and partly because it creates a special hazard, when the gases are toxic or inflammable. But it is not necessary to liberate the escaping gas at or near the work place, and it can often be discharged where it will not constitute a hazard to property. Hence this objection is not altogether well founded. In fact, relief valves should be provided in all cases, and the discharge problem should be considered on its own merits in each individual plant. It is often, and perhaps usually, practicable to have the discharge delivered back into the piping system on the low-pressure side of the compressor, so that there is no economic loss, and no hazard to the men nor to property.

Discussion of Hydraulic-Transmission

(Continued from page 241)

ciency at constant torque, so that the author's curve would be better at constant horsepower. This was a condition which was of great interest in many applications where it was possible to get increased torque with decreased speed and full horsepower within a reasonable range.

Of course a full horsepower output could not be obtained throughout an infinite speed range. If one ordered a machine for a 10 to 1 range at a constant capacity and needed only a 5 to 1 range, he would have to buy a machine of twice the capacity actually necessary.

In closing the discussion the author said that Mr. Manly had raised an important question in his comment on the increased efficiency shown in his tests at constant horsepower. He did not know whether a similar condition existed in the Oilgear, as it depended on the relative values of the different components of the total loss, such as mechanical and hydraulic friction.

Of greater practical importance was the method of obtaining the constant horsepower output. If this was done by varying the pump stroke, the working pressure would increase as the pump stroke was reduced. This amounted to underrating the machine in order to call it a constant-horsepower machine. If it was to operate at half-stroke with 1000 lb. per sq. in. pressure and at full stroke with 500 lb. per sq. in. to give constant horsepower, it might as well carry doubled rating at full stroke, unless limited by bearing pressures or speeds, or by overheating.

Regarding Mr. Crain's remarks on the subject of costly construction, the author believed that the simple plane and cylindrical parts used in the Oilgear would lead to a reduction of cost. This prospect had led him to believe that the machine-tool field and similar fields should be considered open for hydraulic-transmission methods.

The variable-stroke oil pump as a power transmitter had the following outstanding characteristics:

- *a* Complete speed control of the driven motor
- *b* Transmission of maximum torques to the driven motor without requiring large power input
- *c* Automatic regulation of power input at all speeds to the amount actually required to deliver the power output
- *d* Perfect lubrication and consequent extreme durability
- *e* Negligible idling load
- *f* Ability to operate as a disengaging clutch by setting the pump at zero stroke.

No other power transmitter combined these properties, and very few power transmitters had any of them. The direct-current electric motor, however, had been highly developed as a variable-speed drive, and had a large field appropriate to it in which the hydraulic drive would not compete.

It was very important to get a clear idea of the essential distinction between hydraulic variable-speed drive as herein presented and the ordinary types of hydraulic machinery. Every Oilgear transmission comprised a pump, a motor, and an oil circuit connecting them. The volume of the liquid flow and hence the speed of the motor was determined only by the pump displacement. The pressure of the working fluid was determined only by the resistance encountered by the motor, and rose and fell with the load to be driven. There were no throttle valves and no reduction of pressure in the working liquid except when it passed through the motor. Then the pressure instantly fell to exhaust pressure, the drop being just sufficient to compel the motor to turn against the mechanical resistance to be overcome, because the high pressure was determined and caused by this same resistance.

The ordinary hydraulic system, including an accumulator, required a maximum pressure to be delivered by the pump whether the work needed this pressure or not, and the surplus was wasted or wiredrawn through the throttle valve between the accumulator and the working machine. This throttle valve controlled the movement of the working ram both as regarded speed and the pressure delivered. That part of the power not needed to drive the working machine at the required speed was lost, and was also used to cut the working parts and destroy the mechanism itself.

Performance Tests of Steel Belts with Compressed-Spruce Pulleys

Particulars Regarding an Investigation of the Performance of Welded and Continuous Steel Belts Running on Compressed-Spruce Pulleys Not Specially Faced

By GARTH L. YOUNG[1] AND GUIDO V. D. MARX[2]

FROM the data available it would appear that the possibility of using thin ribbons of steel in place of leather or composition belting for power transmission was conceived by Eloesser in Germany some fifteen years ago, but that at first various mechanical troubles stood in the way of extensive adoption of the new device. It was not until a few years ago that these troubles were overcome to a sufficient extent, and it is stated that at present close to 1,000,000 hp. is being transmitted by steel-belt drives.

The authors have carried out a series of tests with continuous steel belting and compressed-spruce pulleys. Heretofore the two outstanding difficulties with steel belts have been the impossibility of securing a satisfactory joint and the fact that the pulleys must be specially faced in order not to run metal on metal, which would ultimately, perhaps after a short period of satisfactory operation, give rise to excessive slip and consequent power loss. Because of this the combination of continuous belting and compressed-spruce pulleys would appear to be of particular interest.

Compressed-Spruce Pulleys

The driver and driven pulleys were 20 in. in diameter, 6 in. face,

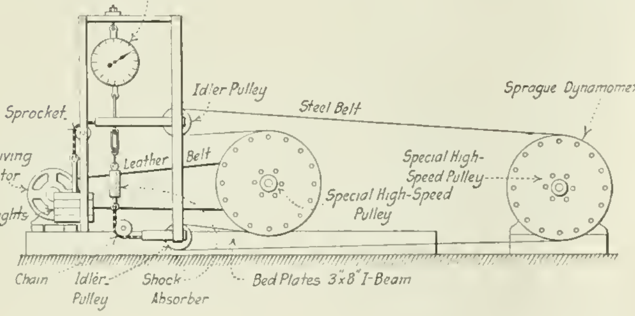

Fig. 1 Diagrammatic Sketch of Steel-Belt Testing Machine

compressed spruce, and the idlers 12 in. in diameter with 4 in. face. According to the manufacturers, "The method used in constructing these pulleys is to lay up $^3/_8$-in. thick lumber in square blocks with the alternate layers at right angles, glueing with Casco casein joint glue to whatever thickness is desired, place in a hydraulic press and compress the block perpendicular to the plane of the layers, clamp and hold for from 48 hours to a week. The clamps are then removed and the block remains compressed with practically no expansion. The block is then bored with a hole that is slightly smaller than the outside of the cast-iron hub. The machined hub is then pressed in by hydraulic pressure and the pulley turned on a mandrel in an engine lathe. The pulleys are then doweled with fir dowels, the set-screw hole (if required) bored and tapped, placed on the mandrel again, and sanded and finished." A block of this material was compressed under a pressure of 4800 tons per sq. ft., or around 68,000 lb. per sq. in. without having it fail by spreading out, and although these pulleys have never been tested to destruction by centrifugal force, it would appear from the foregoing that the wood in tension will carry up to far above ordinary driving speeds.

Abridgment of a thesis submitted by the authors in June, 1922, to the Department of Mechanical Engineering and Committee on Graduate Study of Leland Stanford Jr. University in partial fulfillment of the requirements for the degree of Engineer.

Belt Material and Joints

The material used for belting in these tests was what is known commercially as clock spring. It is a very high-carbon charcoal steel apparently rolled and ground to size and drawn to a dark blue temper. The belt used was 0.01 in. by 0.75 in. by 35 ft. This material may be obtained in varying widths, thicknesses, and tempers. In the 0.01-in. thickness the widths obtainable are from $^1/_2$ in. to 3 in. in tempers of light straw, dark straw, and dark blue.

First tests made to determine the tensile strength of the belt were unsatisfactory due to the fact that the material was so weakened by the scarf marks in the grips of the testing machine that the belt failed in the jaws at loads of from 225,000 to 250,000 lb. per sq. in. This difficulty was obviated by looping the belt in either grip, thus giving two thicknesses instead of one. The belt then broke cleanly between the grips at a load of 275,000 lb. per sq. in.

The previous work done with belts of this material clearly shows that a silver-soldered lap joint is by far the most satisfactory to use, hence little time was spent on the construction and test of joints of different types. A triple-riveted lap joint was made up and tested, eleven $^3/_{32}$-in. Norway tinned rivets being used. This type of joint was never run on the apparatus as it was clearly far too stiff to stand the reversals of stress over the 12-in. idler pulleys. When tested for tensile strength the rivet heads pulled out and sheared at a load of 108,000 lb. per sq. in., giving an efficiency of 39 per cent.

The silver-soldered lap joint was made as follows: The ends were squared up and scarfed to a razor edge with a file and emery cloth, the length of the scarf being about three-quarters the width of the belt. The ends were then clamped firmly in place and from $^1/_4$ in. to $^3/_8$ in. of $^3/_4$-in. by 1-in. silver solder inserted. A small quantity of borax was used as a flux. Red-hot tongs were then firmly clamped over the joint until the solder melted and flowed evenly. The joint was then allowed to slowly cool, the oxide and surplus solder being polished off.

The joint used in all the test runs, covering a period of at least 50 running hours, was later cut out of the belt and tested for tensile strength in the manner described earlier. The specimen failed at the edge of where the temper had been drawn by the tongs, and not at the joint itself. The breaking load was 153,000 lb. per sq. in., giving an efficiency of nearly 56 per cent. Apparently the joint was so constructed as to be perfectly flexible and the reverse stresses over the 12-in. idlers had not affected its strength to any appreciable degree.

Description of Apparatus Used in the Tests

The apparatus used in these tests amounted essentially to a dynamometer whereby the tensions in the tight and loose sides of the belt could be accurately measured. This was accomplished by using two idlers mounted on swinging frames as shown in Fig. 1. For measuring the slip between the driver and driven pulleys a differential counter was used which was originally built by Helmick for his tests (see Mechanical Engineering, July, 1920, p. 374). The mechanism of the differential counter is such that when the driver and driven shafts rotate equally in opposite directions there is no movement of the ring gear G, Fig. 2. The light chains shown connect the counter to the driver and driven shafts.

Due to the one-to-one ratio of the sprockets and equal diameters of the pulleys there is no motion of the ring gear unless the belt is slipping. When slip occurs the rotation of the ring gear is proportional to the difference in peripheral velocity of the two pulleys. The ratio of the ring gear to its pinion is one to twenty and the ratio of the differential gears is two to one, making the ratio from the wheel shafts to the ring pinion one to ten.

The motion of the ring pinion is transferred to a specially built counter by means of a light chain and sprockets. This counter is engaged and disengaged by an electrically operated dog clutch. The unit wheel of the counter is divided into tenths so that one division of this wheel corresponds to a difference in revolutions of one one-hundredth between the driver and driven pulleys.

The revolutions of the driver pulley are taken with a Veeder counter operating in the same circuit as the differential and direct connected to the differential-wheel shaft.

Test Procedure

As the load on the weight pan and the reading of the dial balance will not give directly the tensions in the belt under test because of the angularity of the belt pull, the apparatus was properly calibrated.

The next problem was to overcome the effect of vibration, which was successfully achieved with certain modifications in the apparatus.

The object of making the tests described herewith was to obtain the relation of the coefficient of friction to the main variables of pressure, driving velocity, slip velocity, and horsepower over a practical driving range. The method followed was to maintain a constant tension in the tight side of the belt and vary the load from the point of little or no slip to a value considered excessive. This was repeated at each tension for all the available driving speeds. It was first desired to check up the work of Hampton, Leh, and Helmick with steel on cork-faced pulleys and see what variations from their results could be ascribed to the use of compressed-spruce pulleys. It was found that the two sets of tests gave results approximating each other quite closely.

The relations found to exist between the coefficient of friction u and the driver velocity V_d, slip velocity V_s, and pressure P showed that the coefficient of friction varied inversely as the 0.533 power of the pressure, inversely as the cube root of the driven velocity, and directly as the 0.174 power of the velocity of slip.

By selecting thirty representative sets of values of the variables a solution was made for the constant K. The average of the thirty gave $K = 32$. The formula in its final form therefore reads—

$$u = \frac{32V_s^{0.174}}{P^{0.533}\,V_d^{0.333}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

and while variations will be found in the cases of extreme values of the coefficient, this equation fits very satisfactorily over the main range of values.

As it was desired if possible to find an equation of simpler form which would fairly closely apply, a determination of the constant was made in ten representative cases when the following formula was used:

$$u = \frac{KV_s^{1/8}}{P^{1/2}V_d^{1/3}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

It was found that this formula could be applied with a little more variation than the one given above, when the value of $K = 32.91$ was used.

A table was constructed to show the relative efficiencies of the various types of pulleys. The method followed was to go over the data and select, at tensions in the tight side of the belt as nearly equal as possible, readings in which the velocity of slip and driver velocity were also constant. The only variable which now could affect the coefficient of friction and the horsepower transmitted was the self-adjusting value of the tension in the loose side of the belt. The coefficient of friction of steel on compressed spruce and the corresponding horsepower is higher in each case than the values of steel with cork-faced pulleys, the average ratio (horsepowers transmitted) of wood to cork being 1.36.

As regards the relation between horsepower, velocity of slip, and tension in the tight side of the belt, the results obtained by the present investigators check very closely with those of Helmick, but in the relation involving the coefficient of friction, velocity of driver, and velocity of slip, there is considerable variation between the results obtained by the two sets of investigations, the equation derived by the authors being as given above in [1], where u is the coefficient of friction, V_s the velocity of slip, V_d the velocity of driver, and P the pressure in pounds on the pulley face. The difference between the two equations shows the relative influence of the variable factors with the two kinds of pulleys.

The next series of tests dealt with the performance of continuous belting on compressed-spruce pulleys. At the time the belts were needed it was impossible to secure belts of more than 20 to 22 ft. open length, and as the specifications from the manufacturer of the belt required 20-in. diameter pulleys when reverse stress occurred, the apparatus as heretofore used became impractical. An effort was made to devise some apparatus which would give a practical drive for the continuous belt and at the same time admit of some method of accurately determining the tensions. This apparatus is described in the unabridged thesis.

Continuous Steel Belt

The continuous steel belt tested was quite different in physical appearance from the welded belt. In appearance it was bright and highly polished, the edges being slightly rounded to reduce the hazard in handling while running, although it should be borne in mind that the safest plan is to align the apparatus so that adjustment of the running belt is unnecessary. The continuous belt is apparently not tempered to the degree of the clock spring used heretofore, and in consequence must be handled more carefully to prevent giving it permanent twists or sets. No physical tests of the material were made as it was not believed that the knowledge to be gained justified the breaking of one of the belts for this purpose.

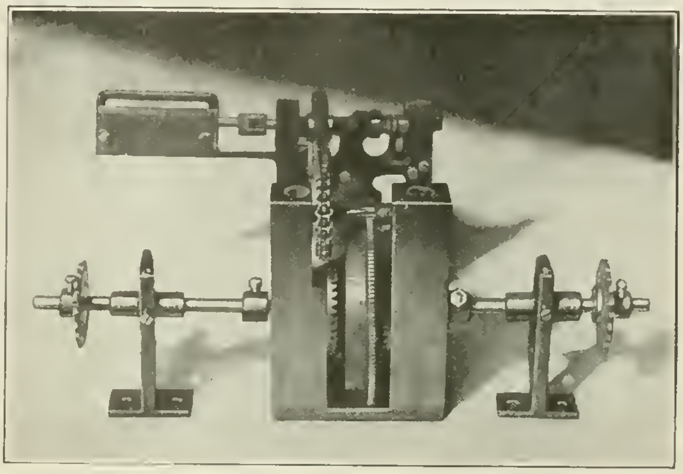

Fig. 2 Differential Counter Used for Measuring the Slip Between the Driver and Driven Pulleys

From tests it was found that the horsepower varies as the 0.78 power of the velocity of the driver, in addition to which the following general relation was obtained:

$$\text{Horsepower} = \frac{1.51\,P^{0.81}V_d^{0.78}}{1000}$$

This formula checks out quite closely with the observed and computed data from which it was taken, with the exception that slight variation occurs at the highest velocities, when the computed value is a little high. The formula has a practical value in determining belt tensions and dimensions knowing the horsepower to be transmitted and the belt speed.

An effort was made to compute the coefficient of friction as a function of various variables in the case of a continuous belt and the values obtained proved to be extremely low, ranging from 0.192 to 0.240 in one series and from 0.198 to 0.257 in another.

The explanation of the extremely low values of u obtained in working out the data in some cases is that the floating pulley allowed the tensions in both sides of the belt to adjust themselves, and naturally at very low horsepowers, values as low as 0.0233 being recorded, the tension in the loose side of the belt became very nearly equal to that in the tight side, with the consequent result that the ratio of (t_1-t_c) to (t_2-t_c) approached unity. The logarithm of this ratio being very small, u approached zero as the limit. At just what point the values of u become reliable is difficult to determine, but it is evident from past experience that values below 0.12 or 0.13 should be disregarded.

SURVEY OF ENGINEERING PROGRESS

A Review of Attainment in Mechanical Engineering and Related Fields

Vibrations in Foundations

By DR. ENG. ERNST SCHMIDT

Description of a method of investigation based on the use of vectors. One of the features of this method is that it employs a so-called "foundation function" which expresses the motion of the foundation for every direction of freedom of oscillation in accordance with the magnitude and phase of the motion at all frequencies.

The development of vibrations in a foundation is dependent on the following elements: First, the force producing the oscillations; second, the inert mass of the machine on the foundation; third, the properties of the foundation itself; and fourth, the action of damping elements.

For theoretical purposes the investigation is limited to periodic processes which are resolved according to Fourier into harmonics, one such harmonic being taken, for example, the basic oscillation. The machine on the foundation may be considered as a rigid unit against which the oscillating masses exert periodically acting forces. The machine is assumed to rest directly or through an elastic intermediary member on a foundation which may be the ground, beams of a structure, etc.

If there is a foundation base rigidly connected to the machine, it can be considered as part thereof. The periodic forces which act on the unit assumed to be rigid are supposed to be known, and the problem is to compute therefrom the movements of the machine and foundation produced by these forces.

Let it next be assumed that the machine under consideration is

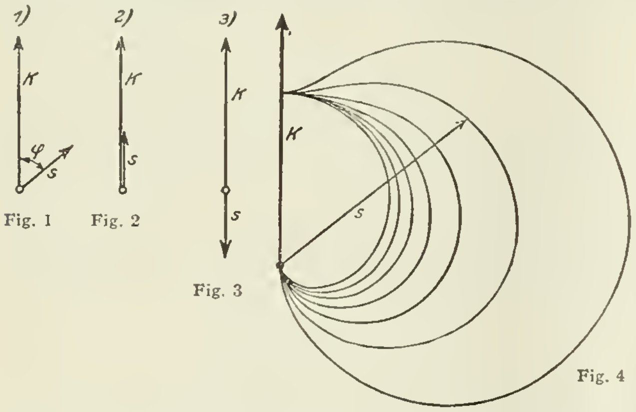

Fig. 1 Fig. 2 Fig. 3 Fig. 4

Figs. 1 to 3 Vectorial Representation of Force K and Displacement s in Foundation Vibrations

Fig. 4 Foundation Function of a Foundation Consisting of an Inert Mass Oscillating with Damping

(The smallest curve corresponds to aperiodic damping; the larger ones belong to smaller values of damping.)

simply floating in space without connection to any kind of a foundation; in that case the inertia forces produced during the motion of the machine by the masses and moments of inertia must be in equilibrium with the forces producing vibrations. Actually, however, the machine does not float in space but rests on a foundation which holds it in a definite position. The first problem, therefore, is to investigate the influence of the "restrictions" produced thereby. Sinusoidal forces or similar moments acting on a foundation produce, when their action is restricted to only small vibrations, sinusoidal motions either of displacement or rotation. The motions generated are, however, as a rule not in phase with the forces producing them but lag somewhat behind them. If, as is usual in alternating-current engineering, the oscillating magnitudes be represented by the projection of vectors on a straight line (Fig. 1) which rotates with an angular velocity corresponding to the periodicity of the oscillations, the behavior of the foundation at any given frequency will be indicated by the vectors of the force K and the motion s, wherein the motion lags behind the force by a phase angle φ. This angle must be between 0 and 180 deg., so long as the energy from the machine is to be transferred to the foundation.

If the foundation were a perfectly elastic spring its motion would be fully in phase with the force producing it (Fig. 2). If, however, the foundation is composed of an inert, freely moving body it will move in a direction opposite to that of the force (Fig. 3). In general, φ may assume any value whatsoever; if it is acute, we approach the case of an elastic spring and the foundation may be called "springy;" if φ is obtuse, the foundation may be described as "massive."

If the frequency changes while the amplitude of the force remains

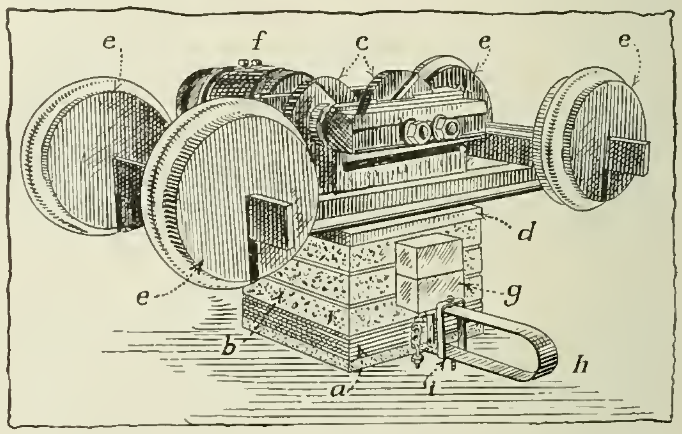

Fig. 5 Device for Investigating the ω Function

constant, the magnitude and direction of the vectors of the motion vary. If the end points of all the vectors of motion produced by the oscillating force at various frequencies be connected, we shall obtain a curve which may be designated as the "foundation function." If the foundation function is known for all the six freedoms of motion, the foundation may be considered as fully determined.

The energy delivered by the vibrations to the foundation may be also determined from the vector diagram as it is proportional to the area of the triangle formed by the vectors K and s.

In simple cases the "foundation function" may be computed theoretically. For example, if the foundation consists of an inert mass held in position by elastic forces and is such that its motions are damped by a friction proportional to the velocity, the foundation functions for the various magnitudes of damping will be somewhat as shown by the family of curves of Fig. 4. At low frequencies the motions and forces will be in phase. With increasing frequency the amplitude and lag of the motion increases, the amplitude reaching its maximum value at the resonance frequency where the motions lag approximately 90 deg. behind the force. From the resonance point on the amplitude begins to decrease while the angle of lag tends to approach 180 deg. At frequencies below resonance the foundation behaves in a springy manner; at frequencies above, like a mass. The foundation function may be also computed for beams yieldingly held at the ends. Since, however, as a rule, the method of holding the beam ends is not known

with sufficient exactness, such computation will not give usefully employable values. In the majority of cases occurring in actual practice, conditions are still more complicated and computation processes cannot therefore be resorted to. Here, however, the foundation function may be determined experimentally, for which purpose apparatus illustrated in the original article (Fig. 5) may be used. On the foundation is laid a plate *a* so perfectly elastic that its change of shape is at each instant proportional to the force acting upon it. For such purpose flat steel plates (Fig. 6) 2.5 mm. (0.1 in.) thick and, say, 30 by 30 cm. (11.8 in. on a side) may be used. These plates should be so held that when loaded they are stressed in bending. It was found by actual test that such plates behaved as if they were practically perfectly elastic. On these springy plates are located three plates *b* made of cork brick, the purpose of which will be indicated below, and on these is placed the vibration generator which produces forces oscillating in a vertical direction. Such a generator consists mainly of two disks *c* with eccentrically distributed masses which rotate about parallel shafts held in a rigid frame. In such an installation the horizontal

of an inclined line an ellipse is produced, the shape of which makes it possible to determine the lag in phase and the magnitude of the beat of the mirror and hence the force acting on the foundation and its motion. The area of the ellipse is a measure of the energy consumed in each vibration.

The stationary mass with respect to which the motion of the foundation is measured is the weight *g* (Fig. 5) held on a base *i* located on the foundation by means of a spring stirrup *h*. The mirror measuring the motion of the foundation is located between the base *i* and the weight *g*. At frequencies from 800 to 2200 per min. the small motions of the mass *g* may be neglected.

By considering the ellipses of vibration at various frequencies one obtains from them point by point the foundation function. Such tests have been carried out on an approximately square concrete plate about 7 m. (23 ft.) long on a side and 27 cm. (10.5 in.) thick, the points under consideration lying in the middle of the slab as well as in the middle of one of the halves. The group of ellipses of vibration obtained in these tests is shown in Fig. 9 where the figures above the ellipses denote the revolutions per minute.

Fig. 6

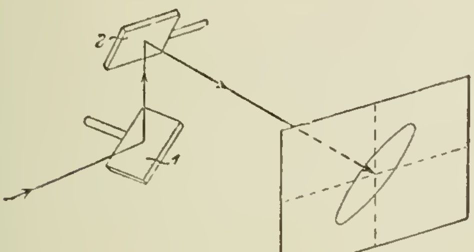

Fig. 7

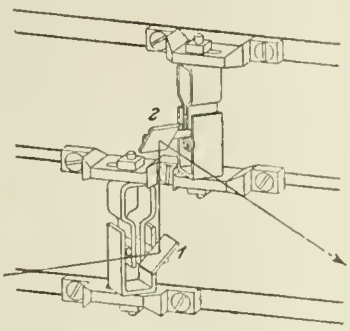

Fig. 8

components of the centrifugal forces are eliminated and only pure vertical vibrations remain. The frame of the vibration generator carries the base plate *d* which transmits the vibrations to the cork-brick plates; it is also provided with stiffening girders supporting weights *e*. By changing the size of these weights and the number and thickness of the cork-brick plates *b*, it becomes possible to do away with undesirable vibrations, for example, lateral vibrations of the whole installation. This also provides a means of changing the magnitude of the forces acting on the foundation. The machine is driven by the electric motor *f*. The compression of the spring plate is measured by an optical indicator by means of a mirror, 1, the rotation of which (Figs. 7 and 8) is proportional to the change in shape of the springy plate and hence the forces acting thereon. The ray of light which arrives in a horizontal direction is thrown upward by the mirror 1 on to a second mirror 2, which indicates the motion of the foundation with respect to a sufficiently large stationary mass and also projects the ray of light in a horizontal direction on to a sheet of sensitized paper where it is photographed as a point of light. The axes of the two mirrors cross each other vertically and their masses are so small that they can keep pace with very rapid motions. When oscillations arise in the foundation the first mirror causes the rapidly moving point of light to appear as a horizontal straight line and the second mirror as vertical straight line. If both mirrors oscillate, then the resultant of the motions is an inclined line, provided the mirrors are in phase. If mirror 2 lags in phase as compared with mirror 1, then instead

The foundation function for the middle of one of the halves of the plate at various speeds is given in Fig. 10. As shown there, it consists of two consecutive slices corresponding to the fundamental oscillation and the first upward oscillation of the plate, where the plate has a junction line in the middle. The component of the amplitude normal to the direction of force K represents the measure of the transmitted energy of vibration. The arrangement described is suitable only for the most important vibrations propagating in the vertical direction, but it may be easily applied to the other freedoms of motion.

Effect of an Elastic Intermediary Layer Between the Machine and the Foundation. Such an intermediary layer when acted on by sinusoidal forces undergoes sinusoidal changes of shape. If it is perfectly elastic the compression is in phase with the force, but if a part of the work of deformation is converted into heat the deformation must lag behind the force. As a rule such an intermediary layer has both springy and damping properties.

In order to investigate the behavior of intermediary elastic layers an arrangement was employed similar to that described above for testing the behavior of foundations. In the course of these tests a perfectly elastic steel plate is laid on a sufficiently rigid foundation layer and upon this a plate of the same size made of the material under investigation, for example, rubber, cork, etc., the whole being submitted to the action of a periodic force. The two plates are connected with a double mirror arrangement such as has been described above, mirror 1 measuring the compression

of the perfectly elastic plate and hence the force, and mirror 2 the change of shape in the plate of the material under test (Fig. 8). From the path of the point of light, which, in the case of imperfectly elastic materials, is an ellipse, and with the knowledge of the amplitude of the force, it becomes possible to determine the deformation with respect to magnitude and phase.

Tests with plates 30 by 30 cm. (11.8 in.) and about 4 cm. (1.57 in.) thick have given under static load an angle of lag of phase of 13 to 18 deg. for rubber, of 6 to 7 deg. for cork brick and of 3 to 6 deg. for natural cork. To these values correspond the following figures of the percentage of conversion of the work supplied for the purpose of changing the shape of the body into heat, namely, 23 to 31, 10 to 12, and 5 to 10, respectively. The larger angles of lag are for higher static loads. Furthermore, it was found that the springy action of the materials under investigation,. i.e., of the component of deformation parallel to the direction of force, has been, in the range of frequencies used of 800 to 2000 per min., only from one-half to one-third that which could have been expected, judging by the curves of elasticity obtained at slow changes of load.

Calculation of Oscillations in a Practical Case. A machine of mass M in which there is a sinusoidal vertical force of amplitude P and frequency ω is placed on a foundation having a given experimentally determined foundation function with an intermediary elastic layer of known properties between the machine and the foundation proper. In order to determine the oscillations that arise and the energy of oscillation loss, we take from the graph of the foundation function the amplitude s_f of the foundation (magnitude and direction, Fig. 11) corresponding to force $K = 1$ and frequency ω. The application of force 1 produces in the elastic intermediary layer a deformation d. If we add vectorially d to s_f, the sum s_m gives the motion of the machine which produces force 1 at the foundation. In order to produce this motion in the phase of the inertia resistance of the mass of the machine it is necessary to exercise a force $+ M \dfrac{d^2s_m}{dt^2}$, for which, in the case of purely periodic processes, may be substituted $-M\ \omega^2 s_m$. If we add this amount to K, we obtain in magnitude and direction the force P which must be applied to the machine in order to produce in it the assumed motion. This value, of course, is not the same as that which really acts in the machine. It is only necessary, however, to magnify or reduce the diagram proportionately or change its scale in order that P shall assume the value necessary to produce the desired oscillation process. The energy given off by the machine at each oscillation is represented by the triangle Ps_m, while the triangle Ks_f represents the energy transmitted to the foundation. The difference between these two or the triangle Kd is converted into heat in the elastic intermediary layer. If the machine has more than one freedom of motion the above calculation should be made for every one of them. Because of symmetry, however, the majority of machines have only few freedoms of motion of importance.

For other frequencies the diagram may be plotted in a similar manner, provided only the corresponding values are taken from the foundation function. By plotting the same kind of a diagram it becomes easy to investigate the probable influence of an increase in the mass of the machine or the greater softness of the intermediate layer. The problem may be solved analytically by using complex numbers instead of vectors. (*Zeitschrift des Vereines deutscher Ingenieure*, Nachlieferungsstuck (Appendix), vol. 67, no. 2, Jan. 13, 1923, pp. 33–35, 11 figs., *ctA*)

Short Abstracts of the Month

AERONAUTICS (See Internal-Combustion Engineering)

ENGINEERING MATERIALS

A New Zinc-Base Die-Casting Alloy, Charles Pack. Some die castings are subject to swelling, warping, and deterioration in service. It is claimed, however, that these troubles are attributable to the alloy used in a given casting and not to the die-casting process. In fact, it is claimed that every case of deterioration of die castings known to the author, who is connected with the Doehler Die Casting Company, has been limited to die castings made from zinc-base alloys, and he gives a brief bibliography on the subject of the deterioration of these alloys. The article claims that the Doehler Die Casting Company has developed a non-corrosive permanent zinc-base die-casting alloy which they call Ni-chro-zink. The composition of the alloy is not disclosed further than by its name. Several tests of the material are described and it is claimed that castings will show a tensile strength of approximately 18,000 lb. per sq. in. and an elongation of 4 per cent, and that fine threads, small holes, and slots can be cast without any difficulty. (*The Metal Industry*, vol. 21, no. 2, Feb., 1923, pp. 53–54, 3 figs., *d*)

FUELS AND FIRING

Tempering Coal and Draft Requirements, Thos. A. Marsh, Mem. A.S.M.E. In an investigation made with western coal the author found that proper tempering helps combustion. He describes in some detail his methods of testing and sets forth the following conclusions which he has reached:

1 Added moisture is beneficial with many coals, certainly with most western coals.

2 Properly tempered coal has less resistance to air flow than either very wet or very dry coal.

3 Very wet coal has less resistance to air flow than very dry coal.

4 The theory of steam formation cracking open pieces of coal does not seem to be correct.

5 Properly tempered western coal burns much more rapidly than coal either too wet or too dry.

6 Properly tempered coal burns to a cleaner ash by decreasing the fuel-bed resistance, thereby reducing the burning of holes in the fuel bed.

7 Properly tempered coal causes less siftings than dry coal, therefore fewer holes occur in the fuel bed and less coal has to be rehandled.

Knowing, therefore, that the advantages of adding moisture to many coals far more than outbalance the disadvantages, and having the above brief study of the action of moisture on air flow, some thought can be given how best to add moisture or temper coal.

Only certain general observations can be made on this subject at present, these being based on the experience of many plants with a great variety of coals. Such observations are:

a Moist coal such as obtained when a car of coal has been rained on the previous day, is usually well tempered.

b Extremely wet coal does not burn as well as coal with medium moisture.

c Moisture added an hour or two before burning is more beneficial than moisture added in stoker hoppers.

d The most usual place to temper coal is at the crusher or in the conveyor. The moisture then has time to mix thoroughly with the coal and agglomerate the fine particles.

e With western coals, one of the important features of plant operation is tempering the coal. With a known coal, intelligent firemen soon become expert in judging the best amounts of moisture for proper tempering. This varies with different coals and coal sizes.

f Exhaust steam for tempering purposes gives very satisfactory results and is used quite extensively. (*Power Plant Engineering*, vol. 27, no. 4, Feb. 15, 1923, pp. 215–217, 3 figs., *cp*)

HYDRAULICS

Experiments on Loss of Head in Valves and Pipes of 1/2 in. to 12 in. Diameter, Prof. Chas. Ives Corp, Mem. A.S.M.E., assisted by Roland O. Ruble. Results of 2200 tests on 48 different gate and globe valves and 425 tests to determine pipe friction.

The loss of head due to gate valves 1/2 in. to 12 in. in diameter was measured for various openings, namely, 1/8, 1/4, 3/8, 1/2, 3/4, and fully open. The loss of head due to globe valves 1/2 in. to 2 in. in diameter, was determined under fully open conditions. As a part of the valve experiments the loss of head in pipes 1/2 in. to 12 in. in diameter was determined, and these results are also included in this bulletin. A bibliography of the subject is appended.

The loss of head due to valves and other fittings occurs in part within the valve or fitting and in part as an added loss in the pipe line downstream where normal flow has been disturbed.

Measurement of the loss of head where the downstream piezometer is attached too near the valve will give a loss in excess of that actually produced. From 20 to 25 pipe diameters beyond the valve will probably give the best position for the downstream piezometer opening. It is undesirable to have a greater length of pipe in the gage length than is actually needed to include all valve loss.

The loss of head in new, clean wrought-iron pipe from $^1/_2$ to 12 in. in diameter is given approximately by the formula $H = \frac{0.0319}{d^{1.16}} v^{1.9}$ in which H is the loss of head in feet per 100 ft. of pipe, v the velocity of flow in the pipe in feet per second, and d the pipe diameter in feet.

Globe valves offer from 15 to 40 times the resistance of gate valves for the same size. This ratio increases with the increase in the size of valves.

The length of straight pipe of the valve size which will produce the same loss of head varies from $^3/_4$ to 4 ft. for fully open gate valves and from 20 to 35 ft. for fully open globe valves. In the case of globe valves the smaller valves are equivalent to the greater length of pipe measured in pipe diameters.

The influence of location of downstream piezometer on valve loss is discussed in an appendix. The conclusion reached is that a valve causes disturbed flow in the pipe line downstream for some distance from it and that a piezometer opening which is connected so as to be in this region will be affected, giving a false record of the pressure within the pipe.

Where there is considerable change of section in passing through the valve the pressure head absorbed at that point to produce the higher velocity of flow is partially recovered in the pipe downstream.

Further, if the loss of head due to flow through a valve be obtained from a piezometer within two or three diameters below the valve, the result will be too large. Not until at least fifteen or twenty diameters of straight pipe intervene between the valve and piezometer will the reading show the true loss.

It follows from this that it is desirable to place the downstream piezometer probably 20 to 25 pipe diameters downstream from the valve. (*Bulletin of the University of Wisconsin, Engineering Series*, vol. 9, no. 1, 1922, 132 pp., 55 figs., *eA*)

INTERNAL-COMBUSTION ENGINEERING (See also Railroad Engineering)

New Fuel-Injection Valves for Compressorless Diesel Engines, Herr Roick. One of the great difficulties that have to be overcome in the development of a small high-speed Diesel engine is the variable metering of small amounts of fuel and their atomization within the very short time available in the course of each cycle. This led to intensive work in the development of proper fuel-injection valves and the present article describes the design proposed by Griev and Livens in their British and German patents. (*Motor und Auto*, vol. 17, nos. 23–24, Dec. 20, 1922, pp. 285–286, 2 figs., *d*)

Statax Three-Cylinder Rotary Engine. An interesting power plant on account of its possible use in "auxiliary" sailplanes has just been produced in Germany. This is the "Statax" three-cylinder rotary two-stroke engine which has been designed and built by F. J. M. Hansen. It is stated to weigh but 17.6 lb. complete with propeller and to develop 7.5 hp.

The chief feature of the Statax is that there is no crankcase but merely a cylindrical induction chamber to which the cylinders are bolted, with their closed ends turned inward. The outer ends of the cylinders are open, and the pistons have their skirts pointing outward. It is claimed that the extremely light weight is a result of so designing the engine that all the most highly stressed members work in tension. From the very brief particulars available (from *Flugsport* of Nov. 15, 1922), it is not quite clear how the force of the explosions and centrifugal force is transmitted from the flat steel straps to the connecting rods or their equivalent. It would appear that, instead of connecting rods, the skirts of the pistons are extended outward, the two extensions carrying lugs for the steel straps coming out from the boss which represents the crankpin. These steel straps are bent over the lugs and then twisted so as to be brought edge-on to the air as the engine is turning.

There are no valves, induction and exhaust ports of usual type, closed and opened by the pistons, being used instead. The combustion chamber is at the inner end of the cylinders, and the mixture is transferred to the combustion chamber through bent induction pipes. Centrifugal force is relied upon to get the charge from the induction chamber out of the cylinders.

The cylinders are of steel, machined from forgings, and are provided with fins of the usual type. The pistons are made of aluminum alloy, as is also the induction chamber, which, owing to the tie rods by which the cylinders are held down, does not have any great centrifugal force to resist. Also, instead of the explosion pressure being added to that of centrifugal force on the cylinders, as in ordinary rotaries, it acts in opposition to centrifugal force.

The propeller blades, of which there are three, are bolted to the induction chamber in the spaces between the cylinders. It would, for this reason, appear to be impossible to cowl-in the engine and as the combustion chambers are near the foot of the cylinders, probably this portion will require ample cooling, so that a cowl could not be used in any case.

The magneto fitted is a Bosch of the smallest type, and the plugs are Bosch-Gnome-Lilliput. The magneto is mounted on the back of the engine as is also the oil pump.

The engine is started by injecting a few drops of the fuel through the exhaust ports, when, on swinging the propeller the engine usually starts after one-half turn. Owing to the centrifugal induction system it has been found that the engine will not function with any regularity at speeds below 500 r.p.m. The maximum revolutions (for long periods) is 1600 r.p.m. At that speed it may be assumed that the propeller efficiency will not be very good in a slow machine.

Following are the main dimensions, etc., of the Statax: Bore, 60 mm. (2 in.); stroke, 70 mm. ($2^3/_4$ in.); speed, 1600 r.p.m.; fuel consumption, 0.705 lb. per hp. per hr.; oil consumption, 0.07 lb. per hp. per hr.; total weight, including a propeller of 4 ft. 11 in. diameter, 17.6 lb. These figures, it is stated, are guaranteed. (*Aviation*, vol. 14, no. 9, Feb. 26, 1923, p. 244, *d*)

The Keith-Whatmough Carburetor

New System of Carburation, G. Keith and W. A. Whatmough. Description of a new type of carburetor which was at first developed as a burner for furnaces using gas as a fuel. Fig. 1 illustrates the apparatus in diagrammatic form.

The air blast is connected at A, and is usually controlled by a valve B. The gas supply is connected to the pipe S, and the mixture flows to the burners along the pipe C. The gas supply is controlled by a balanced valve V connected to a sensitive diaphragm D working in a suitable casing. This diaphragm, which is in itself quite light, is placed vertically, so that even its own weight does not influence its action, and it is loaded on one side by the pressure produced in a tube L by the flow of mixture across the end N, which projects into the mixing tube beyond the throat or constriction M. The end N is cut obliquely, and may be partially rotated in the mixing tube, so that the pressure produced in the tube L with a given flow of mixture may be adjusted to suit the limitations of the gas supply pressure. The gas passes by the valve V until the pressure on that side of the diaphragm is in equilibrium with the loading pressure on the other side. Under this condition there is produced a pressure difference across the obturator O which bears a definite relation to the static and velocity effect produced at the moment by the mixture on the end of the tube L.

It would take up too much time to explain fully the complex variations which take place, but it will suffice for the present purpose to state that so long as the loading pressure on the diaphragm is not greater than the gas pressure existing at S, the proportion of gas to air in the mixture will be constant. The particular quality desired is obtained by adjusting the obturator O, so called to distinguish it from other valves in the apparatus. The quantity of mixture is varied by opening or closing the valve B in the air supply.

This was modified to make it suitable for internal-combustion engines still using gas as a fuel. When, however, it was applied to engines burning liquid fuel it began to boil off the liquid, and, what is more, to do it in such a manner as to prevent boiling off the lighter constituents and leaving the heavier. It was decided to carry on this operation piecemeal in a form of flash boiler capable of working with the heat which would be available from the exhaust.

The first successful type of boiler was of a cascade form in which the fuel was introduced at the top and made to trickle downward over a surface of considerable area, while the exhaust was passed in the opposite direction. By means of baffle plates sufficient turbulence was set up in the gases to enable them to give up heat to the plates of the cascade arrangement so that the liquid was completely evaporated before reaching the bottom of the boiler. This arrangement gave a good deal of trouble and was eventually replaced by the one shown in Fig. 2. In this boiler the exhaust from the engine enters at A, and, after impinging on the casing B, which contains the governing mechanism to be described later, passes in the direction of the arrow, downward, to the boiler proper. This consists of a metal plate P carrying a number of staggered square pins C between which the exhaust passes, and thence upward to the exit D. The staggered pins extract a maximum amount of heat from the exhaust while interposing little resistance to its passage. Depending from the plate P, and in thermal continuity with the heated pins is a block E intersected by a number of vertical saw cuts. A cross-gasway F connects the tops of these saw cuts to an upright gasway leading to the governor. The depending portion is surrounded by a box G, the lower part of which is preferably filled with metal chips. The whole boiler is surrounded by an outer casing H, which is lagged with slag wool below the level of the plate P. Fuel is admitted by the pipe J at the bottom of the box G from the fuel tank, which may be either of the gravity or pressure type. Assuming that the boiler has been heated up

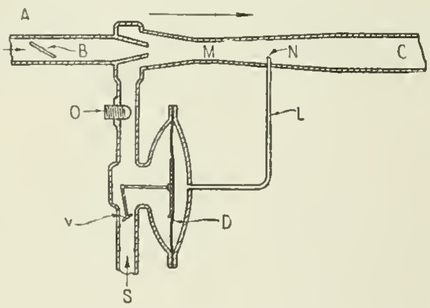

Fig. 1 Gas-Furnace Carburetor-Type Burner

sufficiently and fuel is admitted at the bottom, it will rise through the metal chips until it reaches the lower portion of the block E, which is brought to a point in the center. If the demand for gas is very small, the fuel just touches the lower portions of the saw-cut block and a pressure is set up equal to the head of the fuel entering at J, so that no more will enter. If the demand increases, the level of the liquid rises until it is in contact with a sufficiently large area of surface to give the required quantity of gas. Should the demand be suddenly reduced, the pressure of gas will rise sufficiently to depress the fuel until its area of contact is reduced sufficiently to meet the requirements.

As regards carbon deposits, it was found that none are formed in boilers where completely volatile fuel is boiled without the access of air. In reference to materials it is stated that for light and mixed fuels with equilibrium boiling points not exceeding 200 deg. cent., the boiler proper gives quite satisfactory results if made of cast iron. For fuels with an equilibrium boiling point up to, say, 225 deg. cent., such as Borneo kerosene, brass is a suitable material. With the heaviest practicable fuels, such as lamp oil, with an equilibrium boiling point of, say, 245 deg., an aluminum boiler gives the best results. The reason for the use of different materials is that for the heavier fuels a relatively better thermal conductor is necessary, while with the lighter ones a poorer conductor will suffice.

Means are provided in the boiler to prevent its flooding with the liquid when the latter is not fully vaporized; means also had to be provided to govern the gas. In this case the most satisfactory and practical device was found to consist of a heavy tube with suitable ports. The success of this device is ascribed to the unexpected formation of a kind of soft graphite on the working surfaces, which, with the continuous small movements, due to the pulsation of the engine, produces a beautifully smooth surface which moves with the minimum of friction under the high-temperature conditions prevailing.

Among other things, tests have shown that when an economical mixture was being used on heavy load it was not possible to keep the engine running satisfactorily on a light load or idling, which was found to be due to three causes, the combined effect of which was to reduce considerably the temperature of the exhaust heat, and to the fact that under low-compression pressure a weak mixture failed to ignite, although capable of being fired under high-compression pressure. This led to the development of a device

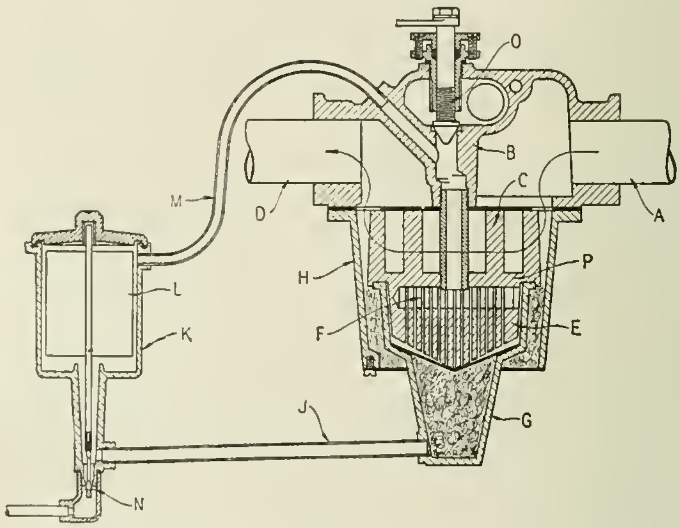

Fig. 2 Fuel Boiler with the Keith and Whatmough Carburetor

for compensation for low-compression pressure when the engine is throttled beyond the mixing point. An auxiliary carburetor is provided to start the engine and heat up the boiler.

The original article reports temperature and road tests. (Paper before the Institution of Automobile Engineers, abstracted through *The Automobile Engineer*, vol. 13, no. 173, Feb., 1923, pp. 55–59, 14 figs., *dA*)

MOTOR-CAR ENGINEERING (See also Railroad Engineering)

A Variable Gear for Motor Cars

Automatic Variable Gear, Eric W. Walford. Description of a mechanism invented by G. Constantinesco, known as the originator of the C.C. gun-control scheme that was used on practically every military aeroplane during the last two years of the war and of wave-power transmission (see Mechanical Engineering, January, 1923, p. 55).

One of the simplest forms of the mechanism is shown diagrammatically in Fig. 3. The shaft of the driving member of prime mover is shown at A, and that of the driven member at B. A crank or eccentric C on the shaft A, by means of a connecting link, causes a lever D pivoted at its lower end to oscillate angularly about its pivot. At its free end this lever has attached to it a pair of links E which at their other ends actuate pawls F, angularly movable around the driven shaft B, and adapted so that one acts on the forward swing of the lever D, while the other acts on the reverse swing, thereby giving a substantially continuous driving action.

So far as it is described there is nothing novel in the mechanism, nor does it act in any way as a variable gear but as a fixed-ratio transmission device only. The central feature of the invention, however, is that the lever D is not pivoted to a fixed, but to a movable member, here indicated by the pendulum G oscillating about

its suspension point at H and carrying the pivot of the lever D at some suitable distance from the point of suspension.

In its broadest and simplest conception the transmission mechanism thus employs between the driving and the driven elements a mechanical device for the storage of energy. This device has a floating connection in the drive, such that if the output of the driving member initially is insufficient to overcome the resistance of the driven member, the energy of the former is stored kinetically in the intermediate receptacle of energy, while the speed of the driving member increases automatically until this stored energy is sufficient to overcome the resistance of the driven member. Conversely, if the resistance of the driven member falls, then a portion of the energy stored between the driving and the driven member is yielded up to the driven member, the amount taken for storage from the prime mover is diminished, and the energy of the latter

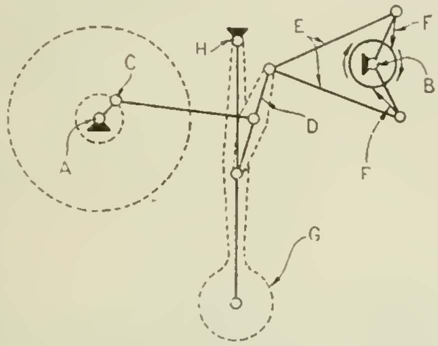

Fig. 3 Diagrammatic View of Constantinesco Automatic Variable Gear for Motor Cars

is then transmitted wholly or in part to the driven member, thus producing in it a corresponding increase of speed.

The action of the mechanism can best be understood by considering that the shaft A is set in motion and that the shaft B is at rest, and (as, for example, would be the case in a motor vehicle) would require a relatively large starting torque to set it in motion. Assuming, therefore, that the driving shaft A is not able to supply by a direct drive (such as would exist if the fulcrum of the lever D were on a fixed member) the torque necessary to start the shaft B in motion, the upper end of the lever D becomes the fulcrum for its angular movements under the operation of the crank C, and the pendulum G commences to swing. Incidentally, it may be noted that the angular motion of the pendulum under these differences is limited to a definite amount, just as would be the motion of the lever D if the pendulum were stationary.

As is well known, the characteristic of a moving body is that the energy stored in it is proportional to the square of its angular or linear velocity. Consequently, the energy supplied by the driving member, which the driven member at first is unable to utilize because it is delivered with insufficient torque, is stored up in the pendulum G. As, therefore, the driving member of prime mover, under these conditions, may be regarded as running light, its speed will increase during the storage of the energy. Here, again, it should be noted that in oscillating movements there is a natural frequency peculiar to the characteristic dimensions of the oscillating member, and that when the rate of oscillation is made otherwise than that which is natural, the frequencies are said to be forced. Such forced frequencies are now produced in the driving of the pendulum, and when its accumulated energy is sufficient, the magnitude of the reaction thrusts on the end of the lever D will cause the latter to move to and fro sufficiently to actuate the pawls F and to start the shaft B in motion.

Such movements of the pawls, at first, will be slight, corresponding to low gear, the ratio of which is accentuated by the speeding up of the prime mover during the storage of energy in the pendulum.

When motion of the shaft B has commenced, and supposing the car to be moving along the level, the resistance will diminish sufficiently for the energy of the driving member so that the supply will now be shared between the driven shaft and the pendulum. The proportion which each receives automatically varies with the resistance to be overcome, the pawls in like manner vary in their angular strokes, and the gear ratio rises or falls automatically in conformity therewith, and with the changes of speed which perforce take place in the prime mover.

The original article gives curves showing the relationship of the driving and driven members under varying conditions of speed and torque. The driving pawls are not of the ordinary tooth type but consist of pads curved around the face of a drum attached to the driven shaft. Their arrangement is such as to insure a secure grip and smooth action, which would not be readily attainable with an ordinary ratchet-and-pawl mechanism.

The most serious objection to the system described as viewed by the author appears to lie in the unbalanced forces set up by the movement of the pendulum, as it is apt to create serious vibrations. (*The Automobile Engineer*, vol. 13, no. 173, Feb., 1923, pp. 52–53, 3 figs., *d*)

POWER-PLANT ENGINEERING

Air-Cooled Condensers. Abstract of patent obtained by the Swedish Ljungström Company. The inventor states that it is sometimes difficult in connection with steam locomotives for the fans used to draw the air through the condenser. He therefore places the fans so close together that they overlap, as shown in the drawing, and the fan blades intermesh more or less after the fashion of the teeth of gear wheels. The fans must, of course, rotate in opposite directions. (British patent no. 189,718, May 1, 1922, published Dec. 7, 1922, abstracted through *The Engineer*, vol. 135, no. 3500, Jan. 26, 1923, p. 107, 1 fig., *d*)

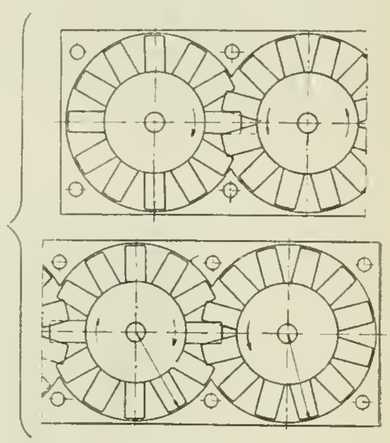

Fig 4 Ljungström Air-Cooled Condenser

A High-Pressure Boiler with Rotating Tubes

Swedish Boiler with Rotating Tubes for 1500 Lb. Pressure, Edvin Lundgren. There are places where an increase of the initial pressure of steam from 300 to 1500 lb. per sq. in. would increase the power obtained from a given weight of steam by from 20 to 60 per cent, and in the case of back-pressure engines or turbines, even 100 per cent or more. With water-tube boilers, however, at least in stationary practice, 350 lb. is considered to be generally the safe limit. In very small boilers steam was produced at higher pressures chiefly by using spiral tubes of a small diameter. There, however, the difficulty of removing sediment proves to be an important obstacle.

There is another factor which, although it has not received much attention, plays an exceedingly important part in the proper service of a boiler, particularly a high-duty boiler. This is the fact that the heat transmitted through the tube walls is far more effectively carried away by water than by steam. In boilers of the ordinary design, equipped with either straight or spiral water tubes, it is, however, practically impossible to keep the inside surface of the heated tubes steadily in contact with the water. On the contrary, the steam generated tends to linger at or near the walls in the form of bubbles, thus increasing the resistance to the flow of heat from the walls. This is, of course, more serious the higher the temperature of the fire and the higher the pressure (and hence the temperature) of the steam produced.

To meet this situation, J. V. Blomquist, a Swedish engineer, designed a new boiler called the "Atmos" in which steam is generated in rapidly revolving tubes. This rotation results in the inside circumference of the tube being entirely covered by a shell of water which is pressed against the walls by centrifugal force. This, in turn, forces the steam bubbles rapidly from the walls into the open central space from which the steam passes out through a central tube of smaller diameter. The diameter of the rotating tubes is made as large as the pressure will permit without requiring an excessive wall thickness.

Moreover, the construction is such that the rotating tubes, or the "rotors," as the inventor calls them, may expand freely without strain. In ordinary boilers it is impossible to avoid those stresses, and it is even impossible to determine them accurately.

The effective cooling of the rotor walls and the freedom from expansion strains make possible rates of evaporation as high as 60 and sometimes even 100 lb. of water per hour per square foot of heating surface. This makes for an exceedingly compact construction.

The rotors form the most important part of the new invention. Referring to Fig. 5, the hot feedwater is admitted through the vertical pipe at the left end to the cover of the stationary bearing housing or shield and enters the rotating part at A in the central pipe shown, which has an outside diameter of $1^1/_2$ in. and revolves in a stuffing box. To keep the packing tight against the pressure of 1500 lb. and simultaneously avoid excessive friction, is of course a serious problem which many practical steam engineers will consider apprehensively. This problem has, however, been solved by admitting oil under pressure to the central distance ring which divides the packing longitudinally into two parts.

The packing material itself consists of ordinary packing braids. The stuffing-box gland is formed like a cap with an opening on the lower side and is tightened by a single bolt located in the center of the bearing shield. This packing has proved to be entirely satisfactory during a continuous service of over twelve months and is distinguished by its low friction. The oil consumption for a 12-rotor double boiler amounts to about one pint in ten hours.

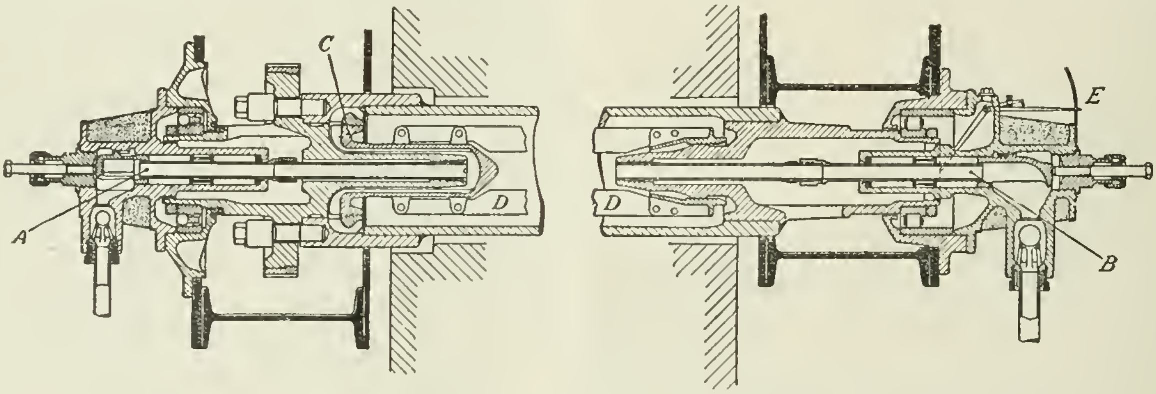

Fig 5 Section through a Rotor of the Atmos Boiler, Showing Feed Connection (Left) and Steam Connection (Right)

The bearing housing on this end of the rotor contains a ball bearing in which the neck of the rotor head revolves. This rotor head is a steel casting and is fastened to the rotor by means of a solid flange on the head, which is kept in place by a number of bolts. To this flange is attached the spur-gear ring which drives the rotor. The head can be readily removed for inspection and cleaning of the interior of the rotor.

The outlet head at the right-hand end of the rotor is screwed into the rotor and then welded to it. The neck of this head, and with it this end of the rotor, is supported by a roller bearing in a manner that allows free expansion and a considerable lateral movement.

As mentioned before, the steam generated is collected in the interior of the rotor and escapes through the central steam-outlet pipe (at the right in Fig. 5) which revolves in a stuffing box of the same construction as that on the water-admission tube.

The chief purpose in designing the flange C like the impeller of a centrifugal pump was to furnish means for measuring the thickness of the water shell and keeping it in correct proportion to the required rate of evaporation.

This is followed in the original article by a discussion of the effect produced by variation in the thickness of the water layer and the various safety devices used.

An installation along the lines described is said to have been made at the Carnegie Sugar Refining Works, Gotenburg, Sweden. Here the steam is generated at a pressure of 900 lb. per sq. in. The boiler is said to have been in continuous daily service under rather unfavorable conditions since December, 1921, and has given satisfactory results. In this boiler the tubes are rotated at 330 r.p.m. (*Power*, vol. 57, no. 7, Feb. 13, 1923, pp. 238–241, 5 figs., *dA*)

POWER TRANSMISSION

Schieferstein Power Transmission by Oscillations. Data on the inventions of the engineer Schieferstein, in connection with the technical utilization of mechanical and electromagnetical oscillations. Schieferstein realizes that all oscillating systems, as for instance pistons operated by cranks, are most favorably employed for yielding useful work if their oscillations are located in proximity to their self-oscillations. In order that such engine parts may follow their self-oscillations, it will be necessary to insulate them mechanically from their driving medium. Hence a system, according to Schieferstein, consists of three essential parts: the energizer, from which the drive originates; the coupling, which transmits the drive upon the freely swinging system; and the energized or resonant part, which yields useful work.

An electrically operated quick-stroke hammer may serve as a practical example of such a system. The energizer in this case would be a crank mounted upon the end of the motor shaft. The stroke of this crank may be very short. As distinct from similar hammers which have already been constructed, the hammer piston is not connected rigidly to the crank by means of a connecting rod, but a coupling spring is interposed between the latter and the hammer piston. If now the turning speed of the electric motor and the self-oscillations of the hammer piston are tuned in respect of each other so that resonance or nearly resonance is produced between the two, the amplitudes of the oscillations of the hammer piston will be far greater than correspond to the stroke of the crank drive. As there is no power required for limiting the stroke of the hammer piston, as would be the case if it were rigidly connected to the crank, and as the reaction upon the crank drive only consists in the pressure of the coupling spring, the energy consumption of the system is said to be much smaller than if the piston were rigidly connected and the crank drive may be constructed with correspondingly smaller dimensions.

The conclusions to be drawn from the example quoted open wide prospects for the possibility of applying this system also to prime movers and power generators in which the forces of acceleration limit the increase in turning speed. The new system may also be employed to great advantage for the driving of mowing-machine knives or gate saws.

Another example shows that Schieferstein's system is applicable also to comparatively slow oscillations. This is the drive of a clock without escapement. Again he uses a crank of small stroke which may be rotated in the customary manner by the weight of the clock. The crank transmits its impulses by means of a connecting rod and through the intermediary of a coupling spring upon an ordinary clock pendulum. The crank as the energizing system and the pendulum as the resonant system must again be tuned relatively to each other in such a manner that resonance is possible. In the present case every revolution of the crank must correspond to one beat of the pendulum. If the pendulum is now set in motion it will receive through the intermediary of the spring just sufficient energy from the crank to keep up its movement, whereas, on the other hand, the coupling spring prevents the crank from causing more than one revolution during one oscillation of the pendulum. It will readily be seen that clocks

working on this system will require only a minimum of weight or spring power and will run for a long time after once being wound up. (*Engineering Progress*, vol. 4, no. 1, Jan., 1923, p. 17, *d*)

PUMPS

Condenser Extraction Pump with Glands under Pressure

Condenser Extraction Pump with Glands under Pressure. Description of a pump recently placed on the market by the Mirrlees Watson Co., Ltd. The chief feature of the new design is the elimination of all air leakage through the gland and stuffing boxes by placing these parts under a pressure corresponding to the external head against which the pump is working. A section of the pump is reproduced in Fig. 6, and serves to show the impeller arrangement and the general details of the design. Two single suction impellers are mounted on opposite sides of the pump suction *A*, and are so arranged that their inlets are facing each other, and the impellers discharge into volutes or pressure chambers *B*. These volutes are interconnected and join up to the common discharge pipe *C*. It will be noted that the two impellers work in parallel,

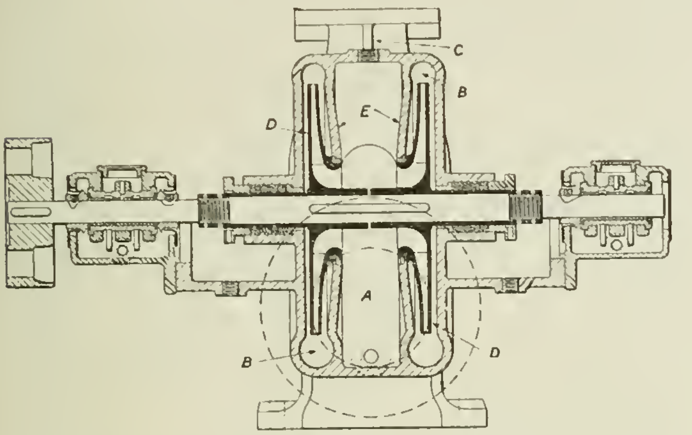

Fig. 6 Mirrlees Extraction Pump with Glands under Pressure

their disposition being such that the end thrust of the one is counterbalanced by the end thrust of the other. The chambers *D* at the opposite ends of the pump casing communicate with the inner ends of the stuffing boxes through which the impeller shaft passes, and are also connected with the volutes by means of the clearance spaces at the peripheries of the impellers. Any possible communication between the chambers *D* and the suction inlet *A* is prevented by the impellers and the diaphragms *E*. The pressure in the chambers *D* therefore corresponds to the discharge head against which the pumps are called upon to work, and as this is well above the pressure of the atmosphere there is no tendency for air to enter the pump casing through the stuffing boxes. As the design is intended for moderate discharge heads, the glands do not require to be very tight in order to prevent leakage.

The casing is split horizontally which facilitates the inspection of the working parts without disturbing the alignment of the pump and motor. The impellers are dynamically and statically balanced and the steel shaft is protected by means of a renewable bronze liner. The new pump has no water seal. The plain stuffing boxes are easily packed, and as the pressure is outwards the hot condensate is not contaminated by the infiltration of oil and grease. The type of pump described is intended for use with a surface condenser, but the design may also be applied to extraction pumps for jet condensers. (*The Engineer*, vol. 135, no. 3502, Feb. 9, 1923, p. 152, 2 figs., *d*)

RAILROAD ENGINEERING

The Next Step in Locomotive Construction, A. F. Stuebing, Mem. A.S.M.E. The author calls attention to the great improvements made in locomotive construction in recent years. He claims that as long as the reciprocating steam engine was the only type of prime mover the locomotive was also well up in the front rank of progress, and it is only since the introduction of the steam turbine and the internal-combustion engine that the efficiency of stationary power plants has shown any marked improvement over the locomotive.

Any new type of motive power if it is to be a success must be adapted to the existing railroad facilities. This means that it must haul a train load approximating that of the steam locomotive and made equal or greater speed. Any new type of motive power should be not only economical in the use of fuel, as simple and sturdy as possible, but, what is perhaps most important, it must be reliable. In a steam locomotive there are very few defects that make it entirely inoperative. It may have leaks and pounds, but it will usually bring the train in somehow.

Fuel economy and locomotive efficiency are not synonymous. The locomotive must be considered as a transportation machine. If a new type of motive power reduces the cost of fuel, but at the same time causes a greater increase in the expenditure for crew's wages, repairs, fixed charges, etc., it is not an economical transportation machine, regardless of its economy from the thermodynamic or mechanical standpoint.

From this the author proceeds to the discussion of the turbine locomotive and the Diesel locomotive, both of which apparently bear important promise for the future but neither of which the author is prepared to fully recommend for the present. (From paper entitled, Are We Due for a Radical Change in Locomotive Construction? read at the January, 1923, meeting of the New York Railroad Club, abstracted through *Railway Age*, vol. 74, no. 5, Feb. 3, 1923, pp. 323–325, *g*)

Report of the Bureau of Locomotive Inspection. Abstract from the eleventh annual report to the Interstate Commerce Commission of the chief inspector of the Bureau of Locomotive Inspection for the year ended June 30, 1922.

The report shows an increase in number of locomotives inspected, with a reduction in the number of defects and number of accidents.

During the year there were 33 boiler explosions, a substantial reduction as compared with the preceding year. Most of these explosions were caused by overheating of the crown sheet due to low water.

Of particular interest is the part of the report dealing with the applications of welding processes. Investigation of accidents where the fusion or autogenous welding process was involved is claimed to support the position previously taken that that process has not yet reached a state of perfection where it can be safely depended upon in boiler construction and repair in places where the strain to which the structure is subjected is not carried by other construction in conformity to the requirements of the law and rules, nor in firebox crown-sheet seams where overheating and failure are liable to occur, nor extensively in repairing long or numerous cracks in side sheets.

Records show that approximately 80 per cent of all autogenously welded seams involved in so-called crown-sheet failures have failed, while only 16.9 per cent of riveted seams have failed under like conditions. The fatalities where sheets tore have been $7^1/_2$ times as great as where they did not tear. From July 1, 1916, to June 30, 1922, autogenously welded seams were involved in 22.1 per cent of the crown-sheet failures, while 44.1 per cent of the total persons killed in crown-sheet accidents were killed where autogenously welded seams were involved.

A large number of accidents have been caused by defective grate-shaking apparatus and the report recommends that a power grate shaker be applied to all coal-burning locomotives. Among the other recommendations the following may be cited:

That power-reversing gears be applied to all locomotives and that air-operated power-reversing gears have steam connections with the operating valves conveniently located, so arranged that in case of air failure steam may be quickly used to operate the reversing gears.

That all locomotives, where there is a difference between the readings of the gage cocks and water glass of two or more inches under any condition of service, be equipped with a suitable water column, to which shall be attached three gage cocks and one water glass, with not less than 6 in., preferably 8 in., clear reading, and one water glass with not less than 6 in., preferably 8 in., clear reading on the left side or back head of the boiler. (*Railway Age*, vol. 74, no. 8, Feb. 24, 1923, pp. 473–474, 4 figs., *gA*)

Is the Steam Locomotive Out of Date? L. G. Coleman. This question is raised by the author who is assistant general manager of the Boston and Maine Railroad. His thesis is essentially as follows:

The steam locomotive today is probably the most uneconomical and unsatisfactory machine in industry. In recent years enormous improvements have been made which have very much increased its efficiency as far as power production is concerned, but these same improvements have so increased the cost and difficulty of maintenance that the time lost in terminals practically wipes out savings due to fuel economy obtained by modern devices and increased unit power.

The inherent weakness of the steam locomotive is its boiler, since when the boiler is out of commission the whole locomotive is out of commission. The limiting factor of long engine divisions is usually the boiler and not the machinery, and a machine that is otherwise ready for service always loses time in terminals by boiler-maintenance conditions, a loss which can be conservatively put down at 50 days each year.

So long as we continue to carry a portable steam boiler on each of our power plants there will be delays, such as washouts, hydrostatic tests, repairs due to leakage and numerous others.

The author believes that this situation can be made better by the use of Diesel engines than by electrification and gives the following calculation as to the former. A modern Santa Fe type locomotive with fully loaded tender weighs approximately 283 tons and will develop, say, 1800 kw. To produce the same useful output by Diesel-electric drive requires a brake horsepower of about 2600, which at 60 lb. per hp. means one or more Diesel engines of an aggregate weight of 78 tons, one or more generators not over 12 tons, a chassis to carry this load, say, 40 tons, or a total weight of 130 tons, to which, say, 20 tons should be added for radiation and accessories.

The possibilities in design are so varied as to offer many opportunities for economies, such as the use of three or four Diesel-engine generator sets mounted on a single chassis which would permit a certain freedom of electrical combinations as to voltage and amperage.

In the discussion which followed the present-day locomotive was vigorously defended, and, in particular, the great value of improvements was pointed out. Thus, it was stated that superheaters are reported to have saved their first cost in from two to three months, feedwater heaters in from 18 months to two years, brick arches in a month, and that boosters save their cost in increased tonnage revenue in from 15 days to three months.

Among other things advocated by the author is the formation by the railroads of the country of a joint bureau for research. (*New England Railroad Club*, Jan. 9, 1923, original paper pp. 190–199 and discussion pp. 199–239, illustrations in the discussion, *g*)

Diesel-Electric Railroad Car, Prof. P. Ostertag. Description of a railroad car intended to operate light trains and built by the Sulzer Brothers at Winterthur.

The car is equipped with two trucks, one of two and the other of three axles. The three-axle truck carries the Diesel engine and the electric generator, which latter is connected to the motor by a flexible coupling. The two-axle truck carries two electric motors acting on the driving shafts. They are located in a cast-iron casing and operate, through gear wheels, layshafts connected by cranks to the driving shafts.

The machinery of the present installation is much simpler than that used before. The crankshaft of the six-cylinder motor is in the longitudinal axis of the car, while the camshaft is parallel to it and runs at half the engine speed. The cylinders are in V, the exhaust pipe being located between the cylinders and the fuel tank on top of it. The Diesel engine is designed to produce 200 hp. at 440 r.p.m., but may carry a load up to 250 hp. for a short period. This gives the car a speed of 70 km. (43.5 miles) per hr. and 60 km. (37.28 miles) with a 30-ton trailer.

The operation of the engine has been simplified and air is no longer used for fuel injection, the atomization of the fuel being effected by means of a part of the explosion gases themselves. As the fuel vaporizes rapidly it ignites spontaneously without the help of either a magneto or hot tube. The compressor of the ordinary Diesel engine is therefore eliminated.

Even starting is effected without compressed air, the generator being fed from a set of storage batteries and acting then as a motor. The cooling water of the cylinders operates in a closed cycle, the hot water being carried by a centrifugal pump into a tubular radiator located on the roof of the car. Means are also provided for varying the surface available for cooling in accordance with the air temperature; in winter the hot water is used for heating the car. A thermometer placed in view of the engineer permits him to control the temperature of water at all times.

As regards the electrical part of the equipment, it is stated that the current is generated by an eight-pole machine with separate excitation and having a continuous output of 140 kw. at 300 volts.

The current to the traction motors is supplied through a Ward-Leonard distribution. The Diesel engines operate at constant speed and full load irrespective of the speed of the car, which insures the minimum consumption of fuel. The traction motors are of the series type with six main poles and six interpoles.

Numerous devices described in the original article are provided for insuring safety of operation. For example, the engineer cannot release the controller, as the circuit opens the instant he does so. These devices in the main do not differ, however, from similar apparatus used on high-speed electric traction lines in America. Numerous tests in Switzerland have shown the simplicity of operation and reliability of the new equipment. Among other things it was found that on down-grade stretches Diesel engines could be shut off, giving an additional economy in the consumption of fuel. The fuel costs generally were found to be very low as compared with similar steam equipment. It is claimed that the cost of operation of the Diesel-driven railroad car is much lower than that of a gasoline-driven car and that in addition a heavy-oil equipment is safer from the fire hazard point of view. (*Bulletin Technique de la Suisse Romande*, vol. 49, no. 2, Jan. 20, 1923, pp. 21–26, 9 figs., *d*)

SPECIAL MACHINERY (See Power Transmission)

TESTING AND MEASUREMENT

Van West Portable Set for Testing Gearing. Description of an apparatus developed in Holland which can be used with the gears in place, provided it is found convenient to measure the axial pitch of the helical teeth rather than the circumferential.

The apparatus consists of a round bar, denoted by *A* in Figs. 7 and 8, and a square steel bar. The square bar is fixed in a groove cut parallel to the axis, and serves as a bed over which the measuring devices can be moved. With the pinion and wheel in true alignment, this square bar will always be parallel with the axes of the wheels when the bar *A* is placed as indicated in Fig. 8. The bar *A* is magnetized, and thus fits itself in between the wheels, and is held firmly without risk of distortion. A rod *C*, which can be clamped by a set screw, as best seen in Fig. 7, serves to adjust the angular position of the magnetized bar by abutting against the pinion shaft as indicated in Fig. 8. On the square bar a block, *B*, is arranged to slide. This block carried the two fingers, *E* and *D*, clearly shown in Fig. 7. The finger *E* can be clamped at any desired point of the rod *F* by the milled head shown, while the finger *D* has a tail piece which abuts against a dial micrometer as indicated. Both fingers can be rotated around or with their supporting rod, *F*, which is secured by a clamp, as shown in Fig. 7. An adjustment is provided at *H* for bringing to zero the indicator of the dial micrometer *G*. If the whole apparatus is pressed in an axial direction, the ends of both fingers come into contact with the flanks of consecutive teeth and the reading of the dial micrometer is recorded. A second set of readings is taken after shifting the apparatus one pitch forward, the operation being repeated till a complete record is obtained. Mr. Van West states that in the case of a pair of smoothly running marine gears, on which he made measurements as above described, the greatest difference found in the axial pitch was only 0.03 mm., or about 0.0012 in.

The device can also be used for testing the teeth of pinions before being put in place. To this end the pinion is laid on a flat surface, as indicated in Fig. 10, and the bar *A* held between the pinion and an angle plate, the measurements being made as before. For testing the alignment of gears the apparatus is placed as indicated in Fig.

9, and the bar turned round until one end of the edge of the square bar touches the teeth. A feeler gage, inserted under the other end, measures the error of alignment. (*Engineering*, vol. 115, no. 2977, Jan. 19, 1923, pp. 74, *d*)

Radiography of Metals at Watertown Arsenal, H. H. Lester. Of interest because of the pioneering nature of the work and unusual completeness of the apparatus available.

The radiographic process is essentially a photographic process. The metal to be radiographed is exposed between the target of a Coolidge X-ray bulb and the photographic film. After exposure the negative is developed in the ordinary way. The photograph obtained is unlike an ordinary photograph in that the latter is superior to the radiograph in the greater amount of surface detail. The radiograph, however, in addition to some surface detail shows in one picture details of both surfaces which can be secured with the camera only by taking two pictures from two sides; further, the radiograph shows details of internal structure which the ordinary photograph does not show at all. In a radiograph white spots represent thin metal. This may be due to the presence of cavities or geometry of the casting. Unfortunately, the majority of the illustrations in the original article cannot be reproduced, thus making it impossible to abstract certain parts of considerable interest.

In radiography it is important to know through what thickness of metal pictures may be taken. Thirty minutes is the upper limit of practical exposure time in the process used at the Watertown Arsenal, although in cases of special importance longer time could be given without, however, corresponding return in penetrability.

Properly developed radiographs indicate not only the presence of defects such as gas cavities but even their exact dimensions. Of still greater importance perhaps than the exact dimensions of the flaws is the question of their detectability. Experiments carried out at the Laboratory of the Watertown Arsenal indicate that where the linear dimension of the flaw, i.e., the dimension parallel to the axis of the X-ray beam, is approximately equal to $1^1/_2$ per cent of the total thickness of the metal in the region adjacent to the flaw, the image may be distinguished. For practical working conditions detectability is placed at 2 per cent, which means that a cavity 0.05 in. in diameter can be detected in metal 2.5 in. thick.

To locate a cavity within the metal the stereoscope is used. In making a stereoscopic examination the area to be radiographed is arranged so that the center of the area, the center of the film, and the target are in line; then the bulb is moved 3 cm. (1.18 in.) to one side of the center line and the exposure made. A second negative is made with the bulb 3 cm. (1.18 in.) to the other side of the center line. These two negatives after development are placed in a stereoscope so arranged that the films may be as far from the eye as they were from the target of the bulb when the exposure was made. When the machine is properly adjusted the picture stands out in bold relief. The surface markings and structural details serve to outline the picture, and the faults appear in their proper places within the material. The picture is quite striking and gives the illusion of looking at a transparent model of the casting. By reversing the negative this model may be turned completely over and one may look through the casting from the other side. The method permits locating details with reference to other details of internal structure. (*Army Ordnance*, vol. 3, no. 16, pp. 210–215, 10 figs., *deA*)

THERMODYNAMICS

Variation of the Specific Heat of Air with Temperature. An article based on a paper read in January before the Faraday Society in London by W. G. Shilling of the East London College, based on experiments carried out by himself and Prof. J. R. Partington.

In the present experiments, the method followed was that of determining the ratio C_p/C_v from the velocity of sound in the gas at definite temperatures. The article describes the method used and gives the results obtained, reproduced in Table 1, where T is the temperature in deg. cent. absolute and V the velocity of sound in meters per sec.

The investigators do not rely upon their values at temperatures above 800 deg. cent., because with the heating tube used it proved difficult to secure a sufficiently long central tube portion of uniform temperature, and experiments are being continued with longer tubes.

For the range up to 700 deg., however, the equation $C_v = 4849 + 0.00036\ T$ (in gram calories) would hold, and that formula, which is in good agreement with previous work, together with the concordance of the observations, places the knowledge of the specific heat of air on a much firmer basis than before.

TABLE 1 VARIATION OF SPECIFIC HEAT OF AIR WITH TEMPERATURE FROM EXPERIMENTS BY J. R. PARTINGTON AND W. G. SHILLING

T	V	C_p/C_v	C_v	C_p
288	340.65	1.403	4.952	6.945
373	387.16	1.399	4.985	6.974
473	435.44	1.396	5.017	7.004
573	478.80	1.393	5.053	7.039
673	518.30	1.389	5.098	7.084
773	555.10	1.387	5.130	7.115
873	589.35	1.385	5.157	7.142
973	621.53	1.382	5.197	7.182
1,073	651.87	1.379	5.237	7.222

Professor Partington considers the figures reliable within 0.5 per cent up to 400 deg. cent. and within 1 per cent or 2 per cent for the higher temperatures. Beyond this, however, the reliability of the equation of state comes in, and possibly preference might be given to the Dieterici equation as compared with that of Berthelot, the former covering a wider range of temperatures. (*Engineering*, vol. 115, no. 2977, Jan. 19, 1923, pp. 82–83, 2 figs., *eA*)

CLASSIFICATION OF ARTICLES

Articles appearing in the Survey are classified as *c* comparative; *d* descriptive; *e* experimental; *g* general, *h* historical; *m* mathematical; *p* practical; *s* statistical; *t* theoretical. Articles of especial merit are rated *A* by the reviewer. Opinions expressed are those of the reviewer, not of the Society.

ENGINEERING RESEARCH

A Department Conducted by the Research Committee of the A.S.M.E.

Apparatus and Supplies for Research

IS AN INSTRUMENT for my present need available or must I design one? Where may a specified type of apparatus be obtained? Where may plans for laboratory construction and ideas about special equipment be had? What are the best sources of certain chemical or other supplies for research? These are samples of recurrent questions from the research laboratory.

With the purpose of helping to meet the growing demand for information the Research Information Service of the National Research Council has assembled catalogs and lists of research appliances issued by makers and dealers. Publications of nearly 500 domestic firms and nearly 200 foreign firms are now on file. They have been classified for effective use and a subject catalog of apparatus has been prepared. The Service has also an up-to-date list of manufacturers and distributors of research chemicals.

Mechanical engineers and investigators who desire assistance in locating special instruments, apparatus, or supplies for use in their laboratories are invited to avail themselves of the resources of this organization.

The address for inquiries is Information Service, National Research Council, Washington, D. C.

Résumé of the Month

A—Research Results

The purpose of this section of Engineering Research is to give the origin of research information which has been completed, to give a résumé of research results with formulas or curves where such may be readily given, and to report results of non-extensive researches which in the opinion of the investigators do not warrant a paper.

Aeronautics A1-23. PREPARATION OF LIGHT ALUMINUM-COPPER CASTING ALLOYS. See *Non-Ferrous Metals A2-23.*

Corrosion A1-23. PROTECTIVE METALLIC COATINGS FOR THE RUSTPROOFING OF IRON AND STEEL. This subject is thoroughly covered by Circular No. 80 of the Bureau of Standards, the second edition of which has just been issued. The nature of metallic corrosion and the principles underlying methods of prevention are discussed in the Introduction. Then follow chapters on types of coatings and methods of application, microstructure with numerous micrographs, preparation of surface before coating and accompanying effects upon the mechanical properties of the steel, methods of testing coatings, and finally recommendations concerning different methods. A selected bibliography on corrosion and its preventive metallic coatings is given as an appendix.

Apply to the Superintendent of Documents, Government Printing Office, Washington, D. C. Price 20 cents.

Electricity Utilization A1-23. ELECTRIC BRASS-FURNACE PRACTICE. See *Non-Ferrous Metals A1-23.*

Forest Products A1-23. MOISTURE-RESISTANT COATINGS FOR WOOD. Technical Note No. 181 recently issued by the Forest Products Laboratory, Madison, Wis., describes an interesting investigation of the relative merits of the various methods now employed for coating wood to protect it from moisture. In a table at the end of this report 17 methods of coating wood are rated according to their efficiency.

Foundry Equipment, Materials and Methods A1-23. ELECTRIC BRASS-FURNACE PRACTICE. See *Non-Ferrous Metals A1-23.*

Framed Structures. A1-23. COMPRESSION TESTS OF STRUCTURAL-STEEL ANGLES. This article presents the results of compression tests of 170 structural angles, made at the Pittsburgh branch of the Bureau of Standards. The object of the tests was to determine the ultimate compressive strength of angles fastened at the ends in such ways as would closely correspond to their connections in the construction of transmission towers. There was also tested a series of angles with square ends. An end fixation factor was found to represent satisfactorily the effect of different types of end connections.

This paper was prepared by A. H. Stang and L. R. Strickenberg. It is known as Technologic Paper No. 218 and may be obtained for 10 cents from the Superintendent of Documents, Government Printing Office, Washington, D. C.

Fuels A2-23. COAL ANALYSES FROM TWENTY-FIVE LABORATORIES COMPARED. The Bureau of Mines has recently conducted a study of results obtained in analyzing similar samples of coal and coke by twenty-five laboratories throughout the country, in comparison with results obtained in the Bureau's coal laboratory at Pittsburgh. The comparison is based on the average of 24 analyses by the Bureau of Mines on each kind of coal, and curves are shown giving the deviation from this average analysis, together with deviations from the check limits of the American Society for Testing Materials.

This report of Investigation, Serial No. 2432, was prepared by A. C. Fieldner, H. M. Cooper, and F. D. Osgood.

Iron and Steel A1-23. PROTECTIVE METALLIC COATINGS FOR THE RUSTPROOFING OF IRON AND STEEL. See *Corrosion A1-23.*

Iron and Steel A2-23. EFFECTS OF CARBON AND MANGANESE ON THE MECHANICAL PROPERTIES OF PURE IRON. This paper which was prepared by R. P. Neville and J. R. Cain of the Bureau of Standards describes the preparation and mechanical properties of an extensive series of pure alloys of electrolytic iron, carbon, and manganese whose compositions were so chosen as to bring out the specific effects on pure iron of additions of manganese, carbon, and carbon and manganese together in varying proportions. The maximum content each of carbon and manganese in each series is about 1.6 per cent; the minimum, 0 per cent, or pure iron.

Address Superintendent of Documents, Government Office, Washington, D. C. Price 10 cents.

Iron and Steel A3-23. STRUCTURE OF MARTENSITIC CARBON STEELS AND CHANGES IN MICROSTRUCTURE WHICH OCCUR UPON TEMPERING. H. S. Rawdon and S. Epstein have recently published as Bureau of Standards Scientific Paper No. 452 the results of their investigation in this field. This study of the changes in structure resulting upon tempering was made in a series of 6 carbon steels ranging from 0.07 to 1.12 per cent carbon, quenched from temperatures varying from 750 to 1250 deg. cent. and tempered for different lengths of time at 100 to 650 deg. cent. Upon quenching, martensite is formed throughout each austenite crystal in a manner strictly analogous to the freezing of solid-solution alloys. A redistribution of carbon takes place and the conspicuous martensite plates are found to be distinctly lower in carbon than the "filling material" between the plates. The enrichment of the carbon in the "filling material" may be great enough in some steels to allow small patches of austenite to persist after quenching.

This report includes reproductions of a large number of micrographs. Address the Superintendent of Documents, Government Printing Office, Washington, D. C.

Metallurgy and Metallography A1-23. STRUCTURE OF MARTENSITIC CARBON STEELS AND CHANGES IN MICROSTRUCTURE WHICH OCCUR UPON TEMPERING. See *Iron and Steel A3-23.*

Non-Ferrous Metals A1-23. ELECTRIC BRASS-FURNACE PRACTICE. In 1911 no electric furnace suitable for melting brass was in existence. The Bureau of Mines then began to study the problem experimentally and to encourage brass melters, electric-furnace designers, and electric generating stations to study it also.

The present report, Bulletin No. 202 prepared by H. W Gillett and E. L. Mack, is published to record the progress so far made in melting brass electrically; to aid the plants which have not yet taken up such melting by pointing out the types of furnaces available, describing their performance and indicating their possibilities and their limitations; and to encourage further experimentations with and the development and installation of electric brass furnaces. It also summarizes the theoretical advantages of electric brass melting.

Eighty different types or different makes of the same type of electric furnace were used in the investigation and are described in this Bulletin of 350 pages.

Address the Superintendent of Documents, Government Printing Office, Washington, D. C. Price per copy 50 cents.

B—Research in Progress

The purpose of this section of Engineering Research is to bring together those who are working on the same problem for coöperation or conference, to prevent unnecessary duplication of work, and to inform the profession of the investigators who are engaged upon research problems. The addresses of these investigators are given for the purpose of correspondence.

Air B1-23. FLOW OF AIR THROUGH ORIFICES. See *Fluid Flow B1-23.*

Fluid Flow B1-23. FLOW OF AIR THROUGH ORIFICES. Under the direction of Associate Professor J. A. Polson of the department of steam engineering of the University of Illinois an investigation on the above subject is now under way. Special apparatus has been designed and built for the tests by F. W. Martin and F. C. Linn.

The air is being weighed in the air weighing plant and passed through the orifice. Various methods of determining the flow at the orifice are to be employed and the results compared with the weight determined from the weighing plant. The calculation of values for the coefficients of flow of the several types of orifices and short tubes employed will then be a simple matter.

Friction and Allied Subjects B1-23. Friction Pressure Drop in Ammonia Pipe and Fittings. See *Refrigeration B1-23.*

Refrigeration B1-23. Friction Pressure Drop in Ammonia Pipe and Fittings. As part of program of research in refrigeration the Engineering Experiment Station of the University of Illinois is undertaking an investigation on this subject. These experiments are being directed by Prof. H. J. Macintire and Mr. J. P. Mullen.

F—Bibliographies

The purpose of this section of Engineering Research is to inform the profession of bibliographies which have been prepared. In general this work is done at the expense of the Society. Extensive bibliographies require the approval of the Research Committee. All bibliographies are loaned for a period of one month only. Additional copies are available, however, for periods of two weeks to members of the A.S.M.E. These bibliographies are on file at the headquarters of the Society.

Ceramics and Glass F1-23. This bibliography covers the technical journal articles and Government reports which the Bureau of Mines have consulted during their investigations on this subject. It covers six typewritten pages and is known as Bureau of Mines Reports of Investigations, Serial No. 2437.

CORRESPONDENCE

Contributions to the Correspondence Department of Mechanical Engineering are solicited. Contributions particularly welcomed are discussions of papers published in this journal, brief articles of current interest to mechanical engineers, or comments from members of The American Society of Mechanical Engineers on activities and policies of the Society in Research and Standardization.

Mathematical Determination of the Modulus of Elasticity

To the Editor:

I read with interest the communication from Mr. David Guelbaum on the above subject in the December issue of Mechanical Engineering, also Mr. Wm. R. Bryans' comments thereon in the February issue. Perhaps the following suggestions would be of interest.

1 Regarding limitations of theory, for a thin strip of material such as must be used in these experiments the error due to assuming an infinite radius of curvature is by far the least of the errors involved. The common theory is only 7 per cent in error when applied to hooks, where the sections are deep and the radii of the order of two or three inches. (See Elasticity and Resistance of the Materials of Engineering, by Wm. H. Burr.)

2 It must be noted that much depends on the accuracy of determination of the moment of inertia I. Suppose we use a strip of metal 0.0500 in. thick by 0.200 in. wide. Let us vary both dimensions by 0.0010 in.

$$I = \frac{b\,h^3}{12} \quad \therefore \; dI = \frac{\partial I}{\partial b}\,db + \frac{\partial I}{\partial h}\,dh = \frac{h^3}{12}\,db + \frac{h^2 b}{4}dh$$

$$\frac{dI}{I} = \frac{db}{b} + \frac{3}{h}\,dh = \frac{0.001}{0.200} + \frac{3}{0.05} \times 0.001 = 0.065 \text{ or } \pm 6.5 \text{ per cent.}$$

Using ordinary machine methods, we may then be as much as $6^1/_2$ per cent in error, even though our other sources of error are negligible. For accurate work our test piece must be ground to size, within ± 0.0001 in.

3 If the type of testing machine should prove to have merits for special work, as it probably will, the form of machine described is handicapped by a complicated mathematical formula. This handicap may be removed by redesigning the machine.

We will agree that $M = EI/\rho$. If we can make ρ = constant, our mathematical work becomes absurdly simple. To do this, it is only necessary to apply a *couple* at the end of the strip. The moment at all points will be constant, E and I are assumed constant, so the neutral axis becomes a circular arc.

The mechanism would be as follows: One end of the strip would be rigidly clamped in a fixed vise and the other end clamped to a vise on a movable carriage on wheels. A capstan drum on the movable carriage would have a cord about it, the ends passing over pulleys fixed to the bedplate, and supporting weight pans. A slight initial deflection would be produced by adding weights to one pan. The position of the end of the strip could be read with a microscope. More weights would be added to the pan, and the new position of the strip end determined. We may be sure of having eliminated initial position errors if $M\rho$ = constant = EI (for elastic materials, of course).

Garden City, L. I., N. Y. Edward Adams Richardson.

To the Editor:

Referring to the letter in the December issue of Mechanical Engineering from David Guelbaum on the mathematical determination of the modulus of elasticity and the comment thereon by Wm. R. Bryans in the February issue, I would call attention to some of the difficulties encountered in calculating the modulus of elasticity from experiments with thin strips.

1 In bending a rod of rectangular cross-section, for example, Fig. 1 (a), the cross-section is assumed to remain plane. Now, let us denote by $d\theta$ the small angle between two neighboring cross-sections, by ρ the radius of curvature, and by δ the extension of any fiber at a distance z from the neutral axis. Then the unit elongation of the fiber under consideration is—

$$e = \frac{\delta}{\rho d\theta} = \frac{z}{\rho} \quad \ldots\ldots\ldots\ldots [1]$$

The corresponding stress is—

$$p = eE = \frac{zE}{\rho} \quad \ldots\ldots\ldots\ldots [2]$$

and integrating over the entire cross-section we obtain the well-known equation of the elastic line—

$$M = \frac{EI}{\rho} \quad \ldots\ldots\ldots\ldots [3]$$

Contrary to Mr. Bryans' statement, there is nothing in this equation that requires the radius of curvature to be practically infinite. The underlying assumptions are (1) that the cross-sections remain plane and (2) that Hooke's law applies. Let us see what this means. In order to be within Hooke's law the maximum stress must not exceed the elastic limit of the material. This stress we obtain from [2] for $z = +h/2$, whence—

$$p_{\max} = \frac{hE}{2\rho} \text{ or } \frac{\rho}{h} = \frac{E}{2p_{\max}}$$

Now for iron $E = 3 \times 10^7$ lb. per sq. in. and $p_{\max} = 3 \times 10^4$ lb. per sq. in., so that—

$$\frac{\rho}{h} = \frac{3 \times 10^7}{2 \times 3 \times 10^4} = 500$$

Therefore the sole proviso in our experiments is that for material such as iron the radius of curvature must be large as compared with the height of the cross-section. The curvature itself may not be large, but in that case the height of the cross-section must be exceedingly small. It follows that because of convenience we shall be obliged to experiment with thin strips of metal where the distortion of the cross-sections must be taken in consideration.

As is well known, an elongation e in one direction causes a contraction in perpendicular directions equal to e/m, where m is Poisson's ratio. Thus [see Fig. 1 (b)] on the convex side with respect to the elastic line the cross-section will be subject to lateral

contraction and on the concave side, where the longitudinal fibers are under compression, there will be lateral dilatation in the plane of the cross-section. As a consequence the cross-section distorts as shown in Fig. 1 (*b*); the neutral axis cannot therefore remain straight and it is easy to see that its curvature will be $1/m\rho$. Until the width b of the cross-section is of the same order as the height h and h/ρ is a small quantity, the additional deflection due to this curvature will be a small quantity of second order, which can be neglected. In this way the fact of the bending of the neutral axis will not interfere with the assumption that the cross-sections remain plane.

2 Now consider a thin, wide strip bent as shown in Fig. 2 (*a*). The full lines of Fig. 2 (*b*) are the boundaries of a cross-section before bending, and if we apply the foregoing considerations we shall arrive at the conclusion that the cross-section distorts as shown by the dotted lines.

Experiments, however, show that this is not the case. It will be found that the middle part of the cross-section remains as before and distortion occurs practically only near the edges as shown in Fig. 2 (*d*). The reason for this behavior is plain. We must not forget our fundamental assumption, which is that bending consists of a rotation of the bar elements around the neutral axis and that the elements of a plane cross-section before bending remain in a plane after bending. This hypothesis has been proved to be substantially true for straight bars of constant cross-section. This being the case, it is evident that the neutral axis must remain substantially such a straight line as, for instance, *x-x*, Fig. 2 (*b*). Now it will be seen that if the distortion of the cross-section is as assumed in Fig. 2 (*b*), the parts *d*, *d*, will lie entirely in the tension zone. If we then cut a longitudinal strip from the bar near its edges, as represented in Fig. 2 (*c*), the cross-sections 1-1 and 2-2 will be subject to tensions only, whose resultants are the forces P. Their resultant is the force R, which evidently prevents the cross-section through the strip from curving upward as assumed in Fig. 2 (*b*). This at once explains why the distortion of the cross-section is more like that shown in Fig. 2 (*d*) and also confirms the statement that the fundamental hypothesis of bending is substantially true.

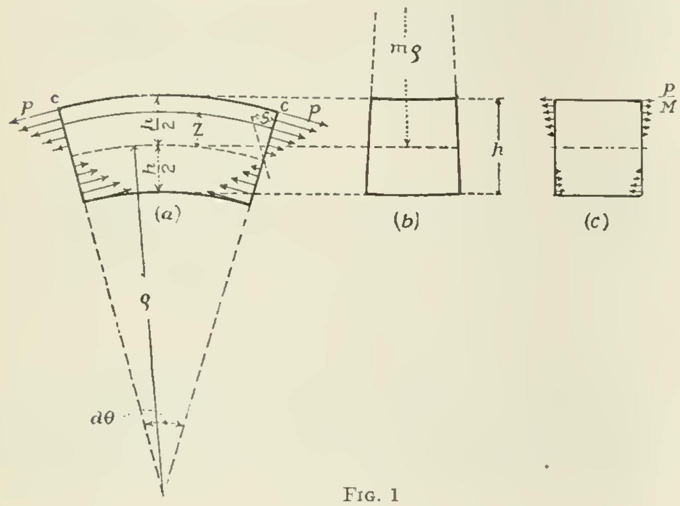

Fig. 1

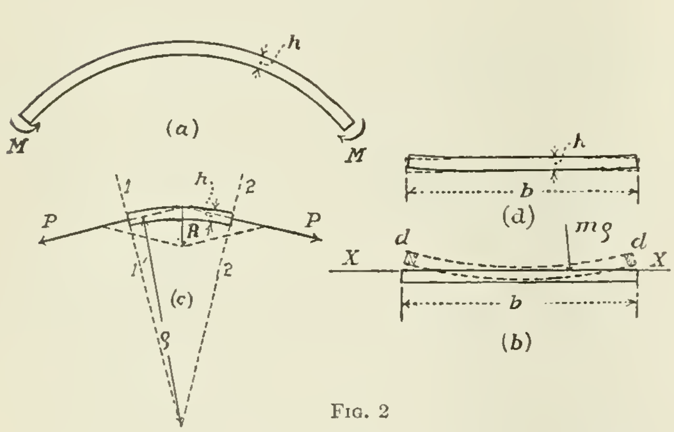

Fig. 2

Since then in the bending of a thin, wide strip the cross-sections (with a negligible distortion at the corners) remain substantially as before, whereas our theory requires a pronounced distortion, it is evident that Equations [2] and [3] should be modified.

Returning to the case of Fig. 1, it is clear that the distortion of the cross-section will be prevented by applying in its plane the forces shown in Fig. 1 (*c*). These forces in turn affect the longitudinal strain. Thus for a fiber *c-c*, Fig. 1 (*a*), the elongation due to the longitudinal stress p alone would be p/E. On this there will be superimposed a contraction due to the stress p/m acting in the plane of the cross-section, and this contraction is—

$$\frac{p}{mE} \times \frac{1}{m} = \frac{p}{m^2E}$$

The total elongation of the fiber *c-c* will therefore be—

$$c = \frac{p}{E} - \frac{p}{m^2E}$$

whence—

$$p = \frac{cEm^2}{m^2 - 1} \qquad [4]$$

Using this value of p in [2], the equation for the elastic line becomes—

$$M = \frac{EI}{\rho} \times \frac{m^2}{m^2 - 1} \qquad [5]$$

This is the formula that should be used in the case of bending thin, wide strips. If we take $m = 10/3$, then—

$$\frac{m^2}{m^2 - 1} = 1.10$$

Hence in experiments on thin strips of comparatively great width, Equation [3] will give a value for E which is about 10 per cent too high.

3 Now Equations [3] and [5] furnish solutions of the problem of bending in two extreme cases. For intermediate cases more detailed consideration of the distortion of the cross-section is necessary. To give the complete theory of these problems would be beyond the scope of the present communication.

For the sake of completeness, however, the writer wishes to state that in the case of a strip acted upon at its terminal cross-sections by equal and opposite bending moments, there is obtained in place of Equations [3] and [5]—

$$M = \frac{EI}{\rho} \times \frac{m^2 - k}{m^2 - 1} \qquad [6]$$

in which the quantity k is a function of the radius ρ, the thickness h, and the width b of the strip. A number of values of k are given in the table below where—

$$\beta b = b\sqrt[4]{\frac{3(m^2 - 1)}{m^2\rho^2h^2}} = 1.286\frac{b}{\sqrt{\rho h}} \qquad [7]$$

$\beta b =$	0.5	1.0	1.5	2.0	2.5	3.0	4.0	5.0	$\beta b > 5$
$k =$	0.999	0.995	0.975	0.877	0.818	0.725	0.534	0.420	$\frac{2}{\beta b}$

For example, for $h = 1$ mm. and $\rho = 500$ mm., we obtain, from [7], $\beta b = 3$; the value of k for $\beta b = 3$, as given in the table, is 0.725. Substituting this value in Equation [6] gives—

$$M = \frac{EI}{\rho} \times \frac{m^2 - 0.725}{m^2 - 1} = \frac{EI}{\rho}(1 + 0.0272)$$

that is, Equation [3] would give a radius of curvature about $2^3/_4$ per cent too large.

The table therefore enables us to estimate in what cases Equation [3] can be used without material error in calculating E from the experiments with strips.

Work of A.S.M.E Boiler Code Committee

THE Boiler Code Committee meets monthly for the purpose of considering communications relative to the Boiler Code. Any one desiring information as to the application of the Code is requested to communicate with the Secretary of the Committee, Mr. C. W. Obert, 29 West 39th St., New York, N. Y.

The procedure of the Committee in handling the cases is as follows: All inquiries must be in written form before they are accepted for consideration. Copies are sent by the Secretary of the Committee to all of the members of the Committee. The interpretation, in the form of a reply, is then prepared by the Committee and passed upon at a regular meeting of the Committee. This interpretation is later submitted to the Council of the Society for approval, after which it is issued to the inquirer and simultaneously published in MECHANICAL ENGINEERING.

Below is given the interpretation of the Committee in Case No. 411, as formulated at the meeting of January 9, 1923, and approved by the Council. In accordance with the Committee's practice, the names of inquirers have been omitted.

CASE NO. 411

Inquiry: Par. 212c which permitted increasing the pitch of staybolts on cylindrical surfaces over that required for flat plates, had, about two years ago, been held in abeyance pending the revision of the Boiler Code, but nothing has been left in its place. In view of this, what rules should be followed pending the publication of the revised Code?

Reply: It has been proposed to revise Par. 212c as follows, and the Committee recommends to the state inspectors that this rule be followed in place of the rules now given in Par. 212c of the Code:
